The nest architectures of social insects (ants, termites, some bees and wasps species) are among the most impressive and complex artifacts built by animals with the notable exception of man (Theraulaz et al., 1998; Turner, 2000a,b). All along the evolution of social insects, there has been a whole set of innovations in terms of architectural designs and construction techniques that proved to be very efficient to solve a large number of problems such as controlling the temperature inside the nest, ensuring the gas exchanges with the outside environment (Bollazzi and Roces, 2007) or adapting the nest structure when colony size is growing (Hansell, 2005). More than fifty years after Pierre-Paul Grassé has introduced stigmergy as a basic principle for the coordination of work in these societies, we are still very far from having a full understanding of the mechanisms that shape architecture and functional designs of the nests (Grassé, 1959). While being

Figure 1: Examples of nest architectures built by ant colonies. (a) Detail of a nest in wood pulp sculpted by the ant *Lasius fuliginosus*. (c) A closer look on the walls and vertical passages connecting chambers inside a nest built by the ant *Lasius niger*.

extremely simple, stigmergy is able to give rise to complex self-organised patterns (Deneubourg, 1977; Bonabeau et al., 1998). Moreover stigmergy is often combined with environmental templates that modulate the expression of individual building rules, thus increasing the range of potential architectures (Jost et al., 2007). Other factors are also likely to play a key role in nest morphogenesis such as building pheromones. Such pheromones have been identified in termites (Bruinsma, 1979) and are likely to exist in some ant species (our unpublished data).

In this paper we present an individual-based model of ant nest construction based on a detailed analysis of individual building behaviours that take into account the logistic constraints imposed by the architecture on the movement of ants. With this model we investigate the role played by the building pheromone on the resulting shape of the nest.

The paper is organised as follows: in section two we introduce the experimental results and describe the individual building rules in the ant *Lasius niger*. In section 3, we present an overview of the 3D agent-based model. In section 4, we report simulation results that illustrate the impact of evaporation rate of building pheromone on the resulting nest architectures. Finally, in section 5, we establish comparisons with related work and draw some conclusions and directions for future work.

## Construction mechanisms at the individual level

We performed a series of experiments to investigate the mechanisms involved in nest construction in the ant *Lasius niger*. These experiments showed that the deposition of material in a particular place stimulates the ants to accumulate more material in that same place, thus creating a positive feed-back. Experiments also revealed that the workers add a chemical signal (a building pheromone) to the building material. The main action of this chemical signal is to attract ants, but there are also indications that it stimulates the deposition of building material.

There was no particular effect of this signal on the extraction of building material, but it was noticed that ants prefer to dig where they have already dug, forming a type of quarry. This may be simply due to physical constraints, in the sense that it is much harder for an ant to extract a pellet from a place where the soil has been solidly packed, compared to a place where the soil surface has been broken (as by a previously digging ant).

The consequence of all these behaviours is the formation of pillars. Once pillars have been erected and have reached a critical height, the workers start to build a canopy on the sides. The height at which the ants attach the pellets on the pillars corresponds approximately to the mean body length of an ant worker. The workers therefore use their body as a kind of template to decide at which height they will stop to increase the size of an existing pillar and start to build a roof from that pillar.

## Behaviour-based model of nest construction

We developed a spatially explicit individual-based model in a discrete 3D cubic-lattice in which we have incorporated the behavioral rules characterized by the experiments

### General principles

The model is stochastic: ant workers are represented by agents whose behavioural rules are modelled according to probabilities to perform simple elementary actions. Moreover, the process is Markovian: the probability of performing a given action is only depending on the current state of the environment around the agent (spatial configuration, quantity and age of the building pheromone, number of

empty cells below). Indeed, agents are memoryless and tireless.

Following Ladley and Bullock's work (2005), our model takes into account the geometric constraints: each pellet of building material occupies a single cell and the ants are represented by agents that move randomly in a three-dimensional discrete cubic lattice ( $200 \times 200 \times 200$  voxels). Each agent occupies a single cell and their movements are constrained by the structures they build: they cannot walk through the built structures. The layers on the bottom and on the sides of the lattice act as borders. Ants simply bounce on the floor and walls when they come into contact. We choose a discrete time step approach. At each step, the system is updated: agents move, then, if they are not already transporting building material, they can pick up a pellet, else drop it, or simply continue their walk without doing anything else. Each agent can only perceive the first twenty six neighbouring cells that surround the place where it is located at a given moment (cell  $c$ ). We denote these twenty-six 3D-neighbours by  $V_{26,c}$ , and the influent neighbourhood for certain behavioural rules may be restricted as detailed below.

### Behavioural rules of an ant

**Motion** The motion of ants is a constrained random walk, which means that they stay in contact with the outer surface of the architecture. The building pheromone that will be introduced in dropped pellets doesn't affect their motion: ants are not attracted or repelled by it.

Ants may only move to adjacent locations, i.e. the six orthogonal cells. We call  $V_{6,c}$  this reduced neighbourhood around the cube  $c$ . A worker cannot walk through an occupied cell (clay, floor, wall or another worker): only empty cells of  $V_{6,c}$  are really available for moving. The second constraint prevents flying ants: they must stay in contact with the surface of the structure. Thus, only adjacent locations, which have at least one  $V_{6,c}$  neighbour cell occupied by clay, floor or walls, are available for moving. The algorithmic description of the motion rule is summarized below (Algorithm 1).

**Picking-up rule** A worker can only pick up a pellet when it stands atop it. If it does, it takes the location of the pellet.

To compute the picking-up probability, the worker simply considers the bottom layer of cells in its neighbourhood. We call  $V_{8,c}$  the eight horizontal neighbours of the cell she is standing on. The probability to pick-up the block she is standing on is not influenced by the presence of pheromone in the material but it slightly decreases as the quantity of building material in this bottom layer increases. This is a simple consequence of the fact that it is much more difficult for an ant to extract a pellet when the ground is packed more solidly. The corresponding picking up probability is shown in Figure 2 (a).

**Algorithm 1** Motion rule – The algorithm used to simulate the workers’ random walk. To simulate agents’ diffusion, one agent performs *nbMove* elementary moves each time step.  $c_w$  is the cube with the worker  $w$ .  $V_{6,w}$  is the list of the six neighbours of  $w$  that share a face with it. We denote by  $A_w$  the list of the accessible immediate neighbours of  $w$  and by Random the random drawing in a discrete set of cells.

```

1: // The worker is in  $c_w$ .
2: for all step  $\in \{1; nbMove\}$  do
3:    $A_w = \text{EMPTYLIST}$ 
4:   for all  $c_i \in V_{6,w}$  do
5:     if ( $c_i == \text{empty}$ ) and (one of  $V_{6,c_i}$  is full)
        // The cube  $c_i$  is accessible.
        then
6:        $A_w \leftarrow \text{concat}(A_w, c_i)$ 
7:     end if
8:   end for
        //  $A_w$  contains all the accessible adjacent neighbours
        // of  $w$ .
        // Random choice of  $c_r \in A_w$ .
9:    $c_r = \text{Random}(A_w)$ 
10:   $c_w \leftarrow c_r$ 
11: end for

```

The algorithmic description of the picking up rule is summarized below (Algorithm 2).

**Building rule** A worker drops its pellet at its current location, provided there exists a cell in the neighbourhood  $V_{26,c}$  where it can move after dropping. This building behaviour is also conditioned by physical constraints, which means that a building pellet can be added to the previous structure only if at least one of its faces is in contact with another pellet located in the neighbourhood (pellets do not stick together by the cube’s corners or edges).

Since we found experimental evidence that clay which has been previously manipulated by workers stimulates the dropping behaviour, we implement a building pheromone. The building pheromone contained in a pellet is renewed each time a pellet has been picked-up and dropped. It does not diffuse to adjacent cells but still undergoes an exponential decay (at some rate), so it directly delivers a local signal about the time elapsed since the pellet was deposited. The probability to drop a pellet or add it to an existing structure is enhanced by the number of pellets previously dropped in the neighbourhood but it decreases with time.

Since we found also experimental evidence that ants use their body as a kind of template to build the canopies on top of the pillars and prefer to drop their load at some height (standing upright along the pillar), we also include a modulation of the dropping probability when a worker is moving over a vertical surface. In those situations, when the potential dropping site has  $h$  empty cells below it, the behavioural

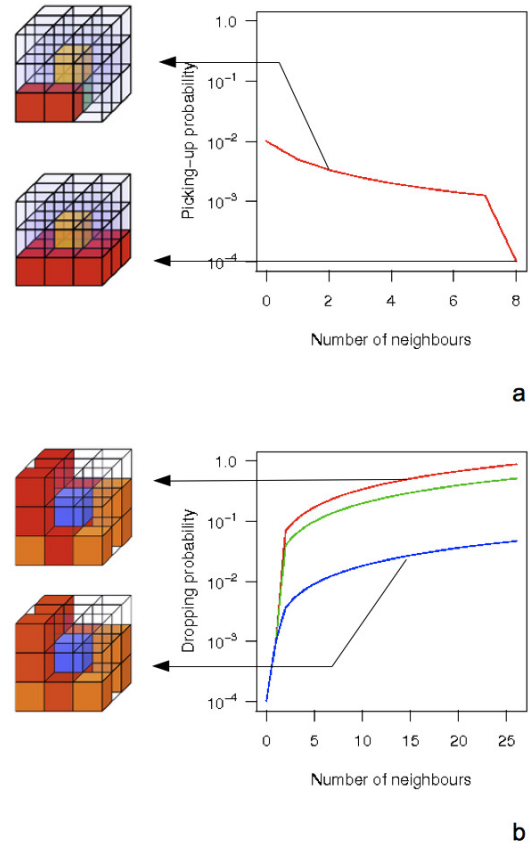

Figure 2: Probabilistic building rules implemented in the model. (a) Picking-up probability as a function of the number of cells containing clay in the bottom layer. The shown curve is implemented as a two-parameter function of the number of neighbours  $n$ , taking the value *spontPick* for  $n = 0$ , *spontPick*/100 for  $n = 8$  and *spontPick*/(*amplifPick* ·  $n$ ) for  $1 \leq n \leq 7$ . (b) Dropping probability as a function of the local density (number of neighbouring cells containing clay,  $n$ ) and of the age of the latest dropped pellet in the neighbourhood. It takes the values *spontDrop* for  $n = 0$  and  $(\text{drop1} + \text{amplifDrop} \cdot (n - 1)) \cdot \exp(-(time - \text{latestDropTime}) \cdot \text{evap})$  for  $1 \leq n \leq 26$ , where *time* is the current time. For parameter values and explanations see Table 1. The red, green and blue lines mark the probabilities where the last dropped pellet is younger to older respectively.

**Algorithm 2** Picking-up rule – The algorithm used to estimate the granularity around the worker  $w$  currently located in the cube  $c_w$ . We denote by  $t_{w,p}$  the target cube for the picking up. Here, the rule  $H_{p,1}$  is that  $t_{w,p}$  is underneath  $c_w$ .  $V_{8,t_{w,p}}$  is the list of the influent neighbours of  $t_{w,p}$ . The variable  $n_{w,p}$  counts the number of full neighbours.  $p_{w,n}$  is the associated picking up probability. Uniform denotes a random number in  $[0; 1[$ .

---

```

1:  $n_{w,p} = 0$ 
2: for all  $c_i \in V_{8,t_{w,p}}$  do
3:   if  $c_i == \text{full}$  then
4:      $n_{w,p} \leftarrow n_{w,p} + 1$ 
5:   end if
6: end for
  // Calculate the picking up probability, associated to
   $n_{w,p}$ .
7:  $p_{w,p} \leftarrow f(n_{w,p})$  // According to a decreasing amplifi-
  cation curve, see figure 2 (a).
8: if  $p_{w,p} < \text{Uniform}$  then
9:   // Pick-up  $t_{w,p}$ .
10:  // Move to  $t_{w,p}$ .
11: end if

```

---

**Algorithm 3** Building rule – The algorithm used to estimate the local density around the worker  $w$  which is located in the cube  $c_w$ . The influent neighbours are  $V_{26,c_w}$ . The variable  $n_{w,d}$  allows to count the number of full neighbours.  $ageOf(c_i)$  corresponds to the date of dropping the pellet  $c_i$ . We define by  $latestDropAge$  the date of the latest dropped pellet in  $V_{26,c_w}$ . Uniform denotes a random number in  $[0; 1[$ .

---

```

1:  $n_{w,d} = 0$ 
2:  $latestDropAge = 0$ 
3: for all  $c_i \in V_{26,c_w}$  do
4:   if  $c_i == \text{full}$  then
5:      $n_{w,d} \leftarrow n_{w,d} + 1$ 
6:     if  $latestDropAge < ageOf(c_i)$  then
7:        $latestDropAge = ageOf(c_i)$ 
8:     end if
9:   end if
10: end for
  // Calculate the dropping probability, associated to  $n_{w,d}$ 
  and  $latestDropAge$ .
11:  $p_{w,d} \leftarrow f(n_{w,d}, latestDropAge)$  // According to the
  increasing curve shown in figure 2 (b).
12: if  $p_{w,d} < \text{Uniform}$  then
13:   // Drop in  $c_w$ .
14:    $ageOf(c_w) = \text{currentStep}$ 
15:   // Use OneMove (Algorithm 1) with  $nbMove = 1$  to
  escape from  $c_w$ .
16: end if

```

---

algorithm includes a multiplication factor of the dropping probability,  $p_{w,d}(h)$ , according to the equation

$$p_{w,d}(h) = p_{w,d} \cdot \frac{h^n}{\bar{h}^n + h^n} \quad (1)$$

with  $\bar{h}$  being the mean length of an ant.

The algorithmic description of the building rule is summarised above (Algorithm 3).

## Simulation results

We implemented the three behavioural rules in the model and we run the simulations with the parameters values given in table 1. The 3D cubic lattice ( $200 \times 200 \times 200$ ) was initialised with 20 bottom layers uniformly filled with pellet and 1000 workers randomly placed on the surface. The maximum value of the spontaneous picking-up probability is reached when the eight horizontal neighbours on the bottom layer are empty. This is fixed in the picking-up probability function by the parameter *spontPick* which we set to  $10^{-2}$ . The decrease in picking-up rate, specified by parameter *amplifPick*, is set to 1.

The spontaneous dropping probability *spontDrop*, when there is only one pellet in its  $V_{26,c}$  neighbourhood, is fixed at  $10^{-4}$ . In case of one additional neighbouring cell we set the dropping probability to *drop1* =  $10^{-3}$  (Fig 2). Dropping probability then increases continuously with the number of pellets in  $V_{26,c}$  to the maximum value of *drop26* = 0.9. The evaporation rate is initially set to *evap* =  $1.6 \times 10^{-5}$  per time step and then modified to explore its impact on the emerging 3D architectures.

Model parameter	Description	Value
<i>spontDrop</i>	Spontaneous dropping probability	$10^{-4}$
<i>drop1</i>	Dropping probability in the case of exactly one marked neighbour	$10^{-3}$
<i>amplifDrop</i>	Factor modulating the dropping probability	0.036
<i>evap</i>	Evaporation rate of the building pheromone	$3.2 \times 10^{-4}$ to $8.0 \times 10^{-7}$
<i>spontPick</i>	Spontaneous picking-up probability	$10^{-2}$
<i>amplifPick</i>	Factor modulating the picking-up probability	1.0

Table 1: Parameters values used in simulations. Rates and probabilities apply to one time step. See Fig 2 for the use of these parameters.

## Pillars and roofs

When running this model one can observe the formation of pillars. When the height of the pillars becomes high enough, pellets are added on the pillars' sides; this rapidly increases

Figure 3: A comparison of the structures built in experiments and in a simulation of the model. (a) An arch that covers a passage between two pillars built by ants in experimental conditions. (b) A close view of a simulation result with the same initial conditions as the ones used in experiments. The model is able to reproduce the characteristic shapes observed in these experiments. The parameter values used in this simulation are listed in table 1.

the surface of the pillar top, leading to the formation of some kind of hat or roof. These roofs look quite similar to the ones we got in the experiments (see figure 3). Moreover, when two roofs are close enough to each other, they can merge. The result is an arch that covers a passage between the two pillars.

Physical stress due to gravity and decreasing cohesion due to evaporating water should finally lead to collapsing roofs and pillars, an event that was sometimes observed in the experiments. The current version of the model does not include these processes, but when inter-pillar distance is not too large this should not be much of a problem.

### Effect of the decay of the building pheromone on 3D architectures

To explore the diversity of nest architectures the model is able to produce, we investigate the role of the decay rate associated with the building pheromone. This is already known to be a key ingredient of the self-organization in social insects, it has a major impact on the collective dy-

namics such as: trail formation and path choice in ants (Goss et al., 1989; Beckers et al., 1992; Jeanson et al., 2003; Sumpter and Beekman, 2003), construction of pillars in termites (Deneubourg, 1977; Franks and Deneubourg, 1997; Bonabeau et al., 1998), construction of wall in ants (Franks et al., 1992), digging networks of galleries in ants (Buhl et al., 2005).

Figure 4 shows that the evaporation rate of the building pheromone is indeed a highly influential parameter on the resulting structures.

When there is a strong evaporation rate ( $evap = 3.2 \times 10^{-4}$ ), the final structure is laminar (figure 4 (a)). In the early steps, agents begin building several tiny pillars on the unmarked initial surface. They cover them with thin roofs or capitals. The surface of these roofs increases, several roofs merge, forming a thin first layer that becomes the first floor. In the next steps, the construction dynamics undergo the same cycle of events, leading to a new floor. Moreover agents can enlarge the pillars by adding new pellets on their sides.

When the evaporation rate is smaller ( $evap = 1.6 \times 10^{-5}$ ), the structure is still laminar, but the layers are less plane than in the previous case (figure 4 (b)). The initial phase is similar to the previous condition, but there is a larger number of pillars and the capitals are thicker. After the completion of the first floor, the construction of new pillars occurs at a faster rate than with the higher evaporation rate. A closer look at the growth and the evolution of the nest structure reveals that while the whole structure remains quite similar in time, it is constantly destroyed and rebuilt. The consequence of this remodelling process, in which the ants destroy what they have built previously, is a progressive drift of all the layers from the top to the bottom. It seems that a kind of wave runs through the whole structure. These traveling waves are indeed the simple consequence of the fact that the only place where the ants can pick up some building material is the bottom layer. So it quite naturally induces a kind of symmetry breaking in the remodelling process.

Finally when the evaporation rate is very low ( $evap = 8 \times 10^{-7}$ , figure 4 (c)), the model leads to a sponge-like structure that looks similar to the nest built by *Lasius niger*. In a first step, pillars also emerge and are covered with capitals that are more spherical than in the two previous cases. Thus, when the capitals merge, the layer is thicker. In a second step, pellets can be dropped anywhere on the new floor. No pillar emerges in this case, the layer is just thickened. Sometimes, a little heap appears by chance, a new pillar is built and starts to grow. This new pillar merges quickly with the structure in its vicinity, leading to the formation of a chamber. The next floor is built when many chambers have been created and closed. In the next steps, the construction dynamics undergoes the same cycle of events: (1) thicken the floor ; (2) emergence of few little pillars ; (3) fusion of the roofs, which leads to the formation of chambers.

Figure 4: The influence of the evaporation rate of the building pheromone on the nests structure. Left : 3D structure. Right : Vertical cut ( $x \in [98; 101]$ ). (a) With a strong evaporation rate ( $evap = 3.2 \times 10^{-4}$ ), the construction process leads to the formation of a laminar structure. The horizontal layers are connected with thick pillars. (b) With an intermediate evaporation rate ( $evap = 1.6 \times 10^{-5}$ ), the structure is still laminar, but sometimes two successive layers can intersect and form a ramp that connects successive floors (c) When the evaporation rate is very low ( $evap = 8 \times 10^{-7}$ ) we get a sponge-like structure.

Figure 5: A closer look on the building dynamics in the case of a very weak evaporation rate ( $8 \times 10^{-7}$ ). (a) to (c) show three successive steps of a simulation. The circle marks a chamber "moving" downwards.

## Discussion and conclusion

In this paper we introduced a 3D model of collective ant nest construction. This model is based on stochastic individual rules derived from the experimental analysis of building behaviour in the ant *Lasius niger*. The model also integrates logistic constraints, that is physical limitations on the movement of ants imposed by the nest architecture. Such constraints have been previously implemented by Ladley and Bullock (2005) to simulate the formation of the royal chamber and covered lanes in termites.

There are two main differences with this previous work. First, in our model there is no chemical template created by the diffusion of pheromones. This contrasts with termites, because the queen releases a pheromone that controls the distance at which workers start to build. At the very begin-

ning, this chemical template strongly interacts with the self-organizing building processes. And this combination gives rise to pillar-like structures formed at roughly regular spatial intervals, but at a specific distance from the queens body. In ants, the effect of the body-template begins to work later in the construction process, when the pillar-like structures have reached a critical size. The consequence is the formation of a double regular spatial pattern: the first one characterizes the spatial distribution of the pillars and the second one characterizes the layered structure of the nest. The second difference is a constant remodelling process that results from the ants activity. In our model, ants continuously destroy what they have built previously. Once a layer is in place, all its surface is eroded as a consequence of the ants digging activity and rapidly the material accumulates on the underneath surface. As a main consequence all the layers drift progressively downwards. And the speed of the travelling and remodelling wave results from a balance between the net deposition rates of building material at the upper and lower surfaces of a layer.

Sometimes, ants may accumulate by chance a little bit more material on the underneath surface of an existing layer. This gives rise to a new pillar growing from top to bottom. Once this pillar is built, it remains in place because the virtual ants can only dig on the bottom layer and not on the sides. This creates a kind of defect that propagates within the structure as the remodelling process goes on. The same process also produces connection areas between different layers close to these pillars. The motion of ants is in turn channeled by the spatial distribution of these connection areas. Then, depending on the evaporation rate, this channeling process may also promote the deposition of building material on the edges of the pillars, thus changing their size and shape.

Our model showed that the resulting nest structure strongly depends on the evaporation rate of the building pheromone. When the evaporation rate is very high ( $evap = 3.2 \times 10^{-4}$ ), only the very latest depositions of material can enhance the accumulation of more material. In these conditions, only a small number of pillars can be built, there is a strong competition among pillars to attract builders and the distance between pillars increases. The second consequence is a much more important enlargement of the capitals on top of the remaining pillars. As soon as a capital is built, the material is deposited at a faster rate on its border and the resulting shape of the roof becomes flat and thin. When the evaporation rate is less important ( $evap = 1.6 \times 10^{-5}$ ), the number of pillars increases and the enlargement of the capitals on top of the pillars is also much more important. Each pillar becomes a seed from which a new layer is growing. Since at each level there exist several seeds from which different layers are growing, it may happen that one of these layers collides with another one that is a part of the next level below. This results in the formation of inter-crossings of ceilings and floors belonging to two successive layers, leading

to the formation of ramps. Finally, when there is a very weak evaporation of the building pheromone ( $evap = 8 \times 10^{-7}$ ), the enlargement of the capitals becomes even more important. After having merged the capitals still increase their size and the floor of the new layer is so attractive that the depositions of building material occur more or less uniformly over the whole surface. Instead of well-defined pillars and floors, ants build globular structures enclosing empty and irregular chambers. The whole structure adopts a sponge-like structure.

The same kind of architectural diversity is observed in *Lasius* species. The ant *Lasius fuliginosus* builds a sponge-like nest (Figure 1 (a)), whereas *Lasius pallitarsis* and *Lasius niger* nests show layered structures (Figures 1 (b) and (c)). Our model shows that the same mechanisms can account for significant changes in the nests shape.

These variations may have several origins: it might be a consequence of the variation of environmental conditions (e.g. temperature and humidity levels). If these conditions change, the same species will be able to build nest structures that look very different, for example in *Acromyrmex* ants (Bollazzi et al., 2008) or in *Macrotermes* termites (Korb, 2003). But this variation may also result from the physical properties of the building pheromone itself. In particular one may imagine that different species of ants or termites can use similar building rules but different chemical cues. Physical and chemical properties of the building pheromone could thus play a key role in the diversity of nest architectures built by ants and termites. This is an important issue that needs to be addressed in future experimental work.

## Abstract

Forest ecosystems play a critical role in the cycles of carbon and water from local to global scales. These cycles and their variability, in turn, play an important role in the non-trivial emergent and self-organizing interactions between forest ecosystems and their environment. Observational evidence, based on micrometeorological eddy covariance measurements, suggests that heterogeneity and disturbance (both human and natural) in forest ecosystems in monsoon East Asia may facilitate to build resilience for adaptation to change. Yet, the principles that characterize the role of variability in these interactions remain elusive. A process network is defined as a network of feedback loops and the related time scales, which describe the magnitude and direction of the flow of energy, matter, and information between the different variables in a complex system. We attempt to delineate and interpret such process networks by analyzing multivariate ecohydrologic and biogeochemical time series data based on information flow statistics.

## Introduction

Complex systems are systems in which large networks of components with no central control and simple rules of operation give rise to complex collective behavior, sophisticated information processing, and adaptation via learning or evolution (Mitchell, 2009). Thus, the science underlying complex systems should focus not only on the concepts of energy, force and matter, but also on those of feedbacks, information, communication, and purpose.

In Asia, it is of great concern that ecosystem services are being degraded by natural disturbance such as monsoon activity accompanied by typhoons reinforced by anthropogenic factors in a changing climate. Recent finding suggests that under projected climate scenarios, terrestrial carbon sinks in monsoon Asia will decline if the monsoon disturbance will exceed its natural range of variation and if there is no enhancement in the resilience of the ecosystems in this region (e.g., Kwon et al., 2010; Hong and Kim, 2011).

Resilience-based system approach suggests that complex systems evolve through active adaptive cycles to cope with change. Ecohydrologic and biogeochemical processes associated with water and carbon cycles in complex forest

ecosystems can be viewed as a network of processes of a wide range of scales involving various feedback loops.

Finding such networks of feedback loops for key ecosystems in monsoon Asia is of great value and concern. However, the traditional correlation-based analysis cannot delineate such complex processes with detailed information on direction and strength of the coupling between the variables. Following Ruddell and Kumar (2009), we examined the dependence between a series of variables measured at the flux towers in AsiaFlux by quantifying the information flow between the different variables along with the associated time lag. The objective of our study is to test the applicability of information theory to ecohydrologic and biogeochemical systems with the datasets obtained at various forest sites in East Asia with different levels of complexity and heterogeneity.

## Methods and Materials

We used Shannon's information entropy as our methodology (Shannon, 1948) and calculated the transfer entropy ( $TE$ ) to measure the reduction in the entropy of the current state of a measured variable  $X_t^{(j)}$  due to the knowledge of prior state in another variable  $X_t^{(i)}$ , which is in addition to the information provided by the immediate prior history of  $X_t^{(j)}$  (e.g., Ruddell and Kumar, 2009). We normalized  $TE$  using  $m$  (set at 11) discrete bins to estimate the probability distribution function. The information flow process network consists of the asymmetric pair wise  $TE$  between the  $i^{\text{th}}$  and  $j^{\text{th}}$  variable from the set of  $n_v$  observed variables and is represented as an adjacency matrix (Kumar and Ruddell, 2010).

We used the time series data in 2008 from two adjacent KoFlux tower flux sites (in deciduous and coniferous forests) located in Korea. The description of the sites and the data can be found in AsiaFlux homepage (<http://www.asiaflux.net>). In this analysis, we selected 15 variables associated with ecohydrologic and biogeochemical processes in forests, which are atmospheric pressure ( $PA$ ), net ecosystem  $\text{CO}_2$  exchange ( $NEE$ ), gross primary productivity ( $GPP$ ), ecosystem respiration ( $RE$ ), latent heat flux ( $LE$ ), precipitation ( $Precip$ ), solar radiation ( $R_g$ ), air temperature ( $T$ ), vapor pressure deficit ( $VPD$ ), soil temperature ( $T_s$ ), soil water content ( $SWC$ ),

sensible heat flux ( $H$ ), canopy temperature ( $T_c$ ), wind direction ( $WD$ ), and wind speed ( $WS$ ). We computed process networks for each of thirty-six sub-daily time lags between 30 minutes and 18 hours. Our spectral analysis shows that this subdaily time scale explained more than 30% of the variances of the above variables associated with carbon and water cycles, reflecting that this range is an important scale of land-atmosphere interactions. In this process, the complexity and heterogeneity embedded in the observed flux data may hinder the application and interpretation of such information flow statistics. Therefore, estimation and methodological issues were examined by comparing these two adjacent forests with different levels of heterogeneity and complexity.

## Preliminary Results

The adjacency matrix for the 15 variables results in 210 potential pairwise couplings, about 25% out of which were found to be statistically significant at one or more time lags for both deciduous and coniferous forests. Preliminary results on network matrix are presented in Tables 1-4.

## Abstract

We report here the use of Aevol, a software developed in our team to unravel the indirect selective pressures (i.e. pressures for robustness and/or evolvability) that act on the genome and transcriptome structures. Using Aevol, we have shown that these structures are under strong – although indirect – pressure due to the mutagenic effect of chromosomal rearrangements. Individuals undergoing high spontaneous rearrangement rates show more compact structures than individuals undergoing lower rates. This phenomenon concerns genome size and content (non-coding DNA, presence of operons, number of genes) as well as gene network (number of nodes and links) thus reproducing parsimoniously a large panel of known biological properties. The results reported here have been published in *Mol. Biol. Evol.* (Knibbe et al., 2007), *Biosystems* (Beslon et al., 2010) and *Alife XII* (Parsons et al., 2010).

## Introduction

Largescale comparative analysis of sequenced genomes has revealed that several molecular traits follow characteristic scaling laws. For instance, the genome size has been shown to scale as a power-law of the spontaneous mutation rate in DNA-based microbes (Drake, 1991). More recently, different genomic properties have been shown to follow power-law distributions (Luscombe et al., 2002). In prokaryotes for instance, it was shown that the number of genes in each functional category scales as a power-law of the total number of genes and that the exponent of this law depends on the functional role of the family: The number of transcription factors, in particular, scales quadratically with the total number of genes while metabolic genes scale linearly (van Nimwegen, 2003). This increase is also correlated with the size of the genome (Konstantinidis and Tiedje, 2004).

The origins of such scaling laws remain an open question. Actually, despite the tremendous advance in the fields of genomics and transcriptomics, it is still not clear whether these “molecular allometric laws” result from selective constraints (e.g., selection for short genomes or integrated networks) or from the neutral dynamics of the evolutionary process.

An original approach to study the origins of genomic structures is to use *in silico* models of evolution. In such

models, the evolutionary forces are precisely tuned and it is possible to test experimentally how they shape the organisms’ structure. *In silico* evolution has already shown that darwinian evolution can have counter-intuitive effects, due to indirect selective pressures. For example, using the avida framework, Wilke et al. (2001) have shown that the long-term survival of a lineage not only depends on its fitness, but also on its mutational robustness. However, most digital genetic frameworks lack a precise description at the molecular level. That is why we have developed Aevol (“Artificial Evolution”) and its extension R-Aevol (“Regulation in Aevol”). It specifically focuses on the molecular level in order to unravel the evolutionary pressures that act on genomes and transcriptomes. We report here the main results we got with Aevol. These results have been published in *Molecular Biology and Evolution* (Knibbe et al., 2007), *Biosystems* (Beslon et al., 2010) and *Alife XII* (Parsons et al., 2010). Aevol is freely available upon request from the authors.

## The Aevol model

In Aevol, organisms own a circular, double-stranded genome of binary “nucleotides”. Predefined signaling sequences as well as an artificial genetic code allow to detect the coding sequences and to translate them into abstract “proteins”. We defined an artificial chemistry that describes the metabolism in a mathematical language: We assume that there is a one-dimensional space of all possible metabolic functions in which proteins are represented by a subset describing their metabolic contribution. This subset is described by parameters encoded in the coding sequence of the protein. Mutations in this sequence change these parameters, hence the metabolic activity of the protein.

In Aevol, the transcription rate of a given gene depends only on its own promoter sequence. In R-Aevol, proteins may have a regulatory activity besides their metabolic activity, thus being able to enhance or inhibit the transcription of other genes by binding to their promoters. The resulting transcription level is used to scale up or down both the metabolic and the regulatory activities of the protein. Due to this regulatory process, the transcription levels of the genes

vary during the organism life and so do the protein activities.

In Aevol as well as in R-Aevol, the global metabolism is computed by combining all the proteins' activities and the phenotype represents the degree of realization of each possible metabolic function. The fitness of the organism is then computed as the distance between the phenotype and a pre-defined target. The fittest organisms are allowed to replicate, with small mutations and large rearrangements (duplications, deletions, inversions, translocations) occurring randomly during the replication. Thus the genome size, gene number and gene order are free to evolve. In R-Aevol, mutations and rearrangements can also modify the regulatory network by either duplicating/deleting genes or promoter regions or by modifying their binding potentials.

## Results

Digital genetics models are experimental models: Population of individuals evolve in different conditions and, by observing the genomic and transcriptomic structures of the evolved organisms, one then links the structures to the evolutionary conditions. Analysis of the lineages then enables to unravel the origins of the observed structures, ideally by discovering invariant properties in all simulations. In Aevol, we classically explore the influence of mutation rates, rearrangement rates and selection strength. The most striking results were obtained by exploring the influence of rearrangement rates on the different organization levels of the model:

I) By observing the genome length of evolved organisms, we observed a linear scaling between the rearrangement rate and the length of the non-coding sequences in Aevol's genomes. We have shown that this scaling is due to an indirect selective pressure acting on the non-coding sequences: Due to chromosomal rearrangements, non-coding sequences have a mutagenic effect on the surrounding genes. This long-term selective pressure offers a new explanation to variability of genome size and content (Knibbe et al., 2007).

II) By reproducing in R-Aevol the same experiment, we have shown that this pressure also acts at the transcriptomic level. Regulation networks evolved under different rearrangement rates show huge structural differences, ranging from very small hardly connected networks (high rates) to large and densely connected ones (low rates). Moreover, like in prokaryotes, the number of transcription factors scales quadratically with the number of genes (Beslon et al., 2010).

III) Finally, we showed that this indirect pressure induces many side effects. In particular, under high rearrangement rates, genome compaction causes a fusion of transcribed sequences favouring operons (Parsons et al., 2010).

Thus, by changing a single parameter in the simulations – the spontaneous rearrangement rate – we were able to reproduce genomic and transcriptomic structures ranging from virus-like structures to prokaryote-like and, ultimately, eukaryote-like ones. Moreover, we were able to show that the best final organisms obtained in all these simulations

share the same variability level. If we measure the probability for the best final organisms to reproduce neutrally (i.e. the product of its offspring number  $W$  by its fraction of neutral offspring  $F_\nu$ ), we always observe that  $F_\nu W \sim 1$ , showing that these very different organisms all share a same exploration-exploitation compromise, an evident hallmark of indirect selection.

Of course, in Aevol many selective and non-selective effects have been neglected (energetic costs, mutational biases...) that may interact with the indirect selective pressure we isolated. However, in the model, this indirect selective pressure appears to be strong enough to overcome direct selective pressure (high rearrangement rates forbidding organisms to increase their gene repertoire). Thus it is likely to have an effect in real organisms. We now use Aevol to better understand the traces that indirect selection may leave in genomes. We will then be able to search for these traces in the sequences that accumulate in databases.

# Scalable Co-Evolution of Soft Robot Properties and Gaits

Davis Knox<sup>1</sup> and John Rieffel<sup>1</sup>

<sup>1</sup>Union College, Schenectady, NY 12308  
rieffelj@cs.union.edu

## Abstract

One of the outstanding challenges in soft robotics is the chicken-and-egg problem of body/brain design: generation of locomotion is predicated on the existence of a locomotion-capable body, and generation of body plans is predicated upon the existence of effective locomotion. This problem is compounded by the high degree of coupling between the *material properties* of a soft body (such as stiffness or damping coefficients) and the effectiveness of a gait. In this work we describe a means by which the material properties of a simulated soft body co-evolve alongside locomotive gaits. Improvements in simulation time, with no loss of overall fitness, are obtained by incrementally increasing mesh density over the course of evolution.

## Introduction

Imagine a soft, resilient and deformable robot able to change shape and squeeze through small apertures. The idea of using such a robot for urban search and rescue holds great appeal, particularly in light of recent tragic earthquakes in China, New Zealand, and Japan. Once the domain of science fiction, soft robots are approaching reality – thanks to recent advances in engineering and material science. Unfortunately, the very properties which make soft robots so appealing also introduce significant obstacles, especially in the domains of design and control. Elasticity and deformability come at the cost of resonances and tight dynamic coupling between components (Trimmer, 2007) – properties which are often assiduously avoided in conventional engineering approaches to robotic design. Small changes to the elasticity of a soft robot can cause unexpectedly large changes in performance.

Absent the analytical design methodologies available to conventional rigid robots, one compelling approach lies in *evolutionary design*, a field which has had considerable success in other complex design domains ranging from satellite antennae (Lohn et al., 2005) to telescope lenses (Al-Sakran et al., 2005) to elaborate tensegrity structures (Rieffel et al., 2009b).

The problems of soft robot design can be summarized with three questions:

- What should a soft robot *look like*? (*Morphology*)
- What physical properties should a soft robot have? (*Material*)
- How should a robot *move*? (*Locomotion*)

Of course, these are not independent variables: solving each problem is predicated upon, and sensitive to, the pre-existence of solutions to the corresponding problems. The design of a soft robot's locomotive gait, for instance, depends upon both its morphology and properties such as elasticity and friction.

This is in a sense an elaboration on the chicken-and-egg problem posed by body/brain design in more conventional robots (Pollack et al., 1999, 2001), with the added complexities which come from the effects of material properties upon a soft body's dynamics. In light of that, our approach to solving the problem will be similar: co-evolution. Earlier work has focused on co-evolving soft robot morphology with gaits (Rieffel et al., 2009a; Rieffel, 2010), and so this research focuses on the related problem of co-evolving material properties alongside gaits.

This paper describes how, given a specific soft robot's *shape*, we are able arrive at effective locomotion by co-evolving gaits – muscle firing patterns – alongside finely tuned material properties such as stiffness and damping coefficient. In doing so, we demonstrate a connection between material properties and gaits. Furthermore, in order to address the computational overhead imposed by soft body simulation, we introduce a method which scales model mesh resolution over the course of evolution, such that a large early portion of evolutionary time is devoted to low resolution models of the robot, and as evolution progresses mesh resolution increases. This resolution scaling achieves fitnesses comparable to those achieved by fixed high resolution while reducing overall computation time.

## Simulating Soft Robots

Once the domain of Finite Element Analysis (FEA) and Computational Fluid Dynamics (CFD), physics simulation is now much more accessible thanks to recent advances in

commercial off-the-shelf video-game physics engines accelerated by massively parallel graphics cards (GPUs). This General Purpose Computing on Graphics Processing Units (GPGPU) can provide speedups of several orders of magnitude over software-only simulation. (Banzhaf and Harding, 2009). In particular, our research uses NVidia's PhysX engine because of its ability to simulate complex three-dimensional *soft bodies*.

### Soft Bodies in PhysX

Soft bodies in PhysX are represented as tetrahedral meshes, where single tetrahedra (Figure 1) are connected to their neighbors at their common vertices. The material properties of a soft body mesh can be tuned by varying a set of constraints placed upon the tetrahedra within a mesh. Two values, stretching stiffness and damping co-efficient, tune the parameters of a spring-and-damper system along each edge of the tetrahedron. A tetrahedral mesh with high stretching stiffness will try hardest to maintain its shape, while one with a low stiffness will flop to the floor like a deflating balloon. The damping coefficient of a soft body changes how fast it returns to equilibrium after a perturbation. A low damping co-efficient allows soft bodies in motion to oscillate more. A third constraint, volume stiffness, determines how hard each tetrahedra attempts to maintain a constant volume – a mesh with low volume stiffness will resemble a flat puddle more than a balloon. Changing each of these values affects the softness of all tetrahedra in a soft body, although not necessarily in a linear manner. As illustrated by Figure 3, by varying these material properties, the behavior of soft bodies in PhysX can range from a near fluid, to rubbery Jell-O to a semi-rigid plastic. Finally, we also chose to vary the friction of the crawling surface, within a relatively narrow range, in order to be able to change how well the soft material gripped the substrate.

The bottleneck for soft bodies simulation is the density of the underlying tetrahedral mesh: simulation slows dramatically as the number of tetrahedra in a mesh grow (Figure 2). The trade-off is that low-resolution meshes, by modeling fewer nuances of the soft body, such as body wall folding, risk having lower fidelity to the real-world behavior of the corresponding soft body.

**Soft Body Gaits** One of the more interesting consequences of soft robotics is the lack of conventional actuators. Because suppleness and deformability are important, devices like servos and stepper motors are not viable. Absent those, one valuable alternative is nitinol “memory wire” (Trimmer, 2007). These artificial muscles act essentially as linear actuators, and can be modeled as applying equal and opposite force vectors to their two attachment points.

Given a fixed set of muscles in a soft robot, a simple way to represent their firing patterns is through a square wave characterized by a duty cycle, a phase offset, and a period

Figure 1: Soft bodies in PhysX are built out of tetrahedral meshes. Each tetrahedron is defined by four vertices and four corresponding faces. The material properties of a mesh can be tuned by changing the stretching and damping coefficients of spring-and-dampers systems along the edge, and by changing the tetrahedron's resistance to volume changes.

(Figure 4). The period of the firing pattern represents the time between the square wave's rising edges. Duty cycle corresponds to the percent of time that a muscle is “on” during that period. Finally, the phase of the firing pattern represents the delay before the first rising edge.

Figure 4: Soft robot gaits are composed of firing patterns for a set eight symmetrical muscles (four per side). Each of the eight patterns is described by a unique duty cycle, phase, and period.

Figure 5 shows the layout of the eight muscles on our model robot. It is worth emphasizing that although the muscle placement is bilaterally symmetric, in our genetic algorithm we place no such constraints on the eight matching firing patterns.

### Co-Evolving Gaits and Material

Our goal was to simultaneously discover a suitably matched gait/property pair, and so it seemed natural to gauge fitness by the linear distance traveled by the soft body over a fixed

Figure 2: The same robot model with low mesh resolution (left) and high resolution (right).

Figure 3: Changing the underlying material properties can drastically affect both the shape and the behavior of a soft body. Images of the same soft body with high (left) and low (right) stretching stiffnesses.

Figure 5: An illustration of the linear actuator “muscles” of the simulated soft body. Although muscles are aligned with bilateral symmetry, no symmetry constraints were placed on the underlying firing patterns.

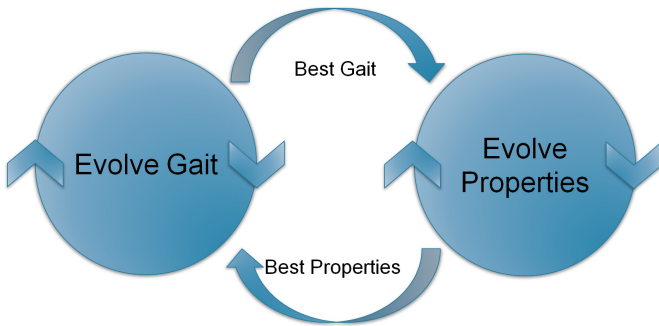

Figure 6: Evolution occurs in two parallel populations: the population of gaits uses the current-best set of material properties, while the set of population of properties uses the current best gait.

number (8000) of simulator time steps. However, the fitness of a specific gait can vary greatly depending upon the underlying material properties, and, similarly, the fitness of a material property set depends greatly upon the gait it is tested against.

Our solution was to co-evolve a population of gaits in lock-step with a population of material properties, each with a common fitness function (but separate fitness values). Figure 6 illustrates our approach. One population was composed of soft body gaits, where a gait genome is composed of eight phase/duty/period tuples, one for each muscle. No other information, such as muscle location, is encoded in the genome.

Values for the properties were limited to keep results realistic. Ranges are as follows (note that in PhysX, like most physics simulators, these properties are unit-less):

Property	Min	Max
Volume Stiffness	0.1	1.0
Stretching Stiffness	0.3	1.0
Friction	0.5	1.0
Damping	0.0	1.0

Initially, a fixed “best guess” of material property values (those which were used to produce the results of our earlier work in Rieffel (2010)) was used for evaluating the fitness of each gait. The second population evolved soft body material properties, where a single genome contained values for a specific set of stretching stiffness, volume stiffness, damping co-efficient and body friction. Initially, for this population’s fitness evaluations, a fixed “best guess” of firing patterns –

in this case arrived at via human trial and error – was used.

Every tenth generation, the gait used for material property fitness evaluation was updated with the current highest-fitness gait from the gait population, and the material properties used for gait population evaluation were updated from the highest-fitness property values.

With population sizes of 40, a typical run took approximately 24 hours to evaluate 100 generations of each population on a 2.66 GHz Core i7 processor with 6 GB of RAM.

## Results and Discussion

We have two analyses of our experiments to offer. The first is a more qualitative description of the gaits produced by our system and some insight into how changing material properties affect fitness. The second more quantitatively explores the effect of scaling the mesh resolution over the course of an evolutionary run.

### Gaits and Material Properties

Our experiments consistently produced interesting and effective gaits, and this suggests that being able to change material properties alongside firing patterns has a positive effect upon the outcome. A qualitative and visual representation lies in videos of the actual gaits, which can be seen at the following URLs:

<http://www.youtube.com/watch?v=dOV33dHRaD8>

<http://www.youtube.com/watch?v=1fJ4IHni5p0>

The first video shows a bilaterally asymmetric gait. Firing patterns on each side of the body co-ordinate in a rough front-to-back wave pattern in order to collectively lift the limbs upwards and forwards during the upswing, before relaxing into the downswing to pull against the ground. The relative softness of the material can be seen in the amount of flexing undergone by each leg. The second video, by comparison shows a more symmetrical gait achieved by a forward-moving wave which produces what almost looks like a gallop.

There were some distinct differences in material property values across these two runs, as summarized below:

Property	Bipedal	Wave
Volume Stiffness	0.986	0.996
Stretching Stiffness	0.982	0.998
Friction	0.598	0.804
Damping	0.0004	0.0

The most notable difference is the friction – corresponding to the stickiness of the robot’s feet, however when watching the videos, the relatively minor numerical differences in the other property values appear, at least qualitatively, to be reflected in the behavior of the soft bodies.

Of further interest is the change in best-of material values properties which occur over the course of an evolutionary run, as shown in Figure 8. While damping coefficient and

volume stiffness show relatively monotonic progress toward a fixed value, stretching stiffness and friction vary consistently across a relatively wide range during evolution. The effect of material property changes on fitness is even more apparent when shown alongside the corresponding fitness graph (shown on the bottom of Figure 8). The large swing in damping co-efficient at generation 7 corresponds to a matching significant rise in fitness. Other, smaller, fitness gains also appear to have corresponding material value changes.

### Scaling Mesh Resolution

Our second analysis is of the benefits offered by scaling mesh resolution over the course of evolution. Recall that the number of tetrahedra in a mesh are the determining factor in simulation run time, as well as in simulator fidelity. We ran a suite of experiments exploring the effects of different scaling schemes, as summarized in Table 1.

Our intuition was that the the bulk of early evolutionary time, which largely consist of the soft robot flailing around – that is attempting to achieve non-zero fitness, could be performed on relatively low meshes, and then as evolution and fitness progressed, mesh resolution could be scaled upwards to raise the emphasis on fidelity at the cost of longer evaluation times. A similar approach, with rigid-bodied multi-resolution robots, is discussed by Auerbach and Bongard (2010).

There were five mesh resolutions available to the system: low, medium low, med, high, and maximum. Runs could switch 0,1,2 or 4 times. All of the non-static runs shown began on the low mesh – runs that are listed with a mesh switch count of one, for instance, changed from the low mesh to their end mesh. Runs listed with a mesh switch count greater than one ran on an intermediate mesh(es) before reaching their end mesh. All other properties, such as population size, remained constant across experiments. Resolution changes occurred every 30 generations.

Fitness	Hours	Mesh Sequence
40.16	34	Low
46.94	42	Low
24.61	72	Max
14.86	25	MedLow
21.47	25	Low,MedLow
11.97	24	Med
12.86	24	Low,Med
15.99	48	Med
16.65	48	Low,Med
15.91	48	Low,MedLow,Med
6.18	46	Low,Medlow,Med,MedHi,Max

Table 1: A summary of results from resolution scaling

Figure 7, which compares evolution with a single (low-to-medium-low) switch to that with a fixed (medium-low)

Figure 7: A comparison of co-evolutionary progress on a static mesh resolution (bottom) vs. a single resolution switch. The sudden drop in fitness corresponding to resolution change is caused by the low-resolution gait working less well on the higher resolution mesh.

mesh resolution show the consequences of this process: fitness in the scalable evolution during its “low” phase progresses much more rapidly during the first 10 hours of simulation. Once the phase change into a higher mesh density occurs, however, there is a dramatic drop in fitness, and the scalable run loses much of the ground it had gained (though it still remains above the fixed resolution result). During the following 15 hours, the scalable run is able to make up much of the lost fitness, and improves more rapidly than the static mesh.

This steep loss in fitness is due to the large extent to which the success of a gait is highly tuned to its specific mesh resolution. The same actually holds true of the evolving material properties as well. Gaits and physical properties evolved at one mesh resolution simply do not translate perfectly when placed in a higher resolution simulation.

This dependence on mesh resolution also has a clear effect upon the the maximum obtainable evolutionary fitness: over similar time scales, even the static meshes show significant differences in final fitness.

The last entry in Table 1 illustrates the cost of switching clearly: the final fitness is less than half of that achieved by any other run. This suggests that, in its current form, sometimes the cost of resolution scaling can be too high. Figure 9 shows a case where even a single switch in resolution results in an equivocal, at best, improvement in overall fitness.

The source of this loss in fitness can possibly be illustrated with an interesting qualitative distinction of gaits evolved at varying resolutions: gaits evolved in a low resolution mesh tended to produce bi-pedal gaits, whereas gaits produced in the “maximum” mesh tended to be more bilaterally symmetric, involving instead a forward-propagating wave-like motion. In other words, sauce for the (low-resolution) goose may not be sauce for the (high-resolution) gander. A high-fitness bipedal gait evolved a low mesh resolution ceases to be competitive when placed in a higher-resolution body.

Mesh scaling certainly holds promise, and in a few cases illustrated above, offers an improvement over static-resolution evolution, despite the large fitness drops associated with resolution switches. While it remains to be seen if this is a viable way to address the issue of long simulation times, we are hopeful of its prospects. In future work, we hope to develop a method which allows for more smooth transitions between mesh resolutions.

## Conclusions

In this work we have illustrated the tight coupling which exists between soft body gaits and the body’s underlying material properties. We have also demonstrated how material properties can be fine-tuned to a gait (and vice versa) via co-evolution. Finally, we have explored a method of reducing simulation time by scaling soft body mesh resolution over

Figure 9: Results comparing the consequence of switching mesh resolution multiple times over the course of evolution. Each time resolution changes there is a dramatic drop in fitness due to the relatively poor translation of gaits and material properties into the higher mesh.

the course of evolution. Collectively, this approach holds promise as a way to discover gaits for dynamically complex soft robots.

This work leaves several compelling unanswered questions which we look forward to addressing. Among them: the mechanisms behind the coupling of material properties and evolved gaits; a comparison to encoding both gait and material properties in a single monolithic genome within a one-population system; an analysis of material property evolutionary trends across resolutions (e.g. a trend toward stiffer bodies as robot speed increases).

Ultimately we are interested in the *trifecta* of simultaneously evolving material properties, gaits, and large-scale morphology (S. Smith and Rieffel, 2010).

In concluding, it is worth emphasizing that this work, while performed in simulation, is grounded in real-world applications. Many ongoing efforts at developing physical soft robots employ silicone elastomers, whose material properties can be changed quite significantly during the mixing process (Trimmer, 2007). Furthermore, this bio-inspired research also ties back into understandings of the incredibly sophisticated biomechanics of completely soft organisms, such as the *Manduca Sexta* caterpillar (Simon et al., 2010).

## Abstract

Identifying and understanding modular organizations is centrally important in the study of complex systems. Several approaches to this problem have been advanced, many framed in information-theoretic terms. Our treatment starts from the complementary point of view of statistical modeling and prediction of dynamical systems. It is known that for finite amounts of training data, simpler models can have greater predictive power than more complex ones. We use the trade-off between model simplicity and predictive accuracy to generate optimal multiscale decompositions of dynamical networks into weakly-coupled, simple modules. State-dependent and causal versions of our method are also proposed.

## Introduction

The study of complex dynamical systems – such as gene regulatory networks (Han et al., 2004), structural and functional brain networks (Bullmore and Sporns, 2009), ecological food webs (Krause et al., 2003), and others (Hartwell et al., 1999, Schlosser and Wagner, 2004) – has frequently uncovered the presence of modularity. Broadly speaking, modular systems are composed of tightly-integrated subsystems, called *modules*, which are in turn weakly coupled to one another.

Numerous explanations have been proposed for the function of modularity in complex systems, only a few of which are mentioned here. Simon (1962) suggested that modularity can contain the effects of harmful perturbations and lead to greater developmental and operational robustness, especially when modules are hierarchically arranged. Kashtan and Alon (2005) argued that modular systems can take advantage of reusability when adapting to changing combinations of fixed environmental tasks. Tononi et al. (1998) proposed that modularity balances the conflicting needs for subsystems that are functionally specialized but also integrated into globally coherent states. Notably, it has also been shown to arise as a result of non-adaptive processes, such as neutral evolution of gene regulatory networks (Force et al., 2005, Solé and Valverde, 2008) and stochastic fluctuations in network connectivity patterns (Guimera et al., 2004).

Though the concept of modularity has acquired a central place in the study of complex systems, its meaning and operationalization varies widely between scientific paradigms, fields, and processes of interest. In the biological sciences alone, one can find references to *structural*, *developmental*, *physiological*, *variational*, and *functional modularity* (Winther, 2001, Wagner et al., 2007), among others. In this work, we propose a formal notion of modularity based on statistical modeling. Our approach applies to a broad class of discrete-time multivariate dynamics, whether represented by dynamic models, such as Boolean or dynamic Bayesian networks, or empirical distributions estimated from time series recordings. Unlike much recent work on community-structure in static graphs, we identify modularity in the organization of dynamically interacting components. We argue that in addition to being useful for analysis of real-life dynamical systems, our approach can shed light on connections between notions of modularity utilized in different domains, as well as the general role of modularity in modeling.

The next section provides a brief background on information theory. We then outline traditional information-theoretic approaches to modularity in dynamical systems, and develop our own treatment in terms of statistical modeling. After applying it to an example dynamical system, we consider state-dependent and causal versions of modular decompositions. We conclude by discussing issues of parameterization, directions for further work, and connections between our method and broader questions of modeling.

## Information theory

Information theory provides principled measures of information transfer and statistical dependence in distributed systems. As such, it is well-suited for quantifying measures of coupling and modularity.

To review, Shannon *entropy* measures the uncertainty in the measurement outcomes of a random variable. If  $X$  is a discrete random variable with an associated probability distribution  $P(X)$ , then its entropy is:

$$H(X) = - \sum_{x \in X} P(x) \log P(x)$$

A random variable that takes a single value with probability 1 has an entropy of 0, while an equiprobable random variable assumes the maximum entropy of  $\log |X|$ , where  $|X|$  is the number of possible outcomes. When the base of the logarithm is 2, as in this work, the units of entropy are *bits* (1 bit is the uncertainty in the choice between 2 equally possible outcomes). Because measuring a variable reduces uncertainty about its value, entropy can also be considered a measure of information.

When provided with a joint distribution over two random variables such as  $P(X, Y)$ , *conditional entropy* measures the expected uncertainty in the value of one variable given that the value of the other is known:

$$H(X|Y) = H(X, Y) - H(Y) = - \sum_{x,y} P(x, y) \log P(x|y)$$

*Mutual information* is a symmetric measure of nonlinear correlation between two random variables. Expressed as the difference between entropy and conditional entropy, it can be interpreted as the reduction in uncertainty about the value of one random variable provided by knowledge of the other:

$$\begin{aligned} I(X; Y) &= H(X) + H(Y) - H(X, Y) \\ &= H(X) - H(X|Y) = H(Y) - H(Y|X) \\ &= \sum_{x,y} P(x, y) \log \frac{P(x, y)}{P(x)P(y)} \end{aligned}$$

Mutual information captures the amount of constraint in the joint distribution of two variables not present in their marginal distributions. It is equal to 0 when two variables are statistically independent, and reaches its maximum possible value of  $\min\{H(X), H(Y)\}$  when one variable is a function of the other.

Mutual information can be extended to the case of more than two variables. Let random vector  $\mathbf{X} = (X_1, X_2, \dots, X_L)$  with distribution  $P(\mathbf{X})$  represent the state of a system composed of  $L$  distinct variables. The total constraint in this system not present in any single variable is measured by a multivariate version of mutual information, often called *multi-information* (Studený and Vejnarova, 1998) or *integration* (Tononi et al., 1994):

$$\begin{aligned} \mathcal{I}(\mathbf{X}) &= \sum_{i=1}^L H(X_i) - H(\mathbf{X}) \\ &= \sum_{\mathbf{x}} P(\mathbf{x}) \log \frac{P(\mathbf{x})}{\prod_{i=1}^L P(x_i)} \end{aligned} \quad (1)$$

*Kullback-Leibler (KL) divergence* is a measure of the difference between two distributions:

$$KL(P||Q) = \sum_x P(x) \log \frac{P(x)}{Q(x)} \quad (2)$$

It is always positive and 0 iff  $P = Q$ , though it is not a

distance because it is not symmetric. Importantly, many information-theoretic measures can be restated in terms of KL divergence. For example, the multi-information of eq. 1 is equal to the KL divergence between the distribution of  $\mathbf{X}$  and a product of the marginal distributions over the individual variables of  $\mathbf{X}$ .

## Modularity in multivariate dynamics

As previously mentioned, multi-information measures the total amount of higher-order constraint present among the variables of a multivariate system. It is 0 when these variables are independent, and increases when more statistical interaction between variables is present (Studený and Vejnarova, 1998). For this reason, many formal approaches to modularity search for system transformations that minimize this measure.

Several kinds of transformations can be investigated. *Independent component analysis* attempts to minimize multi-information over the space of linear mappings (coordinate changes) of a multivariate system (Hyvärinen and Oja, 2000). A different approach, closer to the one pursued here, looks for *partitions* of system variables with low multi-information.

A partition  $\pi$  of set  $S$  is a set of mutually exclusive, nonempty subsets  $B \subseteq S$ , called *blocks*, such that  $\bigcup_{B \in \pi} B = S$ . For example,  $\{\{1\}, \{2, 3\}\}$  and  $\{\{1, 2, 3\}\}$  are two possible partitions of the set  $\{1, 2, 3\}$ . We also use a more concise notation: the two partitions above, for example, can be referred to as 1/23 and 123 respectively. Additionally,  $\pi_0$  is used to indicate the *total partition*, which includes the entire set in a single block, i.e.  $\pi_0 \equiv \{S\}$ .

We look at partitions of  $V = \{1, \dots, L\}$ , the set of indexes of the variables of random vector  $\mathbf{X}$ . For partition  $\pi$  and block  $B \in \pi$ ,  $P(\mathbf{X}_B)$  indicates the marginalization of  $P(\mathbf{X})$  onto the variables whose indexes are in  $B$ . For example,  $P(\mathbf{X}_{\{1,2\}})$  is the marginal distribution of the first two variables of  $\mathbf{X}$ .

We define the multi-information of partition  $\pi$  as:

$$\mathcal{I}_\pi(\mathbf{X}) = \sum_{B \in \pi} H(\mathbf{X}_B) - H(\mathbf{X})$$

This measure quantifies the amount of constraint holding among the blocks of  $\pi$ . Finding partitions with low multi-information corresponds to identifying weakly-coupled subsystems. Variations on this theme appear in information-theoretic treatments of modularity starting from early cybernetics (Conant, 1972) to more recent approaches in computational neuroscience (Tononi and Sporns, 2003).

Multi-information is defined over a time-invariant distribution of system states. Though it does not account for the dynamic flow of information within a system, it can be generalized to this case. Assume a multivariate system with Markovian dynamics represented by  $P(\mathbf{X}' = \mathbf{x}' | \mathbf{X} = \mathbf{x})$ , the conditional probability distribution of transitioning to

Figure 1: A simple four node Boolean network (nodes 1, 2, 3, and 4 perform OR, AND, majority, and OR update functions respectively). Its full state transition table is shown in center. On the right, the stochastic interaction of every possible partition of the network.

each future state  $\mathbf{x}'$  given starting state  $\mathbf{x}$ , as well as  $P(\mathbf{X} = \mathbf{x})$ , the distribution over starting states.<sup>1</sup> The amount of information flowing dynamically among the blocks of  $\pi$  is called *stochastic interaction* (Ay and Wennekers, 2003). It is a conditional version of KL divergence between the transition distribution of the whole system and the product of marginal transition distributions of the variable blocks specified by partition  $\pi$ :

$$\begin{aligned} \mathcal{I}_\pi(\mathbf{X}'|\mathbf{X}) &= \sum_{B \in \pi} H(\mathbf{X}'_B|\mathbf{X}_B) - H(\mathbf{X}'|\mathbf{X}) \quad (3) \\ &= \text{KL} \left[ P(\mathbf{X}'|\mathbf{X}) \left\| \prod_{B \in \pi} P(\mathbf{X}'_B|\mathbf{X}_B) \right\| \right] \end{aligned}$$

These kinds of dynamic generalizations of multi-information have recently been proposed as measures of system-wide coupling in brain dynamics (Balduzzi and Tononi, 2008, Barrett et al., 2011).

A simple demonstration is provided by the Boolean network in fig. 1. It has four nodes, whose update functions are OR, AND, majority rule, and OR respectively. The stochastic interaction of each possible partition is provided, assuming a uniform distribution over starting states. For example, the partition 12/34 is the bi-partition having the lowest stochastic interaction: the block  $\{1, 2\}$  has conditional entropy  $H(\mathbf{X}'_{\{1,2\}}|\mathbf{X}_{\{1,2\}}) = 0$  (nodes 1 and 2 do not depend on the rest of the system, so their marginalized dynamics are deterministic), while block  $\{3, 4\}$  has conditional entropy  $H(\mathbf{X}'_{\{3,4\}}|\mathbf{X}_{\{3,4\}}) = 0.5$ . Because the system as a

<sup>1</sup>We assume that the dynamics are stationary, in that the transition probability distribution does not change through time. Our analysis can also be applied to higher-order Markovian systems, though for simplicity they are not considered here.

whole is deterministic,  $H(\mathbf{X}'|\mathbf{X}) = 0$  and the total stochastic interaction of partition 12/34 is  $H(\mathbf{X}'_{\{1,2\}}|\mathbf{X}_{\{1,2\}}) + H(\mathbf{X}'_{\{3,4\}}|\mathbf{X}_{\{3,4\}}) - H(\mathbf{X}'|\mathbf{X}) = 0.5$ .

Unfortunately, stochastic interaction is not a suitable cost function for identifying modular partitions of a multivariate dynamical system (similarly for multi-information and multivariate non-dynamical systems). In any such system, a minimal stochastic interaction of 0 will be assigned to the total partition  $\pi_0$ , and generally a partition will never have a greater stochastic interaction than any of its refinements (where one partition is a *refinement* of another if every block of the former is a subset of some block of the latter). Selecting partitions using stochastic interaction will thus favor partitions with large blocks, the total partition being a (possibly non-unique) global minimum.

Due to this, several authors have proposed normalizing factors that penalize large partitions (Conant, 1972, Balduzzi and Tononi, 2008). However, the derivation and justification of these normalizing terms is ad hoc. In this work, we approach the problem of identifying modules from the point of view of statistical prediction. This yields principled penalization terms for large partitions and leads us to uncover modular decompositions with clear interpretations in terms of statistical modeling.

## Statistical modeling and modular decompositions

Information theory is intimately connected with statistical modeling (Rissanen, 2007). For example, assume a model that assigns a probability value to data  $\mathbf{x}$ :

$$Q(\mathbf{x}) = \int_{\Theta} Q(\mathbf{x}|\theta) \omega(\theta) d\theta \quad (4)$$

This term, called the *marginal likelihood* in the Bayesian literature, is the expectation of the likelihood function  $Q(\mathbf{x}|\theta)$  with respect to distribution  $\omega(\theta)$  over parameter values.

$Q(\mathbf{x})$  is a measure of predictive fit to data, and its logarithm is often maximized over parameter distributions or model choices. Equivalently, one can minimize the negative of its logarithm, a measure of predictive error called *log loss*. If data samples are drawn from some true probability distribution  $P(\mathbf{X} = \mathbf{x})$ , then the expectation of the log loss of the marginal likelihood is:

$$-\sum_{\mathbf{x} \in \mathbf{X}} P(\mathbf{x}) \log Q(\mathbf{x}) = \text{KL}(P\|Q) + H(P(\mathbf{X}))$$

The KL term (from eq. 2) is non-negative, and reaches its minimum of 0 when the model is perfectly fit, i.e.  $Q = P$ . It is a measure of excess prediction error of the model above the minimum possible. This minimum is specified by the entropy term, and depends only on the true distribution  $P(\mathbf{X})$  and not on model or parameter choices.

A similar situation holds in the dynamic setting. We call

*dynamic models* those that generate conditional distributions of multivariate future states  $\mathbf{x}'$  given starting states  $\mathbf{x}$ :

$$Q(\mathbf{x}'|\mathbf{x}) = \int_{\Theta} Q(\mathbf{x}'|\mathbf{x}, \theta) \omega(\theta) d\theta$$

We look at statistical prediction of dynamical systems from the perspective of an agent who does not possess a perfectly fit model, but must learn a dynamic model given previous observations. The agent is provided with a set of factorized models: for each partition of system variables  $\pi$ , there is a dynamic model  $Q_{\pi}$  whose parameters and marginal likelihood obey the independence conditions imposed by the block structure of  $\pi$ :

$$Q_{\pi}(\mathbf{x}'|\mathbf{x}) = \prod_{B \in \pi} Q_{\pi}(\mathbf{x}'_B|\mathbf{x}_B) \quad (5)$$

The predictive performance of our agent depends on the chosen model and the amount of previously observed data. It can be quantified with a *risk function*, which here is the KL divergence between the true distribution  $P(\mathbf{X}'|\mathbf{X})$  and the distribution predicted by a dynamic model (Haussler and Oppel, 1997). The risk of model  $Q_{\pi}$  on the next sample, after observing  $N$  previous samples, is:

$$r_{N, Q_{\pi}} = \text{KL}[P(\mathbf{X}'|\mathbf{X}) \| Q_{\pi}(\mathbf{X}'|\mathbf{X}, \mathbf{X}^{1..N}, \mathbf{X}^{1..N})] \quad (6)$$

The expectation in the KL term is taken over the next sample of  $\mathbf{X}'$ ,  $\mathbf{X}$ , as well as  $N$  previous i.i.d. samples  $\mathbf{X}^{1..N}$ ,  $\mathbf{X}^{1..N}$ . The Bayesian *posterior predictive distribution*:

$$Q_{\pi}(\mathbf{x}'|\mathbf{x}, \mathbf{x}^{1..N}, \mathbf{x}^{1..N}) = \int Q_{\pi}(\mathbf{x}'|\mathbf{x}, \theta) Q_{\pi}(\theta|\mathbf{x}^{1..N}, \mathbf{x}^{1..N}) d\theta$$

is the marginal likelihood of eq. 4, with the distribution over parameter values conditioned on  $N$  previous data samples. From the point of view of machine learning, such Bayesian updating of parameters in light of observed data corresponds to model *training*, while evaluating the expected model risk on new samples corresponds to model *testing*. More concretely, our dynamic models can be considered *supervised learners*: given data, they infer probabilistic mappings from inputs (starting states  $\mathbf{X}$ ) to outputs (future states  $\mathbf{X}'$ ).

Given the independence assumption of eq. 5, risk  $r_{N, Q_{\pi}}$  becomes:

$$\mathcal{I}_{\pi}(\mathbf{X}'|\mathbf{X}) + \sum_{B \in \pi} \text{KL}[P(\mathbf{X}'_B|\mathbf{X}_B) \| Q_{\pi}(\mathbf{X}'_B|\mathbf{X}_B, \mathbf{X}_B^{1..N}, \mathbf{X}_B^{1..N})]$$

This form draws attention to the two components that contribute to risk (that is, predictive error). The *stochastic interaction term* (see also eq. 3) arises as a consequence of ignoring dynamic coupling between variables in different blocks. It is the minimal excess error of a factorized model (in which the dynamics of the variable blocks induced by partition  $\pi$  are independent) above an optimally fit whole-system model (where interactions between all variables can be captured).

The second term, called the *complexity term*, reflects the excess predictive error of a trained model above the minimum possible. It arises because a model trained on a finite amount of data maintains some uncertainty about optimal parameter values. For a given amount of training data, complex models (with larger parameter spaces) will have greater parameter uncertainty than simpler models, resulting in more excess predictive error. As  $N \rightarrow \infty$ , the complexity term can be asymptotically approximated by  $\frac{d_{\pi}}{2N}$ , where  $d_{\pi}$  refers to the number of parameters of model  $Q_{\pi}$  (Komaki, 1996, Barron and Hengartner, 1998). This yields:<sup>2</sup>

$$r_{N, Q_{\pi}} \approx \mathcal{I}_{\pi}(\mathbf{X}'|\mathbf{X}) + \frac{d_{\pi}}{2N} \quad (7)$$

For a given amount of training data  $N$ , the model with the lowest risk,

$$Q^*(N) = \arg \min_{Q_{\pi}} r_{N, Q_{\pi}}$$

corresponds to the partition providing an optimal predictive decomposition of the system. Models that minimize risk offer a balance between two conflicting constraints: on one hand, low stochastic interaction (better predictions under optimal fit), on the other, low model complexity (easier parameter estimation with limited training data). Because partitions with smaller blocks (which have smaller-state-space dynamics representable by fewer parameters) generally induce simpler models, risk presents a principled cost function for identifying small, weakly-coupled modules. The amount of data  $N$  parameterizes this trade-off: as  $N$  increases, emphasis is shifted from the complexity term to the stochastic interaction term, and groups of variables whose dynamic interactions carry the most information while being easiest to learn are first to coalesce into multivariate blocks of the optimal model.<sup>3</sup> Thus, selecting optimal decompositions while increasing the amount of training data generates a modular multiscale decomposition of system variables. In the infinite data limit, the risk of each model  $Q_{\pi}$  reaches its minimum of  $\mathcal{I}_{\pi}(\mathbf{X}'|\mathbf{X})$ , and the partition corresponding to  $Q^*$  becomes the one with lowest stochastic integration (the total partition being a possibly non-unique minimum).

## Decomposing a dynamical system

The complexity term in eq. 7 depends on the parametric form of the dynamic model. Though a variety of possibili-

<sup>2</sup>This approximation assumes continuously-parameterized models and standard regularity conditions. It also assumes that, for all  $\pi$ , some parameterization of  $Q_{\pi}$  offers a perfect fit to the factorized  $\prod_{B \in \pi} P(\mathbf{X}'_B|\mathbf{X}_B)$ . It is possible to generalize beyond this case, where the factorizations of the true distribution are 'out-of-class' of the models  $Q_{\pi}$ .

<sup>3</sup>Minimizing risk can be seen as a form of information bottleneck (Tishby et al., 1999): it searches for factorized models whose parameters minimize information about training data while maximizing information about system dynamics; the size of the training data serves as a trade-off parameter.

Figure 2: Top: approximate risk for optimally-predictive models of the Boolean network from fig. 1. Dots mark switches of the optimal model  $Q^*$ ; inset shows first two switches. Bottom: cumulative risk, or total accumulated prediction error for models plotted in the top graph. Total modularity ( $T$ ) is asymptotic difference between cumulative risks of  $Q_{1234}$  and  $Q^*$  or, alternatively, area between lines corresponding to (non-cumulative) risks of  $Q_{1234}$  and  $Q^*$ .

ties exist, here our dynamic models are assumed to be products of first-order Markov chains with Dirichlet priors. The number of parameters of model  $Q_\pi$  from this class is:

$$d_\pi = \sum_{B \in \pi} |\mathbf{X}_B| (|\mathbf{X}'_B| - 1) \quad (8)$$

where  $|\mathbf{X}_B|$  is the number of supported starting state outcomes and  $|\mathbf{X}'_B|$  is the number of possible future state outcomes of the variables with indexes in block  $B$ . For example, for a single block of Boolean variables with a fully supported starting state distribution, these are both equal to  $2^{|B|}$ . For this model class, the complexity term scales exponentially with the number of variables in each block.

As an example, we look at optimal decompositions of the network in fig. 1. Its risk, calculated using the approximation of eq. 7 and parameter counts of eq. 8, is shown at the

top of fig. 2.<sup>4</sup> The risk is plotted for those models which reach minimum risk at some point of the training process, as well as that of the overall minimal risk model  $Q^*$  at each  $N$ . Predictive power is initially optimized by the model corresponding to partition 1/2/3/4 (the simplest model which treats all nodes independently). At  $N \approx 3$  (inset), it is replaced by the model corresponding to partition 12/3/4 (variables 1 and 2 now merged into a single block); at  $N \approx 4$  (inset), by the model corresponding to partition 12/34; and finally at  $N \approx 215$ , the most predictive model becomes the one corresponding to the total partition 1234.

## Total modularity

So far, our measure of modularity has been parameterized by  $N$ , the amount of training data. Here, we derive a parameter-free measure of the *total modularity* in a dynamical system.

In our definition of risk (eq. 6), we used the *posterior predictive distribution*  $Q_\pi(\mathbf{X}' | \mathbf{X}, \mathbf{X}^{1..N}, \mathbf{X}^{1..N})$ , the probability assigned to the next data sample by a model trained on  $N$  previous data samples. Given our assumptions, the following relationship holds between the *prior predictive distribution*, the probability an untrained model assigns to  $N$  data samples, and the posterior predictive distribution:

$$Q_\pi(\mathbf{X}'^{1..N} | \mathbf{X}^{1..N}) = \prod_{n=0}^{N-1} Q_\pi(\mathbf{X}'^{n+1} | \mathbf{X}^{n+1}, \mathbf{X}^{1..n}, \mathbf{X}^{1..n})$$

This suggests the *prequential* interpretation of Bayesian prediction (Dawid, 1992): the expected predictive error of a model on  $N$  samples is the sum of the expected predictive errors on each successive sample after training on the previous samples. This accumulated prediction error is termed *cumulative risk* (Haussler and Oppner, 1997):

$$R_{N,Q_\pi} = \sum_{n=0}^{N-1} r_{n,Q_\pi}$$

The risk of eq. 6 can be seen as the rate of change of the cumulative risk as the amount of training data grows.

*Total modularity* is the total gain in predictive accuracy (i.e., decrease in cumulative risk) provided by the optimally predictive models  $Q^*(N)$  versus the unfactorized, total-partition model  $Q_{\pi_0}$ . Let  $R_{N,Q^*} = \sum_{n=0}^{N-1} r_{n,Q^*(n)}$  be the cumulative risk of an agent who selects the risk-minimal model at each  $N$ . The total modularity is then:

$$T = \lim_{N \rightarrow \infty} (R_{N,Q_{\pi_0}} - R_{N,Q^*}) \quad (9)$$

Total modularity measures the overall predictive advantage gained by using factorized models, and is not a function of a particular  $N$ . High values of total modularity indicate

<sup>4</sup>In general, the approximation of eq. 7 is only accurate for large  $N$ . However, it suffices for our explanatory purposes.

Figure 3: Total modularity of two binary variables which copy each others' state with probability  $p$  and maintain their own state with probability  $1 - p$ . Total modularity increases as coupling decreases, and diverges as  $p \rightarrow 0$ .

that simpler models have significantly improved predictive performance during earlier stages of the learning process.<sup>5</sup> To use the previous example, the cumulative risk of the models plotted at the top of fig. 2 is shown at the bottom of that figure. The total modularity of the dynamic network shown in fig. 1 is equal to the asymptotic difference between the cumulative risks of  $Q_{1234}$  ( $= Q_{\pi_0}$ ) and  $Q^*$ . Equivalently, it is also the total area between the lines corresponding to the (non-cumulative) risks of  $Q_{1234}$  and  $Q^*$ .

For another illustration of total modularity, we consider a simple dynamical system composed of two binary variables. Each variable is parameterized in the following manner: at each time step, with probability  $p$  it assumes the value of the other variable in the previous time step, and with probability  $1 - p$  it maintains its own value from the previous time step. The amount of dynamic coupling between the two nodes increases with  $p$ : at  $p = 0$  the variables have no interaction, while at  $p = 1$  their values are completely correlated (with a one timestep lag). This dynamic coupling is illustrated in fig. 3, which plots the total modularity of this system against the coupling parameter  $p$ . The total modularity monotonically decreases as  $p$  increases, showing that greater coupling leads to lower total modularity. As  $p \rightarrow 0$ , the two variables become completely independent and total modularity diverges (in this case, it grows without bound at a rate proportional to  $\log N$ ).

### State-dependent and causal modularity

The way information flows within a dynamical system can depend on the system's state. For example, a partition's stochastic interaction can be different in different attractors. We can quantify this by different choices of the starting

<sup>5</sup>Minimization of accumulated error by online switching from simpler to more complex models is related to a learning framework recently proposed by van Erven et al. (2007)

Figure 4: Risk for two systems, each having two binary variables: in system  $A$  (left column) each variable copies previous value of the other, in system  $B$  (right column) each variable takes opposite of its own previous state. a) and d): Risk under uniform starting state distribution. Lowest risk model of  $A$  becomes the total one, while factorized model remains optimal for  $B$ . b) and e): Risk and optimal decompositions depend on the starting state distribution. Computed over  $P(\mathbf{X} = (0, 1)) = 0.5, P(\mathbf{X} = (1, 0)) = 0.5$ , risk and optimal decompositions become the same for  $A$  and  $B$ , though their causal organization is different. c) and f): Causal risk leads to different decompositions of  $A$  and  $B$ , even when computed over same starting state distribution as in b) and e).

state distribution,  $P(\mathbf{X})$ . Though we have generally taken  $P(\mathbf{X})$  to be a fully-supported uniform distribution, it can be weighted preferentially over some subset of starting states.

For example, consider two systems, each composed of two binary variables. In system  $A$ , each variable copies the previous value of the other, while in system  $B$ , each variable takes the opposite of its own previous state. Fig. 4 shows the risk plots for both  $A$  (left column) and  $B$  (right column), where 4a and 4d are calculated for a uniform starting state distribution. The risk, as well as the optimal decompositions, is different between the two systems:  $A$  (which performs the copy operation) eventually chooses the total partition  $\{\{1, 2\}\}$  as the most predictive, while  $B$  (whose variables perform independent state flips) never does.

If, however, a non-uniform starting state distribution is chosen, risk and optimal decompositions can change. The risk for starting state distribution  $P(\mathbf{X} = (0, 1)) = 0.5, P(\mathbf{X} = (1, 0)) = 0.5$  are shown in fig. 4b and 4e (for systems  $A$  and  $B$  respectively). Different parts of the start-

ing state space induce different risk values and optimal decompositions: for this distribution, fig. 4b shows that the total partition  $\{\{1, 2\}\}$  is never chosen as the optimally predictive one for system  $A$ .

Additionally, for these starting states the transition distributions of  $A$  and  $B$  are identical: if either system is started in state  $(0, 1)$ , it deterministically transitions to state  $(1, 0)$ , and similarly for the transition from  $(1, 0)$  to  $(0, 1)$ . Because the observed dynamics of the two systems are identical, the risk functions and optimal decompositions are also equal. Though systems  $A$  and  $B$  are defined using different causal architectures, here their modular organizations are indistinguishable. Specifically,  $A$  is postulated to have a causal connection among its variables but – for this starting state distribution – they display no stochastic interaction.

This example highlights the difference between statistical correlation and causal interaction. To properly handle the latter, we utilize a notion of causality based on semantics of intervention (Pearl, 2000), recently developed in an information-theoretic direction by Ay and Polani (2008). In Pearl’s treatment, conditional probability distributions represent not only correlations, but also responses of variables to externally-imposed interventions. This is especially natural when dynamics of interest are generated by causal models, such as dynamic causal Bayesian or Boolean network models frequently used in artificial life and systems biology.

In our example, the functional organization of systems  $A$  and  $B$  can be differentiated – even within the non-uniform starting state distribution mentioned above – if the starting states of the systems can be intervened upon. This is because in system  $A$  – but not system  $B$  – changing the starting state of one variable can change the other variable’s future state.

We consider interventions formally by noting that the risk  $r_{N, Q_\pi}$  of eq. 6 need not take the same starting state distribution for training data as for the testing data. Instead, we take the starting state distribution for training data to be drawn i.i.d. from a fully-supported and uniform distribution  $\hat{P}(\mathbf{X})$  (the distribution of interventions), while the testing starting states can be drawn from any  $P(\mathbf{X})$  of interest. We refer to risk evaluated under this learning scenario as *causal risk*:

$$\hat{r}_{N, Q_\pi} = \sum_{\mathbf{x}, \mathbf{x}'} P(\mathbf{x}) P(\mathbf{x}' | \mathbf{x}) \left[ \log P(\mathbf{x}' | \mathbf{x}) - \sum_{\mathbf{x}^{1..N}, \mathbf{x}'^{1..N}} \hat{P}(\mathbf{x}^{1..N}) P(\mathbf{x}'^{1..N} | \mathbf{x}^{1..N}) \log Q_\pi(\mathbf{x}' | \mathbf{x}, \mathbf{x}'^{1..N}, \mathbf{x}^{1..N}) \right]$$

As  $N \rightarrow \infty$ , the posterior predictive distribution of model  $Q_\pi$  approaches  $\prod_{B \in \pi} \hat{P}(\mathbf{X}'_B | \mathbf{X}_B)$ , where  $\hat{P}(\mathbf{X}'_B | \mathbf{X}_B)$  is the whole-system transition distribution  $P(\mathbf{X}' | \mathbf{X})$  marginalized onto variables in block  $B$  using  $\hat{P}(\mathbf{X})$ . Then,  $\hat{r}_{N, Q_\pi}$  can be approximated by:

$$\mathcal{I}_\pi(\mathbf{X}' | \mathbf{X}) + \sum_{B \in \pi} \text{KL} \left[ P(\mathbf{X}'_B | \mathbf{X}_B) \parallel \hat{P}(\mathbf{X}'_B | \mathbf{X}_B) \right] + \frac{d_\pi}{2N}$$

where  $\mathcal{I}_\pi$ ,  $d_\pi$ , and the expectations in the KL terms use the testing starting state distribution. The KL divergence between  $P(\mathbf{X}'_B | \mathbf{X}_B)$  (the whole-system transition distribution marginalized onto variables in block  $B$  using  $P(\mathbf{X})$ ) and  $\hat{P}(\mathbf{X}'_B | \mathbf{X}_B)$  reflects the amount of extra perturbation that active interventions inject into block dynamics. The two distributions need not be equal, unless  $P(\mathbf{X}) = \hat{P}(\mathbf{X})$  or the partition under consideration is the total one. Because KL divergence is non-negative, causal risk  $\hat{r}_{N, Q_\pi}$  is not less than the statistical risk  $r_{N, Q_\pi}$  (compare above to eq. 7).

Fig. 4c and 4f show the causal risk for systems  $A$  and  $B$  (respectively) with  $P(\mathbf{X} = (0, 1)) = 0.5$ ,  $P(\mathbf{X} = (1, 0)) = 0.5$ . In 4c – but not 4f – the total partition model assumes a lower risk than the factorized model, indicating that for the starting states in question, system  $A$  – but not system  $B$  – has causal interactions between its variables.

## Conclusion

Modularity is normally treated as an objective property of a system’s organization. Our approach instead considers from the perspective of modeling and prediction. In the context of inferring dynamic models from limited data, modularity allows for models that are predictive but simple, with the amount of training data controlling the trade-off. Our statistical treatment connects to previous information-theoretic approaches, but goes further by providing principled terms for identifying small modules.

Our approach can also be used to find state-dependent modular organizations, both in statistical and causal (interventional) senses: models trained on interventional dynamics but tested on arbitrary distributions give rise to a measure that identifies causal modules. This is related to existing information-theoretic measures of causal interactions between subsystems (Tononi and Sporns, 2003), but here emerges naturally from the framework of statistical modeling. This framework also produces a measure of total modularity present in the system, which quantifies the overall predictive advantage that modularity provides through the entire model inference process.

As a side note, if the learning of real-world cognitive systems (such as scientists or organisms) proceeds in a manner somewhat similar to the statistical framework presented here, our approach suggests why such systems may infer modular organizations in the external world: under conditions of limited data, this assumption can simplify learning and lead to gains in predictive power.

One important issue with our treatment is its model-dependence. The complexity penalization term of eq. 6 depends on the model class, and different model classes may have different parameterizations and functional forms. Our examples employed products of Markov chain models, a rather general dynamic model class but one heavily parameterized; others could be used. The choice of model class can be thought of as a null model of system dynamics.

Several generalizations suggest themselves. For example, it is possible to infer module timescales by searching not only over decompositions, but also model orders (numbers of previous states on which transition probabilities depend; for inferring Markov chain order, see Strelhoff et al., 2007). Fuzzy modular organizations, in which a variable can belong to more than one module, can be accommodated by allowing partially-overlapping blocks. More generally, the model search space could include other structures besides partitions (e.g. trees or networks) to impose independence constraints on information flow between blocks.

Identifying modularity in dynamical systems is important in complex systems research in general, and biological systems modeling in particular. Our method differs from recent community-detection methods that find modularity in static graphs, in that it focuses on the organization of interactions between dynamic system components. In future work, we hope to apply it to the analysis of regulatory and signaling control in biochemical networks, as well as inference of functional neural organization from brain recordings.

## Abstract

Artificial chemistries have been analysed mostly under the precondition of a well-stirred reaction vessel. In other words, the localisation of molecules is ignored for simplicity. Here we drop this assumption and replace it with a spatial distribution of molecules given by a flow, i.e. molecules move according to a given vector field. This can be seen as a particular type of dynamics. It also gives additional parameters to the control over the development of the chemistry over time. In particular, the modelling of membranes and transport processes which occur in cells, for example, can be described using continuous vector fields instead of giving a discrete formulation. We give some examples and ideas for analysing such chemistries via a stochastic simulation, a PDE and chemical organisations.<sup>1</sup>

## Introduction

So far many *artificial chemistries* assume a well-stirred reaction vessel (Speroni di Fenizio, 2002). This is a special type of dynamics for the application of rules of the chemistry. In particular, it means that any molecule in the reaction soup can potentially react with any other molecule in the soup at any time. Or in other words, there is no *localisation of molecules* taken into account. On the one hand, this is easier to handle from a technical point of view (Dittrich et al., 2001). In a well-stirred reactor the change of concentration of molecules in the vessel is often seen as a stochastic process and can be simulated using the Gillespie algorithm (Gillespie, 1977, 1976) or can be approximated using ordinary differential equations (ODE), e.g. with the assumption of mass action kinetics. On the other hand, thinking of molecules as not being localised is unrealistic in many situations, e.g. in living cells with their compartments, membranes and transport processes, or when modelling the origin of life (Fishkis, 2010).

There are several approaches to include the spatial organisation or localisation into artificial chemistries. Some of

them employ means of *discrete spatial structures*, like P systems (Păun, 2000), vessels with dynamic compartments using Gillespie's algorithm (Versari and Busi, 2007) or MGS (Giavitto and Michel, 2001), some work with *continuous* additions to the dynamics, like reaction diffusion systems (Adamatzky, 2005). In the first case compartments and their creation and dissolution operations structure the reaction vessel. This gives a discrete description of geometrical information, where the definition of the chemistry is separate from the membrane structure, i.e. the membranes are not formed by molecules. Each of the compartments is subject to a well-stirred stochastic or deterministic dynamics. In the later case, molecules are localised in a Euclidean space. The assumption of a well-stirred domain is replaced by a diffusion process which results in a PDE model. This model describes the dynamics of the artificial chemistry accounting for the reactions and the movement by diffusion. This means that there is no further control over the behaviour possible except of the choice of diffusion constants.

The two examples show that including space into the dynamics brings more *complexity* with it. Still, there is extensive theory at hand for both of them. Going a step further in terms of complexity, we loose this advantage of rigid theoretical descriptions. For example, we have molecular dynamics simulations which can also be combined with rule-based spatial models (Grünert et al., 2010). They use the full generality of possible movement and reactions of molecules at the price of computational costs, predictability and controllability. Furthermore there are approaches, like the swarm chemistry (Sayama, 2009) using space for the representation of molecules.

Here we propose using *vector fields* for modelling spatial organisation and transport processes in artificial chemistries. By this we mean that molecules move along the flow lines of the vector field of a region in  $\mathbb{R}^N$  (most of the time  $N$  will equal to 2 or 3). Reactions are only applicable if enough molecules of the left hand side can be found together close enough. In other words, we do not intend to stir the reactor with our molecules well, but just stir in a particular way defined by a vector field. We can still formulate this as a

<sup>1</sup>further information and videos available at <http://www.biosys.uni-jena.de/Research/Projects/Reaction+Flow+Artificial+Chemistries.html>

stochastic process and approximate it with a partial differential equation (PDE). Another advantage is the gain of control over the behaviour of the chemistry by using different types of vector fields in contrast to, for example, diffusion, where we only have the diffusion coefficients as parameters.

The description of *transport processes* and *membranes* with vector fields, i.e. continuous objects, rather than discrete structures, does not seem to be as convenient or powerful at a first glance. To our understanding membranes and transport are integral part of the dynamics and should therefore be handled with continuous objects fitting in with the usual modelling via ODEs, for example. Therefore we would like to give a proof of concept for non-discrete membranes, compartments and transport. Also we focus here on the spatial aspect rather than on the artificial chemistries and their reactions used.

The paper is organised as follows. First we give the definition of a general reaction flow artificial chemistry. Then a differential model, using a PDE and Mathematica for a numerical computation of solutions is presented. We also describe a stochastic simulator providing us with a tool to run example chemistries. Then we show how to analyse the behaviour of reaction flow artificial chemistries with the help of chemical organisations (Dittrich and Speroni di Fenizio, 2007; Speroni di Fenizio and Dittrich, 2007). Finally we give more examples.

## Reaction Flow Artificial Chemistries

Let  $M$  be a set and  $R$  be a subset of  $\mathcal{P}_{mult}(M) \times \mathcal{P}_{mult}(M)$  where  $\mathcal{P}_{mult}(M)$  denotes the set of multisets over  $M$ . The pair  $(M, R)$  is called *reaction network* and we call  $M$  the set of *molecules* and  $R$  the set of *reactions*.

By *applying* a reaction  $(l, r) \in R$  to a multiset over  $M$  we mean replacing the subset  $l$  by the subset  $r$ . To be able to do so, we assume that the multiset considered is large enough, i.e. that it consists of enough molecules as required on the left hand of the rule.

For  $(l, r) \in R$  we also write  $l \longrightarrow r$  or

$$\sum_{m \in M} l_m m \longrightarrow \sum_{m \in M} r_m m$$

where we denote by  $l_m, r_m \in \mathbb{N}_0$  the multiplicity of  $m$  in  $l, r$  respectively. This resembles notation from chemistry. Furthermore the *support* and the *product* of  $(l, r)$  are

$$\text{supp}(l, r) := \{m \in M \mid l_m > 0\},$$

$$\text{prod}(l, r) := \{m \in M \mid r_m > 0\}.$$

Let  $A$  be a subset of  $M$ . We define  $R_A$ , the set of reaction applicable to  $A$ , by setting

$$R_A := \{(l, r) \in R \mid \text{supp}(l, r) \subseteq A\}.$$

Abusing notation we use a reaction  $(l, r) \in R$  as an index as well and define the *stoichiometric matrix*  $S_A \in \mathbb{R}^{|A| \times |R_A|}$  for  $A$  by

$$(S_A)_{a, (l, r)} = r_a - l_a, \quad a \in A, (l, r) \in R.$$

If we add to a reaction network  $(M, R)$  a domain for the molecules and an algorithm that determines how the rules are applied to the molecules within the domain, we get an *artificial chemistry* (Dittrich et al., 2001). For a *reaction flow artificial chemistry* we choose a region  $U$  in  $\mathbb{R}^N$  as the domain. The elements of an initial multiset are placed in this region. Molecules can then only react if they are “suitably” close. What this means exactly is of course to be defined from case to case. Here, we will always choose a small number for the maximum distance in which molecules can still react. Additionally, molecules change their position according to the flow lines of a given *vector field*  $V : U \rightarrow \mathbb{R}^N$ . This means that in one iteration of the algorithm a molecule at position  $\mathbf{x} \in \mathbb{R}^N$  changes to the position  $\mathbf{x} + V(\mathbf{x})$ . We assume that the new position is again in  $U$ . The described way of movement can be interpreted as mixing molecules according to a fixed scheme or algorithm. In contrast to a reaction diffusion system even after a long time period there is no guarantee that the multiset of molecules will be stirred well.

Figure 1: Stochastic simulation of the reaction flow artificial chemistry  $(M_1, R_1)$  in the region  $U_1$  with vector field  $V_1$  after 400 iterations, for details see Section II. Species are marked with colours from black for  $a$  to yellow for  $d$ .

Figure 1 shows the state of the following reaction flow artificial chemistry after 400 iterations. The reaction network we chose is  $M_1 = \{a, b, c, d\}$  with

$$R_1 = \{a + b \rightarrow a + 2b, a + d \rightarrow a + 2d, b + c \rightarrow 2c, c \rightarrow b, b + d \rightarrow c, b \rightarrow \emptyset, c \rightarrow \emptyset, d \rightarrow \emptyset\}.$$

As a domain  $U_1 = [-1, 1] \times [-1, 1]$  is used and a starting set of molecules of size 2500 is placed randomly around  $(0, 0)$ . The vector field responsible for the movement is a swirl given by

$$V_1(x, y) = \frac{1}{\sqrt{2}} \left( (1 - \sqrt{2})x - y, x + (1 - \sqrt{2})y \right),$$

see Figure 2.

Figure 2: The vector field  $V_1$  in the region  $U_1 = [-1, 1] \times [-1, 1]$ . The length of vectors is scaled by 0.3 for a better readability.

The parameters of the simulation (for the detailed description see Section IV) we set to  $n = 1600$ ,  $s = 400$ ,  $rad = 1.0$ ,  $u = 1.0$  and  $r = 0.1$ .

We see a development of patches of the species  $b$  over time. This is a rather different behaviour compared to the same reaction network, when investigated using a well-stirred system or diffusion. When we do a simulation using these dynamics in our particular case of the reaction network  $(M_1, R_1)$ , the system is completely described by concentration alone without taking position of molecules into account.

We give some ideas for slight *generalisations* of this approach, though they are not used here. Separate flows for different molecular species can be used, i.e. there is a set of fields  $V_{m_1}, \dots, V_{m_{|M|}}$  such that each field is responsible for the movement of a single species. Maybe this makes sense if, for example, taking the different weight of molecular species or semi-permeable membranes into account. Also the vector field(s) could be time depended, i.e. there is a dynamical change of the transport of molecules over time. Another interesting way of extending the concepts is by letting the underlying reaction network influence the vector field, e.g. particular types of (bigger) molecules could block (smaller) other ones.

We investigate two models for this kind of artificial chemistry. The first one is a PDE describing the continuous change of concentration of the molecules. The second one is a stochastic simulation of the movement of molecules in the flow and the reactions they take part in.

## Differential Model

We concentrate on the case  $N = 2$  to keep it simple, but still easily generalisable. For the differential model we assume that every point  $(x, y) \in \mathbb{R}^2$  bares concentrations of all the species  $M = \{m_1, \dots, m_{|M|}\}$ . The concentration of a species  $m_i$ ,  $i \in \{1, \dots, |M|\}$  in  $(x, y)$  at time  $t \geq 0$  is  $[m_i](x, y, t)$ , so

$$[m_i] : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^+ \rightarrow \mathbb{R}.$$

For readability we omit the coordinates and write simply  $[m_i]$ .

We describe the change of concentration over time with two summands. The change of molecule concentration given by the vector field  $V$  is the *directional derivative* of  $[m_i] \cdot \|V\|$  in the direction of  $V$ . This is exactly the formalisation of the statement that molecules follow the flow lines of the vector field. The change caused by the reactions is summarised in the *reaction terms*  $R_{\mathbf{k},i}$ . They depend on the concentrations of all molecules  $[m_1], \dots, [m_{|M|}]$  and the constant reaction rates  $\mathbf{k} \in \mathbb{R}^{|R|}$ .

When assuming the mass action kinetics for the dynamics of the reaction network  $(M, R)$ , we can write down the reaction terms as follows. Let us denote the *flux vector function* by

$$v_{M,\mathbf{k}} : \mathbb{R}_{\geq 0}^{|M|} \rightarrow \mathbb{R}_{\geq 0}^{|R|}.$$

Still abusing notation we use a reaction  $(l, r) \in R$  as an index as well and define

$$(v_{M,\mathbf{k}}([m_1], \dots, [m_{|M|}])(l, r)) = \mathbf{k}_{(l,r)} \prod_{i=1}^{|M|} [m_i]^{l_{m_i}}.$$

The  $i$ th reaction term is the  $i$ th component of the vector yielded by the product of the stoichiometric matrix with the flux vector function,

$$R_{\mathbf{k},i}([m_1], \dots, [m_{|M|}]) = (S_M \cdot v_{M,\mathbf{k}}([m_1], \dots, [m_{|M|}])(l, r))_i.$$

The equation defining the behaviour of the reaction flow artificial chemistry is

$$\frac{\partial [m_i]}{\partial t} = -\frac{1}{\|V\|} \langle \nabla ([m_i] \|V\|), V \rangle + R_{\mathbf{k},i}([m_1], \dots, [m_{|M|}])$$

where the gradient  $\nabla = \nabla_{(x,y)}$  is taken for  $(x, y)$ ,  $\|V\| = \|V(x, y)\|_2$  is the Euclidean norm of the field and  $\langle \cdot, \cdot \rangle$  denotes the Euclidean scalar product.

In the case of an integrable field, i.e. there is  $f : \mathbb{R}^2 \rightarrow \mathbb{R}$  with  $\nabla f = V$ , the molecules follow a gradient flow to the sinks of the function.

As a simple example we numerically solve the equation for the reaction flow artificial chemistry given by the reaction network  $(M_1, R_1)$  as defined before with the radially symmetric field

$$V_2(x, y) = \frac{\cos 10r}{10r}(x, y),$$

i.e. the above case with  $f(x, y) = -0.01 \sin 10r$ , where we abbreviate  $r = \|(x, y)\|_2 = \sqrt{x^2 + y^2}$ . We assume mass action kinetics with all reaction constants equal to 1.

Since the directional derivative is independent of the chosen coordinate system and since our field is radially symmetric, it suffices to solve the equation for one spatial dimension. Therefore we solve the equation dependent on  $r$ . The solution on  $\mathbb{R}^2$  is then the solution we get in the one dimensional case extended to  $\mathbb{R}^2$ , i.e. we apply it to the distance  $\sqrt{x^2 + y^2}$ . We arrive at the equations

$$\begin{aligned}\frac{\partial[a]}{\partial t} &= -0.1 \frac{\partial[a] \cos 10r}{\partial r} \\ \frac{\partial[b]}{\partial t} &= -0.1 \frac{\partial[b] \cos 10r}{\partial r} + [a][b] - [b][c] + [c] - [b][d] - [b] \\ \frac{\partial[c]}{\partial t} &= -0.1 \frac{\partial[c] \cos 10r}{\partial r} + [b][c] - [c] + [b][d] - [c] \\ \frac{\partial[d]}{\partial t} &= -0.1 \frac{\partial[d] \cos 10r}{\partial r} + [a][d] - [b][d] - [d].\end{aligned}$$

This can be numerically solved. We assume an initial constant concentration of 1 for all species and use Mathematica's NDSolve to get Figure 3 compared to the stochastic simulation Figure 4.

Figure 3: Numerical solution to the equation system at time 0.4 in one dimension.

## Stochastic Model

Additionally to the rather theoretical approach via a PDE we also implemented a stochastic simulator for the reaction flow artificial chemistries. This allows us to run some concrete examples.

We assume a reaction network  $(M, R)$  is given. As the domain or region the set  $[-1, 1] \times [-1, 1] \subset \mathbb{R}^2$  is used for all our examples even though the size of the square is variable.

Different ways of initially placing molecules can be used. In the examples shown here, we initially place  $n$  molecules randomly around the origin in a circle of radius  $rad$ . More precisely, in Figure 4 we choose random coordinates  $x$  and  $y$  such that  $\sqrt{x^2 + y^2} < rad$  to achieve a uniform distribution of molecules. In the other examples we choose a random

Figure 4: Stochastic simulation of the reaction flow artificial chemistry  $(M_1, R_1)$  in the region  $U_1$  with vector field  $V_2$  after 0, 1, 2 and 3 iterations. Parameters are  $n = 10000$ ,  $rad = 1.0$ ,  $u = 1.0$  and  $r = 0.01$ .

angle between 0 and  $2\pi$  and a random length between 0 and  $rad$  to position them. Each starting molecule is assigned a random type of species.

For  $s$  simulation steps we apply the vector field  $V$  and the rules of  $R$  in the following manner. A molecule at position  $(x, y)$  is moved to position  $(x, y) + V(x, y)$ . As mentioned before, we assume that the new molecule position is again in our region  $[-1, 1] \times [-1, 1]$ . If this is not the case, we can use cyclic or solid boundary conditions or increase the size of the region. Typically several vector fields are added up or are applied at suitable parts of the domain region to account for different effects in time and space to generate the required behaviour.

Then the reaction rules are applied to a randomly chosen  $u$  percent of the molecules present in the domain. For each chosen molecule  $m$  with, we assume, position  $(x, y)$  we look at neighbouring molecules, i.e. molecules with no more than distance  $r$  to  $m$ . Let  $A_r(m)$  be this multiset of molecules found in

$$U_r(m) = \{(x', y') \mid \text{dist}((x', y'), (x, y)) < r\} \subset \mathbb{R}^2.$$

There are several different ways of applying rules to  $A_r(m)$  possible. For the examples given here only the following is used. A number of  $|R|$  reaction rules are randomly chosen from  $R$ . It is checked whether they are applicable and if so applied to the multiset  $A_r(m)$ . By this we mean that if molecules have to be removed, they vanish from the domain and if they are added they are positioned randomly in  $U_r(m)$ .

## Analysis through Chemical Organisations

A subset  $A$  of  $M$  is *closed* if for all reactions  $(l, r) \in R_A$  we have  $\text{prod}(l, r) \subseteq A$ , i.e. if  $(A, R_A)$  is a reaction network.  $A$  being closed means that by applying reactions from  $R_A$  to multisets over  $A$  we do not get molecules outside  $A$ .

A subset  $A$  of  $M$  is *self-maintaining* if there is a vector  $v \in \mathbb{R}^{|R_A|}$  with strictly positive entries such that  $S_A v \in \mathbb{R}^{|A|}$  has only non-negative entries.  $A$  being self-maintaining means that applying reactions from  $R_A$  at certain rates to a multiset over  $M$  does not reduce the number of molecules of any species of  $A$ .

A subset of  $M$  is a *chemical organisation* (Dittrich and Speroni di Fenizio, 2007) if it is closed and self-maintaining. The set of organisations is called  $\mathcal{O}$ .

As proposed in (Speroni di Fenizio and Dittrich, 2007) we can look at the chemical organisations at different spatial scales at different times. The idea is to identify functional units when looking at the development of a chemistry in the domain over time. Only the organisations, as the closed and self-maintaining sets, are able to stay in the domain for a longer time period. Therefore persistent structures should be an organisation. This can also be interpreted as identifying higher level units.

In the described stochastic model we looked for organisations in the following way. The domain is divided into squares of size  $orgRad$ . The species present in each square are collected and then the biggest organisation contained in this set is computed. In the examples presented here  $orgRad$  is 0.1.

As an example for this analysis via organisations we demonstrate the formation of a membrane, see Figure 5. The used reaction flow artificial chemistry is defined by  $M_2 = \{m, p1, p2, p3\}$ ,

This reaction network is constructed such that arbitrary combinations of the producer molecules  $p1, p2, p3$  build the membrane molecule  $m$ . The other reactions account for the rebuilding of the producers over time if enough of all three different species  $p1, p2, p3$  are present. The desired behaviour corresponds to the organisations  $\mathcal{O} = \{\emptyset, \{m\}, \{m, p1, p2, p3\}\}$  the reaction network  $(M_2, R_2)$  exhibits. In this example we can think of  $\{m\}$  as the representation of the membrane and of  $\{m, p1, p2, p3\}$  as the membrane producing core. The vector field is defined by

$$V_2(x, y) = \begin{cases} 0.0005 \frac{e^{5r}}{r}(x, y) & 0.2 < r < 0.8 \\ V_1(x, y) & \text{else} \end{cases}$$

where  $r = \sqrt{x^2 + y^2}$  and  $V_1$  is the earlier defined field. The field accounts for a mixing close to the origin, a transport away from it and a movement of the membrane. All molecular species are transported by the field, but the rules are constructed such that most of the producer molecules  $p1, p2, p3$  are destroyed on their way to the membrane. Of course, we cannot guarantee that none of them appears in the membrane built by molecules of type  $m$ . The analysis via chemical organisations suggests that even if they make it to the membrane, they will not be able to stay for long, see Figure 6. When using separate flows for different molecular species, the formation of a membrane is even easier realised.

Figure 5: A core emitting molecules which form a membrane around the core. State after 100 iterations. Parameters are  $n = 2500$ ,  $rad = 0.2$ ,  $u = 1.0$  and  $r = 0.15$ .

Figure 6: Analysis via chemical organisations. The biggest organisation  $\{m, p1, p2, p3\}$  (yellow) shows primarily in the core, the smaller one  $\{m\}$  (red) as the membrane. State after 100 iterations.

## Further Experiments and Examples

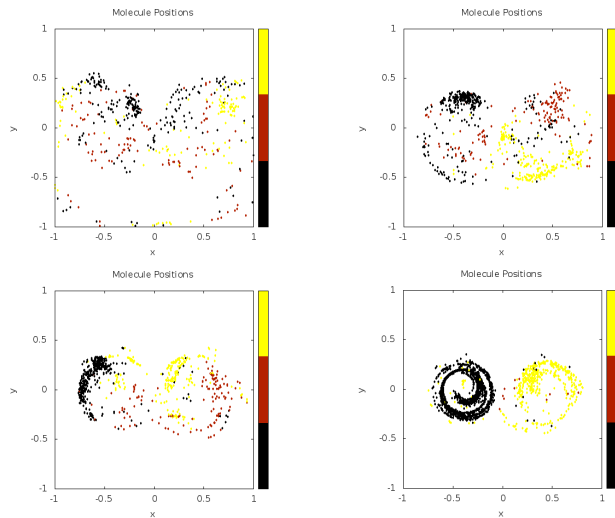

Figure 7: Formation of two compartments. State after 5, 15, 30 and 150 iterations. Parameters are  $n = 2500$ ,  $rad = 0.8$ ,  $u = 1.0$  and  $r = 0.1$ .

**Formation of Compartments.** This example shows the slow formation of two compartments in a domain for a reaction network of three competing species. Initially the molecules are distributed over the region. Due to a vector field pushing them to the left and right hand side respectively they gather in two different areas where they are stirred by another two fields, see Figure 7. The parameters for the simulation are as follows. The network is taken from (Neumann and Schuster, 2007) as a model for the rock-scissor-paper game. There are three different competing species present  $M_3 = \{s_1, s_2, s_3\}$  with the reactions

$$R_3 = \{s_i \rightarrow 2s_i, 2s_i \rightarrow s_i, \\ s_i + s_j \rightarrow s_i, s_i + s_j \rightarrow s_j \mid i \neq j\}.$$

The vector field, see Figure 8, is given by

$$V_3(x, y) = \begin{cases} -0.01e^{5x}(x, 0) + V_1(x + 0.4, y) & x < 0 \\ 0.01e^{-5x}(x, 0) + V_1(x - 0.4, y) & x > 0 \end{cases}$$

Similar to  $V_2$  in the last section the first part of  $V_3$  accounts for the pushing of molecules away from the centre. The second part is a shifted swirl, as described in Section II.

**Emergent Behaviour.** In this example we use the same vector field  $V_3$  as before, but with a different reaction network ( $M_4, R_4$ ) and parameters. The network is the central sugar metabolism of *Escherichia coli* as described in (Puchalka and Kierzek, 2004) with the adaptations made in (Centler et al., 2007). We do not give the full definition here due to the size of the chemistry,  $|M_4| = 92$  and  $|R_4| = 198$ .

Figure 8: The vector field  $V_3$  in the region  $[-1, 1] \times [-1, 1]$ . The length of vectors is scaled by 0.3 for a better readability.

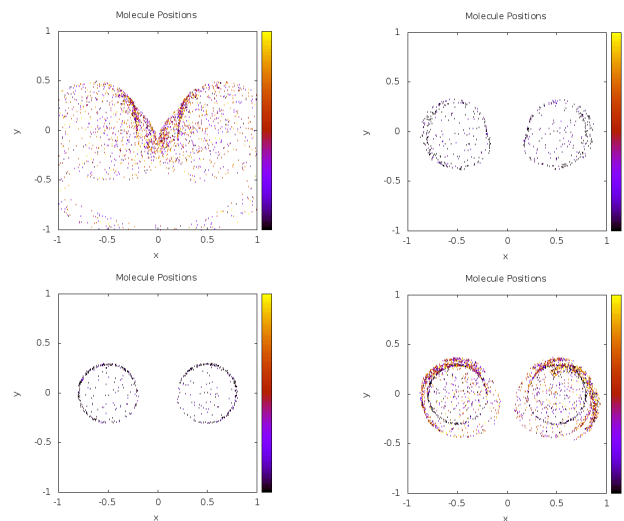

Figure 9: Emergent behaviour. State after 5, 15, 65 and 70 iterations. Parameters are  $n = 2500$ ,  $rad = 1.0$ ,  $u = 1.0$  and  $r = 0.15$ .

Here due to the movement of molecules an unexpected effect happens, in particular unexpected from the chemical organisation point of view. From Figure 9 we see that after 15 iterations (second picture) the chemistry seems to stabilise since till iteration 65 (third picture) no qualitative change happens. There are formed two rings of many molecules of one species. Then, due to the transport, there are reactions possible again, so that a qualitative change seems to happen (fourth picture). Molecules of other species are build again swirl around the ring and vanish after some more time.

## Conclusion and Outlook

We suggested a new approach for introducing a structured space into the dynamics of an artificial chemistry. This is done by using a vector field to generate a flow of molecules

located in a Euclidean space. The introduction of vector fields as defining part for the movement of molecules in space gives additional parameters for the control of the dynamics. We have shown that by this means we can describe membranes, membrane channels and transport processes.

Our system can now be applied to study the influence of different flow structures on the *evolvability* of a chemical system. It is known that compartmentalisation is in a certain sense beneficial for pre-biotic (chemical) evolution (Fernando and Rowe, 2007). Since in a pre-biotic scenario various flow structures were likely present (Martin et al., 2008), it would be interesting to study whether and how particular flow structures can lead to “improved” chemical evolution. Note that space has already a positive effect when just assuming diffusion by counteracting on parasitism (Boerlijst and Hogeweg, 1991; Fishkis, 2010). But could a flow structure add further evolutionary benefits?

Another direction of research could investigate the role of different flow structures for *bio-chemical information processing*. Does a particular flow contribute additional information processing capability to those of reaction-diffusion systems (Adamatzky, 2005)? For a given (artificial) chemistry, we could evolve the flow instead of the chemistry itself. By doing so, we could study the role of flow for certain functions, separated from the reactions going on. This could have practical implications in the development of novel bio-chemical information technologies, since, it should be easier to change the flow, e.g. within a microfluidic system, than the chemistry.

Finally we can use the scenario presented here to extend the notion of a *spatial chemical organization* (Speroni di Fenizio and Dittrich, 2007) including flow and diffusion.

## Abstract

Autonomous production of biological energy is one of the primal processes in living cells. In cells, the bio-energy presents as adenosine or guanosine triphosphate (ATP or GTP) is used for the most of cellular reactions. ATP is produced through the glycolytic cycle by a series of dedicated enzymes in cytosol, or through the oxidative phosphorylation of adenosine diphosphate (ADP), operated by ATP synthase, which is located on lipid membrane. For instance, in mitochondria, the proton potential across the membrane, generated by an electron transport chain, is eventually dissolved through FoF1-ATP synthase (FoF1). The flux of protons drives FoF1 and activates the synthesis of ATP, from ADP and Pi. On the other hand, bacteriorhodopsin (bR) is widely known as proton pump machinery that transports the protons to the other side of membrane due to light stimulation. Therefore, our idea is that if the bR and FoF1 were synthesized on a liposome membrane, the resulting liposome is able to generate ATP (see Figure 1).

**Figure 1.** Schematic of bR-FoF1 liposome. Light induced bacteriorhodopsin pumps  $H^+$  into liposome and produced  $H^+$  gradient is used for FoF1-ATP synthase to synthesize ATP.

Racker and Stoeckenius (1) have studied a model system by combining purple membrane, which contains bR, and isolated ATP synthase in phospholipid vesicles. In order to design and construct a synthetic cell in the synthetic biology context, this kind of “bioreactor” should be autonomously

built up through an internal metabolic process such as gene expression. If both bR and FoF1 proteins were synthesized in the presence of organelle-sized vesicles, it would be possible to construct *in vitro* the bR-FoF1 liposomes as a consequence of the artificial protein synthesis and the self-organization of the synthesized proteins. Additionally, so produced bR-FoF1 liposomes can be applied as a bioenergy-producible plant that activates further biological reaction. For instance, if the produced ATP could be used for protein synthesis reaction, the whole system would represent an energetically independent autonomous system.

In the ECAL11 meeting, we present some experimental achievements toward the construction of bR-FoF1 liposome (2, 3). Our recent results show that bR was synthesized in a cell-free protein synthesis system (4) in the presence of liposomes and all-*trans* retinal. Fo complex, the membrane integrated part of FoF1, was synthesized *in situ* and formed the desired FoF1 complex in combination with a supplied F1. FoF1 complex was fully functional, by showing ATPase driven  $H^+$ -translocation activity. These results imply that the bottom up construction of an artificial organelle, which is capable of generating the bioenergy, is experimentally feasible. We believe that our bR-FoF1 liposomes will be essential machinery for constructing artificial cells.

## Abstract

Genetic transposition (GT) is a process of moving sequences of DNA to different positions within the genome of a single cell. It is recognized that the transposons (the jumping genes) facilitate the evolution of increasingly complex forms of life by providing the creative playground for the mutation where the latter could experiment with developing novel genetic structures without the risk of damaging the already existing, well-functioning genome. In this work we investigate the effect of a GT-inspired mechanism on the efficiency of genetic programming (GP) employed for coevolution of locomotion gaits and sensing of the simulated snake like robot (Snakebot). In the proposed approach, the task of coevolving the locomotion and the sensing morphology of Snakebot in a challenging environment is decomposed into two subtasks, implemented as two consecutive evolutionary stages. At first stage we employ GP to evolve a pool of simple, sensorless bots that are able to move fast in a smooth, open terrain. Then, during the second stage, we use these Snakebots to seed the initial population of the bots that are further subjected to coevolution of their locomotion control and sensing in a more challenging environment. For the second phase the seed is used as it is to create only part of a new individual, and the rest of the new individual's genetic makeup is created by a mutant copy of the seed. Experimental results suggest that the proposed two-staged GT inspired incremental evolution contributes to significant increase in the efficiency of the evolution of fast moving and sensing Snakebots.

## Introduction

Snake-like robots feature potential robustness characteristics beyond the capabilities of most wheeled and legged vehicles, such as: the ability to traverse challenging terrain and insignificant performance degradation when partial damage is inflicted. Some useful features of snake-like robots include smaller size of the cross-sectional areas, stability, ability to operate in difficult terrain, good traction, and complete sealing of the internal mechanisms (Dowling, 1999; Hirose, 1993). Moreover, due to the modularity of their design, the snake-like robots feature high redundancy and fault tolerance (Tanev et al. 2005). Robots with such properties can be valuable for applications that involve exploration, reconnaissance, medicine and inspection.

Designing a controller that can achieve optimal locomotion of a modular Snakebot is a challenging task due to the large number of degrees of freedom in the movement of segments of a Snakebot. The locomotion gait of such bots is often seen as an emergent property; observed at a higher level of consideration of complex, nonlinear, hierarchically organized systems, comprising many relatively simply-defined entities

(morphological segments). In such complex systems the higher-level properties of the system and the lower-level properties of comprising entities cannot be directly induced from each other (Morowitz, 2002). Therefore even if an effective incorporation of sensing information in fast and robust locomotion gaits might emerge from intuitively defined sensing morphology and simple motion patterns of morphological segments, neither the degree of optimality of the developed code nor the way of how to incrementally improve this code is evident to the human designer (Koza et al. 2000). The previous research demonstrates that the control for a fast moving modular robotic organism could be automatically developed through various nature-inspired paradigms, based on models of learning and evolution. The earlier work demonstrates the use of GP (Koza, 1994) for evolution of sensorless sidewinding Snakebots in various environmental conditions (Tanev et al. 2005). Furthermore, the coevolution of active sensing and the control of the locomotion gaits of Snakebots was achieved (Tanev and Shimohara, 2008). The morphology of the sensors, attached to each of the segments of the bot, coevolve with the way to incorporate the sensory readings into the control of locomotion of the bot. The genetically optimized morphological traits of the bot include the initial orientation, the timing of switching on, and the range of the simulated laser range finders (LRF) attached to each of the segments of the bot. The emergent features of the evolved gaits include both the contact and contactless wall-following navigation accomplished via adaptive, sensory-controlled differential steering of the fast moving sidewinding bot. Despite the abovementioned evidence of the feasibility of coevolution of active sensing and the locomotion, the resulting wall-following behavior is achieved in an environment that is too simplified, and therefore too distant from the real-world applications: a simple curved corridor with a plain, smooth surface.

In this work we further investigate the coevolution of the active sensing and locomotion control of sidewinding Snakebot in a more complex environment that, in addition to a narrow corridor, features several large obstacles and many randomly placed small obstacles constituting a rugged terrain within this challenging environment. The sensors on the Snakebot used in this paper follow the same model as proposed in (Tanev and Shimohara, 2008): each segment of the Snakebot is provided with a fixed, immobile LRF with evolvable initial orientation, range and timing of firing. Thus the evolutionary task is not only to determine the time patterns of turning angles and the incorporation of sensor values for effective sensing and locomotion, but also to optimize the

initial orientation, effective range and the timing of activation of module sensors. Hence, the Snakebot genotype is represented as a triple consisting of a linear chromosome containing the encoded values of the three relevant parameters of LRF, and two parse trees corresponding to the algebraic expressions of the temporal patterns of the desired turning angles in horizontal and vertical directions (further detailed in Section “Algorithmic Paradigm”). The most efficient locomotion gaits of Snakebot are not necessarily associated with the forward, rectilinear motions (and sidewinding might emerge as a fast and robust locomotion). Therefore, the eventual fusion of the readings of many sensors mounted in all the segments of the bot would provide Snakebot with the capability to perceive the features of surrounding environment along its whole body. In addition to the widening of the area of the perceived surroundings, multiple sensors offer the potential advantages of robustness to damage of some of them, dependability of the sensory information, and an ability to perceive the spatial features of the surrounding environment due to the motion parallax.

The poor scalability is a common problem in the simultaneous evolution of multiple features of simulated creatures, as the search space of evolution increases faster than linearly with the increase of the number of simultaneously evolved features. The considered case of Snakebot implies that the size of evolutionary search space can be seen as a multiplication of the sizes of the search spaces of the following interdependent evolutionary subtasks:

- Evolution of *control of locomotion*: the time patterns of turning angles of actuators that result in a fast locomotion of the bot,
- Evolution of the *morphology of the active sensing* – initial orientation of the sensors, their range, and timing of their activation, and
- Evolution of the *incorporation of the sensor signals* into the control of locomotion of the bot.

The large search space of the evolution of the considered Snakebot results in an intractable computational effort. Therefore, we propose an approach of decomposing the initially defined task into two subtasks, implemented as two consecutive evolutionary stages. As the first stage we employ GP to evolve a pool of simple, generic sensorless bots that are able to move fast in a smooth, plain terrain. During the second stage, we use these Snakebots to seed the initial population of the bots that are further subjected to coevolution of their locomotion control, sensing morphology, and the method of incorporating the sensor signals into the locomotion of the bot in the given environment.

In this paper we propose an incremental evolution through the elaborated two stages, interfaced by a new approach to seeding. Inspired by genetic transposition (GT), we use the seed from the bots evolved during the first stage to create only a part of a new individual in the second stage. The rationale for proposing such an approach is based on the observations that the evolved fast moving Snakebots with sensory abilities exhibit some emergent locomotion traits that are pertinent to the generic, sensorless sidewinding locomotion (Tanev and Shimohara, 2008). We speculate that a better computational efficiency of evolution can be achieved if we first allow these generic features to evolve in sensorless bots moving in a smooth, plain terrain (with the task featuring a narrow

evolutionary search space), and then–incorporating the genotypes of these bots into the evolution of the morphologically more complex bots (with sensors) in a challenging environment. The proposed mechanism of incorporation of these generic features of locomotion is based on seeding the initial population of GP (employed for the evolution of the bot with sensors) via the GT-inspired mechanism. Using the proposed mechanism of GT, the seed does not form the whole genome of an individual Snakebot, but only a part of it. We believe that, similar to the nature, the latter would offer the opportunity to preserve the genetic makeup of the generic locomotion features intact, while incrementally “upgrading” it with the new sensing abilities.

From another perspective, our work is inspired by the discoveries in the neurobiology suggesting that the complex navigation behaviors of species in nature can be achieved through an appropriate real-time modulation, controlled by the sensory inputs, of the generic neural signals produced by sensorless central pattern generators (CPG) (Levitin and Kazczmarek, 2002). Within this context, we would like to investigate whether (i) the separation of the genotype into two parts, mimicking the natural CPG and its modulation via sensory processing, respectively, and (ii) evolving these two parts in two consecutive stages would contribute to the improvement of the efficiency of evolution of the Snakebot.

In the remaining of this document we will provide a brief background related to GT, followed by a section elaborating on both the evolutionary and the experimental frameworks used in this paper. Next, we will discuss the obtained experimental results, and finally draw the conclusions of the work presented and detail future work.

## Genetic Transposition in GP

Discovered by Barbara McClintock in maize (*Zea mays*), the *transposons* (jumping genes) are sequences of DNA that can move around to different positions within the genome of a single cell, in a mechanism called *transposition* (McClintock, 1950). In the process, they can cause mutations and change the amount of DNA in the genome. It is recognized that the transposons, facilitate the evolution of increasingly complex forms of life by providing the creative playground for fast mutations where the latter could experiment with developing novel genetic structures without the risk of damaging the already existing, well-functioning genome (Nowacki et al. 2009; Strand and McDonald, 1985).

The related transposition-inspired research in evolutionary computation (EC) started by the work of Simoes and Costa (Simoes and Costa, 1999; Simoes and Costa, 2000) on the favorable effect of transposition on the performance of genetic algorithms (GA). The first of their methods is intended to enhance the crossover operation in GA by exchanging only the genetic material that is specifically marked as a transposon (Simoes and Costa, 1999). Their second approach, (termed “asexual transposition”) models the mutation of GA as a “cut and paste” operation observed in biological GT (Simoes and Costa, 2000). Chan et al demonstrate a successful implementation of a GT inspired mechanism in multi-objective optimization, which is shown to have superior performance in achieving pareto optimal solution in comparison to multi-objective optimization without the GT

mechanism (Chan et al, 2008). Liu et al employ a similar GT inspired mechanism in a clonal selection algorithm, which is shown to provide improved performance in automatic clustering problem (Liu et al, 2009). In a related research, McGregor and Harvey use a mechanism similar to transposition which they termed as “plagiarism” (McGregor and Harvey, 2005). The “plagiarism” copies one part of the genotype into another, replacing the latter completely. The authors demonstrated that the proposed mechanism improves the performance of the evolution of solutions to the Boolean logic problems. Spirov et al. also develop an original implementation of artificial transposition, used as a form of mutation operator for the simulated evolution of evolving a finite state machine as a solver of the artificial ant problem (Spirov et al. 2009).

In these aforementioned works, as well as in the biology, GT can occur frequently during the evolutionary cycle (just like other common evolutionary operations, such as crossover). In the approach we propose, however, GT occurs only once for each “seeding phase” (which, in turn, is only once per evolutionary run – at the stage of creating the initial population), and not invoked during the evolutionary run. Therefore, although the source of inspiration is the same, the implementation of the proposed model differs significantly from the previously developed GT-inspired mechanisms in EC. However, for the rest of the paper, we will refer to the GT-inspired mechanism introduced here as genetic transposition (GT) for simplicity and succinctness.

In our work we are especially interested in achieving higher efficiency in GP for coevolution of locomotion gaits and sensing of the simulated Snakebot. At the initial stage of the proposed approach, we evolve a pool of generic fast-moving sidewinding bots in a flat, smooth terrain. Then, during the second stage, we use these Snakebots to seed the initial population of the bots that are further subjected to coevolution of their locomotion control and sensing in a more challenging environment. During the seeding process the generic, fast moving, sensorless bots are subjected to genetic retro-transposition (i.e., duplicated within the same genome). The resulting transposon (connected with the seeding genome via a randomly initialized “control gene”) is subjected to 100% random mutation in order to allow for the incorporation of the sensing information into the locomotion control of the bot. The schematic parse tree of the genotype of Snakebot, created during the initialization of GP via the GT-inspired mechanism is illustrated in Figure 1.

Seeding of the initial population by means of including the previously evolved successful (or partially successful) solutions has been shown to be an effective way of improving the efficiency of simulated evolution. For example, Nolfi et al. (Nolfi et al. 1994) evolve the controller of simulated robot and then re-evolve (or, adapt) the obtained results on real robots to accelerate the evolutionary process. Other examples of successful seeding include the work of Vassilev et al. (Vassilev et al. 2000) on the optimization of the existing digital circuit design; Thomsen et al. (Thomsen et al. 2002) on the use of solution obtained from a domain-neutral algorithm as a seed to evolve an even better performing solution; Langdon et al. (Langdon and Nordin, 2000) on seeding the evolutionary population with hand-coded solutions that allow a better generality of the evolved results.

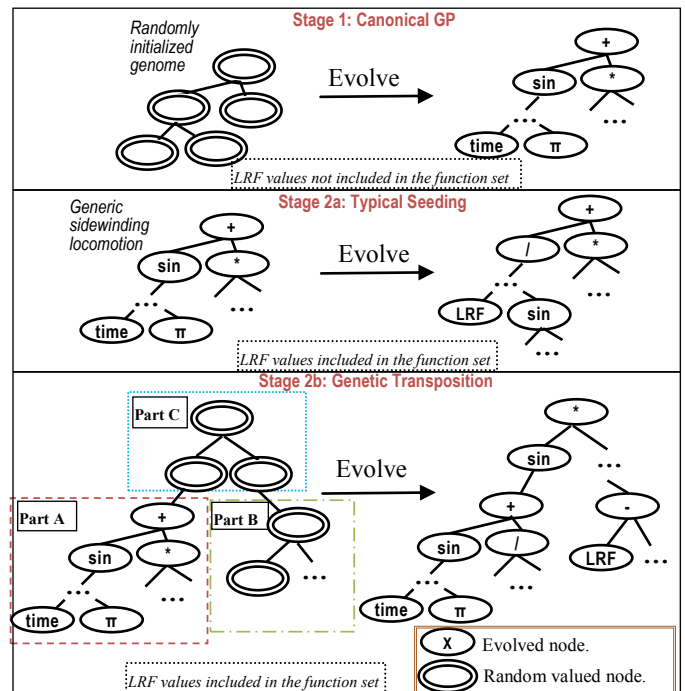

Figure 1: The mechanism of proposed genetic transposition in GP (Stage 2b) and the typical seeding process (Stage 2a). Both of these cases need to make use of a preliminary seed, and in the proposed approach this seed comes from a previously evolved sensorless Snakebot (Stage 1) that achieves fast locomotion on a smooth open terrain. In either of the Stages 2a and 2b, the resulting genome from Stage 1 is used as a seeding individual and further evolved, with additional sensory abilities (illustrated by the terminal symbol LRF) in a more challenging terrain. For Stage 2a the seed from Stage 1 makes up the whole genome of the initial Snakebot. For Stage 2b, the seed from Stage 1 is only a part (Part A) of the initial genome of the Snakebot. The rest of it contains a clone of the seed that has gone 100% mutation (Part B), and a randomly initialized group of control gene (Part C) which connects Parts A and B.

In addition, by utilizing the previously evolved solutions, seeding has also been applied to improve the performance of evolution of solutions from scratch. This technique, termed by Perry as “population enrichment” (Perry, 1994), has been demonstrated to be more efficient in discovering solutions in GP. “Population enrichment” is a form of seeding that is closest to the GT technique described in this paper. The main difference in these methods is the form of initialization, where in the “population enrichment” the seed is used to create the complete individual (see Stage 2a in Figure 1), while in GT the seeded genotype only forms a part of the genetic makeup of the newly created individual in the initial evolutionary population (see Stage 2b in Figure 1).

## Evolutionary Framework and The Simulation Environment

In the experiments presented in this work we employed a DOM/XML-based implementation of GP (Tanev, 2004). The

benefits of representing the genetic programs as DOM-parse tree featuring text-based XML-representation of genetic programs are (i) fast prototyping of GP by using standard built-in API of DOM-parsers for traversing and manipulating genetic programs, (ii) generic support for the representation of grammar of strongly-typed GP using W3C-standardized XML-schema; and (iii) human-friendly, text-based representation of the evolved solutions.

## Representation of the Snakebot

We employ open dynamics engine (ODE) as a simulation platform for the Snakebot. ODE is a free, industrial quality software library for simulating articulated rigid body dynamics (Smith, 2004). It is fast, flexible and robust, and it has built-in collision detection. Therefore, ODE is suitable for a realistic simulation of the physics of an entire Snakebot when applying actuating forces to its segments. The ODE related parameters of the simulated Snakebot are same as elaborated in (Tanev et al. 2005).

Snakebot is simulated in ODE as a set of 15 identical spherical morphological segments ("vertebrae"), linked together via universal (Cardan) joints (Figure 2). All joints feature identical angle limits and each joint has two attached actuators ("muscles"). A single LRF sensor, with a limited range is rigidly attached to each of the segments.

The functionality of the LRF can be defined by the values of the following set of parameters: (i) orientation, measured as an angle between the longitudinal axis of the sensor and the horizontal axis of the joint, (ii) range of the sensor (in cm), and (iii) the timing of activation, expressed as a threshold value of the turning angle of the horizontal actuator. The reading of LRF is a scalar value which corresponds inversely to the distance between the sensor and an object (if any within the sensor's range), measured along the longitudinal axis of the LRF. In the initial standstill position of Snakebot the rotation axes of the actuators are oriented vertically (vertical actuator) and horizontally (horizontal actuator) and perform rotation of the joint in the horizontal and vertical planes respectively.

Figure 2: Horizontal and vertical actuators attached to the joint perform rotation of the segment #i-1 in vertical and horizontal planes respectively.

Considering the representation of Snakebot, the task of designing the fastest locomotion can be rephrased as developing temporal patterns of desired turning angles of horizontal and vertical actuators of each segment that result in fastest overall locomotion of Snakebot. The proposed representation of Snakebot as a homogeneous system comprising identical morphological segments is intended to

significantly reduce the size of the search space of the GP. Since the size of the search space does not necessarily increase with the number of morphological segments of the Snakebot, the proposed approach offers a favorable scalability.

## Algorithmic Paradigm

For the evolution of the Snakebot, the genotype is represented as a triple consisting of a linear chromosome containing the encoded values of the three relevant parameters of LRF, and two parse trees corresponding to the algebraic expressions of the temporal patterns of the desired turning angles of both the horizontal and vertical actuators, respectively (Figure 3).

The encoding of the parameters of LRF is as elaborated in Figure 3. The same figure also illustrates the function set and the terminal set of the GP, employed to evolve the control sequences of both actuators. Because the locomotion gaits by definition are periodical, the periodic functions sine and cosine are included in the function set of GP in addition to the basic algebraic functions. Terminal symbols include the variables time, segment\_ID, an automatically-defined function (ADF), the reading of the sensor (LRF), and two constants: Pi, and a random constant within the range [0, 2]. The incorporation of the terminal symbol segment\_ID (a unique index of morphological segments of Snakebot) allows GP to discover how to specialize (by phase, amplitude, frequency etc.) the

genetically identical motion patterns of actuators of each of the morphological segments of the Snakebot.

The rationale of employing ADFs is based on the observation that the evolvability of straightforward, independent encoding of desired turning angles of both horizontal and vertical actuators is rather poor. Even without ADFs, GP is able to adequately explore the potentially large search space and ultimately discover the areas that correspond to fast locomotion gaits in the solution space. However, it was observed in the previous work of Tanev et al (Tanev et al. 2005) that not only the motion patterns of adjacent segments are correlated, but the motion patterns of horizontal and vertical actuators of each segment in fast locomotion gaits are highly correlated too. Moreover, discovering and preserving such correlation by GP is associated with enormous computational effort. ADFs, which provide a way of introducing modularity and reuse of code in GP (Koza, 1994), are employed in our approach to allow GP to explicitly evolve the correlation between motion patterns of horizontal and vertical actuators as shared fragments in algebraic expressions of desired turning angles of both actuators. Furthermore, we observed that the best results are obtained by; (i) allowing the use of ADF as a terminal symbol in algebraic expression of desired turning angle of vertical actuator only, and (ii) evaluating the value of ADF by equalizing it to the value of currently evaluated algebraic expression of desired turning angle of horizontal actuator. The main GP (hence the EA) parameters are summarized in Table 1.

**Genetic Operations.** We employ a binary tournament selection and a single point crossover. The crossover point is randomly selected between the three components of the genotype (as shown in Figure 3). The mutation randomly alters either a value of an allele in the linear chromosome

representing the parameters of LRF, or a sub-tree in one of the two parse trees that correspond to the temporal patterns of the control sequences of actuators.

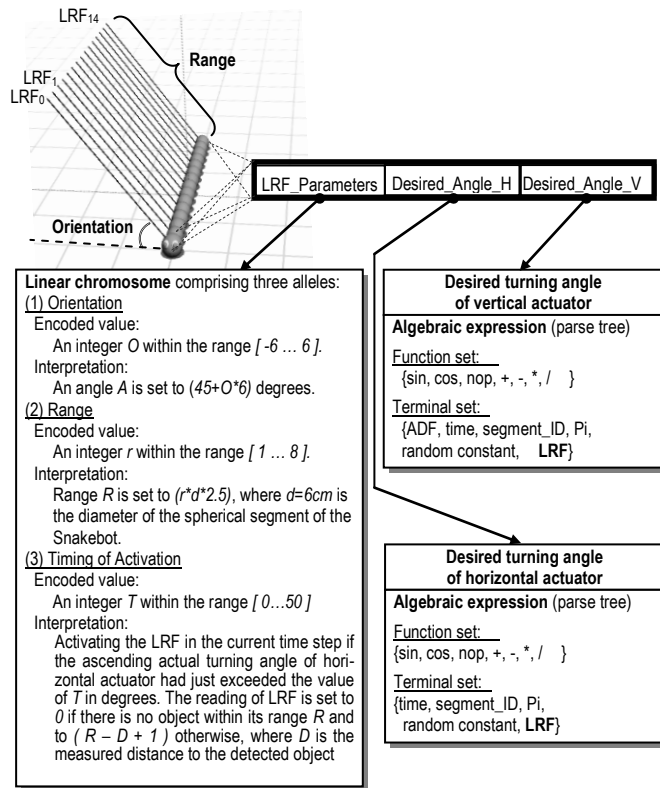

Figure 3: Genotype of the Snakebot, represented as a triple containing the values of the parameters of LRF and two algebraic expressions of the temporal patterns of the desired turning angles of horizontal and vertical actuators, respectively.

**Fitness Evaluation.** The fitness function is based on the average velocity of Snakebot, which is estimated from the distance traveled during the trial. As we shall elaborate later in the “Experimental Setup” section, the confined environment used in the trial is a narrow corridor covered with obstacles of various sizes (Figure 4). The velocity of locomotion needed to clear the final obstacles towards the end of the corridor for the given time of the trial (16s) corresponds to a fitness value of 100. The evolution is terminated if the bot reaches the fitness of more than 120 (fitness required to clear the whole corridor) or if the maximum accumulative number of 80 generations is reached. 80 generations was set as the cumulative maximum as a result of the experience from earlier experiments. Earlier experiments used in achieving locomotion of modular Snakebot had used 40 generations, which was a sufficient limit for the evolution of locomotion. Ideally, addition of a new feature should not require a much larger computational effort. Therefore, 40 generations per individual feature of the Snakebot was decided to be an acceptable cost.

**Experimental Cases.** In order to investigate comparatively the efficiency of proposed approach, we used three methods to evolve the locomotion of Snakebot with sensors:

Category	Value
Population Size	200
Selection	Binary Selection ratio: 0.1 Reproduction ratio: 0.9
Elitism	4
Mutation Rate	1%
Trial Interval	16s (400 time steps of 40 ms per step)
Termination Criterion	(Fitness=120) or (Num. of Generations=80)

Table 1: The GP-related parameters.

- I. *Canonical GP* (single stage approach): In this case the evolution of the Snakebot is done from scratch; i.e. evolution starts with a population of randomly created individuals and optimizes these individuals to satisfy the target fitness. The limit of the evolutionary generations of GP is set to 80.
- II. *Typical seeding* (two-staged approach): The genotypes of six best sensorless Snakebots that have already been evolved to achieve fast sidewinding locomotion in a plain, smooth terrain (Figure 1, Stage 1), is used to create the initial population. This evolved genotype is used as an elite individual to seed the initial population, where the exact copies of these six sensorless bots are used to form a small part (6 bots) of the initial evolutionary population. The remaining part of the population (194 bots) is randomly generated. This seeded population is then evolved to fully satisfy the target fitness (Figure 1, Stage 2a). The limit of the generations of both stages of evolution is set to 40.
- III. *GT* (two-staged approach): The first stage of the proposed approach is identical to that of the typical seeding method. Similarly, the six best sensorless genotypes are used as elite individuals in the initial population of the second evolutionary stage. To create the remaining 194 bots of the initial population, however, we use the evolved best sensorless genotypes to form only part of these newly created individuals. The remaining parts of these individuals are created randomly, as elaborated in the section titled “Genetic Transposition in GP”. These 194 partially seeded and partially random individuals and the six fully seeded individuals are used to form the initial evolutionary population (Figure 1, Stage 2b). The created population is evolved to fully satisfy the target fitness. Similar to the typical seeding, the limit of the generations of both stages of evolution is set to 40.

## Experimental Setup

The experimental environment (Figure 4a and 4b) is formed of a straight narrow corridor (the width is the same as the length of the Snakebot) that has two groups of tall boxes that protrude to about 40% of the width of the corridor. In addition, part of the corridor is covered by many, randomly located and sized, small boxes that are designed to create a

rough terrain and noisy environment for the sensors. The length of the corridor is set to seven times the length of the Snakebot. Starting from one end of the corridor, the aim of the bot is to reach the other end within the given time-span. We designed this environment with the intention to encourage the evolving bot to develop the following abilities: (i) fast locomotion (long enough corridor), that is (ii) not hindered by rugged terrain (small boxes), (iii) following of obstacles that cannot be overcome (walls), and (iv) circumnavigating obstacles that cannot be overcome (tall boxes).

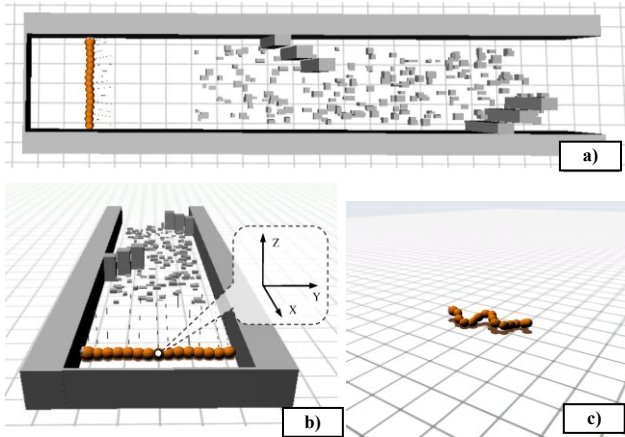

Figure 4: The experimental setup of the scenes.

For experimental case I and Stage 2 of experimental cases II and III, the Snakebot is initialized with 15 modules, on full stretch at the dead end of the corridor with its longitudinal axis perpendicular to the intended direction of movement (Figure 4a, and 4b). Initially, the rough terrain is not present to facilitate the evolution of basic locomotion on smooth terrain. After a fitness value of 60 is reached (i.e. the first set of large obstacles can be cleared by the Snakebot), a large portion of the corridor is filled with randomly initialized boxes (random size and location). The initial orientation of the Snakebot and the corridor is influenced by the previous work suggesting that sidewinding is the fastest and most robust locomotion gait for a Snakebot. Therefore, the Snakebot would be expected to enter a corridor featuring a similar orientation.

For Stage 1 of experimental cases II and III, a plain surface with no obstacles is used as the environment (Figure 4c), and the LRF is excluded from the GP function-set.

## Experimental Results

The Snakebot is evolved applying the three different evolutionary approaches as described in the “Experimental Cases” section, and under the experimental conditions as outlined in the “Experimental Setup” section. For each approach we executed 38 independent runs. The fitness convergence characteristics of these runs are shown in Figure 5. As Figure 5a depicts, the canonical GP features average fitness (over all independent runs) of about 40, which corresponds to the 40% of the length of the corridor, which also corresponds with the position of the first set of tall

obstacles. The pace of the improvement of the fitness is rather slow, with average value of about 30 at generation 40. These results suggest that the bot is struggling to discover the generic locomotion gaits that can result in a fast enough locomotion even in the absence of obstacles. The large search space of the evolution, caused by the need to additionally evolve the sophisticated morphology sensing (LRF), and the way to properly incorporate the sensing signals into the locomotion control is one of the reasons for the poor efficiency. Another reason is the challenging environment—the walls and various obstacles, which implies that the fitness landscape of evolution features fewer (compared to the previously tested cases [Tanev et al. 2005; Tanev and Shimohara, 2008]) and narrower optimal areas. Indeed, even if fast locomotion emerges during the initial stages of evolution, its survival value could be easily “underestimated” by evolution because the bot gets stuck at the first obstacle. Hence the large difference between the progression of the results displayed in Figures 5a and 5b.

	Canonical	Seeding	GT
Average Fitness	43	69.3	91.2
Median Fitness	37	67	91
Std Dev. of Avg. Fitness	23.5	27.2	19.4
Runs with Fitness >100	1 (2.6%)	3 (7.9%)	8 (21%)

Table 2: Statistics of the experimental results.

Conversely, the results of the first stage of both the typical seeding and GT (Figure 5b) indicate that the evolution of the locomotion of a Snakebot is more efficient, when relieved from the burden of dealing with the sensors and the sophisticated environment. The velocity of 100, which would be sufficient to clear the obstacles, is now easily achievable within 10 to 36 generations.

Then, when six of these best moving generic bots are incorporated via typical seeding into the initial population in the second stage of evolution (Figure 5c), and allowed to evolve for additional 40 generations, the average fitness value is 1.6 times higher than the result obtained by canonical GP (Table 2). However, the best efficiency of evolution is achieved when GT is used—the average fitness is more than 90 with 8 successful runs, and a smaller deviation in the fitness values achieved (Figure 5d and Table 2).

The proposed approach of employing GT allows the evolution to experiment with the way of processing the sensory signals without the risk of damaging the already evolved, fast locomotion control. Therefore, the transposition could facilitate the protection of the already evolved beneficial building blocks from the destructive effects of genetic operations. Conversely, since the locomotion control comprises 100% of the genotype of the bots created via typical seeding, any incorporation of the sensing information as a result of the genetic operation would most likely result in damage of this control. Indeed, the genotypes of the successful results achieved via GP with GT, the resulting genotype always had a portion in the form of Equation 1. Equation 1 (with C1 and C2 being constants) is the general form of the controllers achieved via the evolution experiments for the locomotion of a Snakebot on a smooth, empty terrain,

i.e. Figure 5b. The resulting genotypes were simply the modulation of these controllers via the LRF signals. On the other hand the successful solution achieved by canonical GP and typical seeding runs did not have an exclusive part of their genotype that resembles Equation 1; instead a large, complicated equation that is hard to comprehend was the result.

$$C1 * \sin(ID + time + C2) \quad (1)$$

In fact, when re-run on maps with differently arranged obstacles (to that of the environment present during evolution), the most robust Snakebots are observed to be from the GP runs using GT. We believe that the following are the reasons for the significant improvement in the efficiency (computational effort) of evolution due to GT:

- A wider spread of the initial seed into the population (than the typical seeding) of genotype that features generic ability to move,
- A better value of the initial fitness of the bots as they already feature the generic ability to move in their genotypes, and
- A separation of the sensing and locomotion parts of the genome, which may create a more efficient control mechanism for the bot.

We would like to point out that latter of the above mentioned arguments might provide a further insight into the design of robotic control systems and their sensorimotor control. The locomotion property of the Snakebot can be viewed as a continuous process that needs to be applied regularly under normal conditions, and the sensing property of the Snakebot can be viewed as a reflex that only needs to affect the actions of the bot when an event occurs. Such a concept might be seen as analogous to the reactive behavior related to the reflexes observed in biological organisms. For example, the collision-free flight of locusts in a crowded swarm is recognized to be achieved by direct, real-time input of the sensory signals into the wings muscles. The latter serve as a mediator for both the (i) “default” oscillating signals (generated by CPG) and (ii) the visual sensors (Uvarov, 1977).

From another viewpoint, our results can be seen as an evidence of the computational benefits of mimicking the neurobiological concept of achieving complex navigation behaviors of species in nature through sensory-controlled modulation of CPG. The moving trajectory of a sample best of run bot (Figure 6) illustrates the emergence of the following abilities of the bot: (i) fast locomotion (clearing the corridor), that is (ii) not hindered by rugged terrain (overcoming small boxes), (iii) following obstacles that cannot be overcome (walls), and (iv) circumnavigating obstacles that cannot be overcome (two groups of tall boxes).

The successful Snakebots from the results presented demonstrate the incorporation of sensor information within the control mechanism of the Snakebots for steering the Snakebot away from the large obstacles. The evolved Snakebots use the sensor signals as repulsive forces on the individual modules, which gradually change the course of the whole Snakebot.

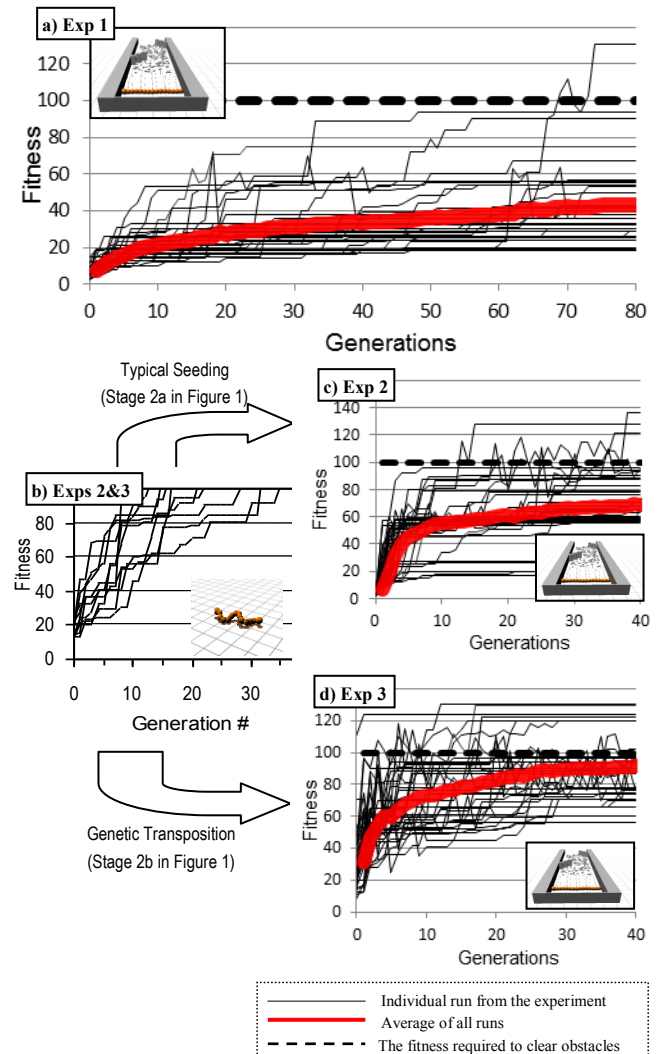

Figure 5: Fitness convergence characteristics of the three approaches used to evolve the Snakebot in the confined environment: single-staged canonical GP (a), and incremental two-staged typical seeding (b then c) and GT (b then d), respectively. The graphs show the fitness convergence of all 38 runs from each experiment.

## Conclusions

We demonstrated that the evolution of a modular sidewinding Snakebot in a challenging environment with multiple forms of obstacles is a computationally demanding task. Dividing this task into two subtasks, implemented as two consecutive evolutionary stages, contributes to the significant improvement in the efficiency of evolution.

We introduced a genetic transposition inspired seeding technique to further improve both the quality of the bots and the computational effort required to evolve them. The proposed technique offers a significant improvement over typical seeding when applied to the evolution of an active sensing of fast moving Snakebot. The presented technique could be seen as a promising approach to incremental coevolution of multiple features of morphologically and

behaviourally complex bots situated in challenging environments.

Figure 6: The moving trajectory of the central segment and the center of gravity (COG) of a sample best-of run Snakebot, evolved by incremental GP with GT.

In biology it is recognized that the transposons (the jumping genes) facilitate the evolution of increasingly complex forms of life by providing the creative playground for the mutation where the latter could experiment with developing novel genetic structures without the risk of damaging the already existing, well-functioning genome. The results shown in this paper demonstrate that this biological occurrence is also applicable to EC, and the proposed genetic transposition inspired seeding mechanism also facilitates the artificial evolution of increasingly complex systems.

As part of future work, we aim to analyze the Snakebots evolved in detail in order to gain an understanding of how the sensory signals are integrated with locomotion, and to infer the definition (understandable by human designers) of the control mechanism of the Snakebot. Furthermore, we plan on studying and designing mechanisms that can accompany genetic transposition in bringing a more efficient and robust evolution of complex robotic systems with multiple evolving features. Finally, we aim to generalize the proposed technique and define the properties of the tasks in evolutionary robotics that can be efficiently solved via this approach.

## Abstract

The study of complex systems consists in considering entities submitted to interactions which define the dynamics of the system. Virtual reality opens the way to interactive simulation of complex systems, so called the *in virtuo* experimentation. For that purpose we use multi-interactions systems, based on the reification of interactions and multi-agent systems, in a phenomenological approach. Interaction agents represent the modeler understanding of the relations between the constituents of the system. Such descriptive models lead us to define parameters *a priori*. Moreover these parameters can be fluctuant, or even unknown, during a simulation in relation to the system dynamics or user interventions. To respond to this problem, we expose in this paper a redundant multiscale architecture which rests upon the fact that we can establish models of a same phenomenon at heterogeneous time and space scales. Heterogenous Multiscale Methods provide a general framework to mix levels of description of a system. Our intention is to implement this framework in multi-interactions systems by means of a *Scale-Interaction* agent. Then we illustrate our architecture through a pharmacokinetics application. Indeed biochemical kinetics abounds of parametric phenomena. Finally we discuss about some questions raised by this methodology, such as synchronicity, organization detection and genericity.

## Introduction

The study of complex systems consists in considering entities in interaction. These interactions affect the entities behaviors and then change the system dynamics. The entities are most often heterogeneous by their natures, their interactions and their scales. Moreover, their great number is a major obstacle to their understanding. Thus we have to model these systems, even roughly, in order to get out some new knowledge. It's generally difficult formally to prove that a model is exact. That's why we need to experiment our models so as to compare simulations and observations.

Virtual reality enables us to manipulate these models (Fuchs et al., 2006). An expert can be immersed in real time within a virtual laboratory, mock up the system he wants to study and experiment it, without any danger or consequences. This is called the *in virtuo* experimentation by analogy with *in vivo* and *in vitro* methods. It allows

the modeler to build his model incrementally, by successive additions of phenomena. This is a "phenomenological approach" for modeling (Parenthoën, 2004).

For that purpose we use multi-interactions systems (MIS), based on the reification of interactions and multi-agent systems. It consists in changing our point of view to describe phenomena just as we observe them. Thus agents are not the entities anymore but the interactions binding them. This method has been repeatedly successfully applied, validated (Redou et al., 2007) and today, there are several models and methodologies that can be used to experiment complex systems with multi-agent systems (Desmeulles et al., 2009).

In addition, this kind of modeling has the advantage of reducing the computation time because phenomena are described macroscopically with the help of ordinary differential equations (ODE). The price is that we often have to define parameters in models, like diffusion coefficients for instance. Moreover these parameters can fluctuate, or even unknown, during a simulation in relation to the system dynamics or user interventions (Béal et al., 2010).

To respond to this problem, we propose in this article to make maximum use of the knowledge we have about the phenomena. We expose then a redundant multiscale architecture which rests upon the fact that we can establish models of the same phenomenon at heterogeneous time and space scales. Parameters of a macroscopic model are in fact related to the system dynamics at microscopic scale. For instance, diffusion rate of a chemical concentration can be determined using brownian motion of molecules and statistical physics (Frenkel and Smit, 2001).

Therefore, our idea is to run parallel simulations of multiple description scales in order to parameterize phenomena. Interactions between the scales will be supported by agents, which is the core of this article.

We will illustrate our architecture through a pharmacokinetics / pharmacodynamics (PK / PD) model of the vitamin K antagonists (VKA). Chemical kinetics is indeed a perfect example of parametric phenomena. For this occasion we will discuss about some questions raised by our method.

## Heterogeneous multiscales modeling

In the perspective of a phenomenological approach, we are interested in the effects of the phenomena over entities. These effects are usually described by differential equations at a macroscopic scale. This approach is very successful for large classes of problems but it favours efficiency over accuracy introducing empirical closures and parameters in equations that are often partially known or understood. Besides, the system dynamics can be unpredictable. So an acceptable closure or parameter at a given instant could become wrong at the next one. In the case of more complex systems it seems to be necessary to call upon different methods, particularly by coupling models with different levels of description in order to achieve a balance between accuracy and efficiency. We talk then about multiscale methods.

Multiscale methods have been existing for a long time, such as adaptative mesh refinement methods (Debreu et al., 2008). Their purpose is to mix different scales, solved separately, into a global simulation. Such an idea can be applied in the context of stiff ODEs resolution using splitting methods (Le Bris, 2005; Guibert, 2009).

Let us consider the example of a system  $z$  composed of  $C$  operators where  $A$  (resp.  $B$ ) are non-stiff (resp. stiff) operators :

$$\frac{dz}{dt} = Cz = Az + Bz \quad (1)$$

We can solve  $z$  over each time step  $[n\Delta t, (n+1)\Delta t]$  with

$$\begin{cases} \frac{dz^{**}}{dt} &= Bz^{**} \\ z^{**}(n\Delta t) &= z^*((n+1)\Delta t) \end{cases} \quad (2)$$

A different solver could be used for each part of the system in this way, potentially with a smaller time step for the stiff one.

Classical multiscale methods are extremely accurate but their cost can be huge. Indeed, their efficiency is closely dependent on the smaller time step used in the simulation.

That's why recently developed multiscale methods aim at one step further : in order to cut down the computing time, they try to capture the macroscale behavior of the system from local microscale simulations run over a limited time (Horstemeyer, 2009).

Heterogeneous multiscale method (HMM) (Weinan et al., 2007) relies on the following concept : coupling redundant scales in order to take into consideration possible variations of the system. In some cases, the macroscopic model is not explicitly available or is invalid in some part of the domain. The microscopic model is used then to supply the necessary data for the macroscopic model. Scale separation is exploited so that coarse-grained variables can be evolved on macroscopic scale using data that are predicted based on the simulation of the microscale ; see figure 1.

Figure 1: Schematics of HMM framework (Weinan et al., 2007)

We consider a macroscale with a state variable  $U$ . We have seen that this state depends on the system dynamics and / or parameters. We have at our disposal a microscopic model, such as molecular dynamics, that describes the microscopic state variable  $u$  of the same system. Let's not forget that we are dealing with different levels of description of an unique system.

The two scales are related one to each other by the use of reconstruction ( $Q$ ) and compression ( $R$ ) operators :

$$\begin{cases} Q.u &= U \\ R.U &= u \end{cases} \quad (3)$$

with the property  $Q.R = I$ , where  $I$  is the identity operator. The role of these operators is to translate the system structure and dynamics from a scale to the other. The main difficulty lies in the definition of these operators. Indeed it would be naïve to think that a macroscale phenomenon could be the result of an unique microscopic one. Most often we would be interested in a group of local interactions from which emerge a global behavior. This underlines one of primary interests of multiscale and complex systems simulation : we may increase our understanding of phenomena by observing their entanglements (Lesne, 2003).

Finally the idea is to make round-trips between the two scales regarding to the system dynamics. As soon as there is a lack of data in the macroscale ensued from a dynamics variation, we use  $Q$  to rebuild a microscale which we run and observe over a given duration. Thus we can make data estimations with the help of  $R$  so as to set new parameters in the macroscale.

HMM give guidelines on how to design redundant multiscale systems. It is a general framework which is lacking implementation. We intends in this paper to fill this lack by the use of multi-agent systems.

We saw that HMM deduce the macroscale behavior according to emergent processes and data from the microscale. Concept of emergence is one basis of multi-agent systems (Demazeau, 1995). Into such systems, autonomous entities evolve with only a partial knowledge

of their environment. The addition of their individual interactions results in a collective behavior. Then multi-agent systems appear as very good tool to model complex systems by the way of splitting the whole problem in smaller subparts. Today, it has been successfully applied to molecular dynamics for instance (Parisey, 2007). However, it implies to simulate each entity separately which is a very costly method. That's why we can say that classical multi-agent systems match much more to a microscale method.

As we have seen before, multi-interactions systems offer an original approach to model efficiently the links between entities. We can also discern that HMM operators could be considered as links between scales. That's why we propose in the following section to implement this process into multi-interactions framework which we use to perform *in virtuo* experiments.

### Virtuo framework : MIS implementing HMM

Multi-interactions systems were first presented in the RéISCOP meta-model (Desmeulles, 2006). The motivation was to enable an expert to describe a system as he observes it in the nature, usually with the help of ODE. Subsequently, we pursued this work bringing the reification of numerical methods of solving used to make the system evolve during the simulation (Le Yaouanq, 2010). This allows us to keep control over the convergence and stability of the system. This modification and others prompted us to propose a new framework that implements MIS : we called it Virtuo.

Our will is now to take the advantage of redundant multiscale methods in order to parameterize macroscopic descriptions of phenomena. *In virtuo* experimentation puts interactivity first. It implies to consider some constraints such as real-time computing and reactivity of the simulation. In this context, we can not use classical multiscales methods which impose the choice of small time steps. That is where we join the HMM framework. Our idea is to simulate critical phenomena at a microscale selectively and for a limited duration so as to complete their description.

In this section, we detail Virtuo architecture and how it makes possible to model multiscale systems taking inspiration from HMM.

### How to design the model of a given scale ?

As said above, we are interested in systems composed of numerous entities. They are represented by the *Entity* class in our model ; see figure 2. To fit reality, we introduce a concept of hierarchy between entities. Thus an entity can contain other entities. It is important to note that we are still talking about a same level of description. This ability is just a way of considering spatial organizations into a system. For instance, from a macroscopical point of view, a human body is composed of organs. But it doesn't mean that there are two different levels of description. The decisive element that will encourage us to consider multiple scales into a

Figure 2: Class diagram focusing on Scale designing (Le Yaouanq, 2010)

simulation is the time / spatial reach of interactions. This will be discussed thereafter.

Multi-interactions systems argue in favour of considering that active agents in the system are the interactions between passive entities. So an *Interaction* agent associates one or many entities and compute their local effects on each other. The systems's dynamics is the addition of these local modifications.

An *Interaction* computing consists in solving independently a part of an ODE system. For this we use numerical methods to make the system evolve on each time step (Ascher and Petzold, 1998). Even if they have been validated in the context of multi-interactions systems, they force us to take care of the system convergence and stability (Redou et al., 2010). Actually, if the time step is chosen too large, some interactions could induce an irreversible instability of the whole system. That is why we add the *Integrator* agent whose job is to manage the interactions. It would be able to control *Interactions* actions and order them to recompute more precisely if needed.

The desynchronization of interactions eases a modular and incremental building of the numerical model. Firstly, this is especially useful for online models building, since the modeller usually selects, subjectively, the phenomena that are most likely involved, and runs the model. If results are not correct enough, the model is incremented with other interactions, etc., until a satisfying model is obtained. Secondly, the need of *Interaction* instantiation could emerge from the system's dynamics. There we introduce the *Phenomenon* agent which will create or delete interactions in certain conditions. It leads us to consider that an interaction is the manifestation of a phenomenon.

Let us consider two empty compartments (*Entities*) *A* and *B* related by a *DiffusionPhenomenon*. If we add a concentration of a chemical species *C* in compartment *A*, the *Phenomenon* automatically instantiates a *DiffusionInteraction* between *A* and *B* to diffuse *C*. As soon as concentration of *C* is equal in the two compartments, the *DiffusionPhenomenon* destroys the *DiffusionInteraction*.

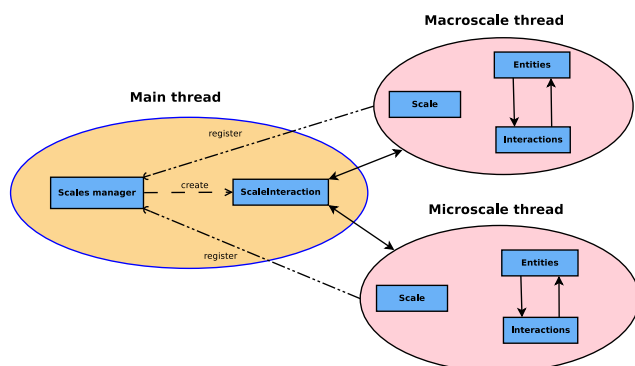

Figure 3: Diagram of threads distribution.

No useless calculation is done this way. Modularity makes this process natural and doesn't require to stop the simulation to modify the code of equations.

Until now, we detailed the different pieces we use to design a single *Scale* using the Virtuo framework. It is time to explain how we proceed to make multiple scales interact into a simulation.

### Multiple interacting scales

Virtuo framework offers the possibility to build simulations composed of several *Scales*. Each one can be run independently in relation to each other. This allows us to improve performances by means of parallelization. As we can see it on figure 3, each *Scale* is distributed into separated threads. They are managed by the *ScalesManager* class that plays the role of a server on which a client *Scale* can log. Once again modularity enables this process to be done while the simulation is running.

We have seen before that multiscale modeling is a useful tool which may be used when a phenomena is not understood or when there is a lack of essential data in a macroscopical model. That is the point that leads us to make multiple *Scales* coexist. These *Scales* must of course be connected so that they can communicate. So we plan to implement this link thanks to a *Scale-Interaction* agent, as well as *Entities* are connected with *Interactions*

This new agent manages exactly two different *Scales*. It is in charge of doing translation work of structure modifications that may appear in each one. There we meet again HMM operators. A *Scale-Interaction* agent provides the two of them : compression from microscale to macroscale and reconstruction from macroscale to microscale. It does itself the translation and acts directly on the two *Scales* components, both *Entities* and *Interactions*.

Such a process requires to ensure data consistency. Indeed *Scales* are not paused and their structures still independantly change in course of the simulation. So we have to use locking mechanisms on *Scales* constituents such as any multi-threaded model. However, they can't guarantee the

system's coherence alone. In fact the autonomy of *Scales* raises some questions about the *Scale-Interaction* action. The following exposes a first and non-exhaustive list of these questions and preliminary answers.

### When should we introduce new microscales ?

As said previously, we need microscales because of a lack of data for solving interactions into the macroscale. This can appear further to a structural evolution induced by the system's dynamics or an intervention from the user. However, microscale simulation implies the choice of a very small time step in relation to spatial units and interactions intensities. Obviously, we can't simulate microscale permanently. So we would only introduce microscales selectively and for a limited time.

### What should we observe to make data estimation ?

Given that a microscale is built from a need to explain explicit parts of a macroscale, the observation is inevitably directed. Thus the microscale's initial state does only contain *Entities* and *Phenomena* we choose to describe it. Though its dynamics could change and drive to take into consideration emerging behaviors then data estimation would mainly be done watching to the *Entities* states and their evolution through the observation duration. But in every instance, it seems that the rules and structure of the microscale must be defined *a priori* and on *ad hoc* basis, in the same way as the macroscale.

### How long should we observe a microscale ?

Since microscales are simulated for a limited time, the observation duration must be short regarding to the macroscale time step. Additionally, the macroscale isn't turned off while the microscale is running. In most cases, the observation would be done until an equilibrium state which can be defined *a priori* or detected as a decrease of interactions intensity.

### How and when to reflect the data estimation ?

Once data estimation is done, *Scale-Interaction* have to reflect it on the macroscale by affecting its structure. This process must be done carefully in order not to provoke instabilities in case of too brutal variations. Sometimes it would be executed progressively and at the right moment which could be difficult to identify.

We have explained principles and problems of the Virtuo framework, from "how to design the model of a scale ?" to "why and how to make scales interacting ?". In the next section, we illustrate our modeling method through a pharmacokinetics / pharmacodynamics application.

## Application to PK / PD of VKA

Our objective on the long term is to provide a virtual laboratory for complex systems in which experts could

build models and conduct experiments. The domain of biochemical kinetics lends itself perfectly to this vision. Moreover, a lot of chemical phenomena involve multiple levels of description. That is why we chose to exemplify the Virtuo framework by means of a PK application.

## Context

The development of a new medicine is very long process which requires clinical trials. They are divided into several stages and lead to identify pharmacokinetics properties of the substance :

- **Absorption** : how it enters the blood circulation
- **Distribution** : how it is disseminated throughout the fluids and tissues of the body
- **Metabolism** : how it is transformed by the body
- **Excretion** : how it is eliminated from the body

Pharmacokinetics may be simply defined as what the body does to the drug, as opposed to pharmacodynamics which may be defined as what the drug does to the body (Benet, 1984). Such practicals aim at measuring adapted dose which should be administered to the patient. They are very expensive and not totally safe. Thus biologists are more and more interested in numerical simulations. The *in virtuo* method allows to be ahead of classical *in silico* simulations thanks to the interactivity with model (Tisseau, 2001). Indeed, multi-agent systems used in the context of a phenomenological approach allows to add sense on phenomena to observe their individual and coupled effects on the system.

Figure 4: Simplified coagulation cascade (Kerdélo, 2006)

Our study focuses on vitamin K antagonists, a kind of medicine used to cure thrombosis. This work follows those done in the context of *in virtuo* blood coagulation in (Kerdélo, 2006). Blood coagulation, or clotting, is the outcome of a complex reactions cascade that implies coagulation factors ; see figure 4. Generally it arises when a blood vessel is damaged in order to stop the blood loss. Sometimes, this process can be thrown off balance due to a dysfunction of coagulation factors synthesis, which results in clots occurring without any necessity obstructing

the flow of blood through the circulatory system (Abgrall et al., 2004). This synthesis should be regulated in another reactions sequence which can be affected by an excess of vitamin K (figure 5). VKA are prescribed in this instance so as to balance this problem. The chemical reactions entanglements and individual variations of patients make the right dose hard to define (Siguret, 2007). That's why biologists are looking for tools to simulate this process.

Figure 5: Coagulation factors synthesis (Siguret, 2007)

## Macroscopic model

Classically, PK analysis consists in compartmental models which use kinetics to predict the concentration-time curve in each compartment. More complex PK models, called physiologically-based pharmacokinetics (PBPK) models, rely on the use of physiological information to ease development and validation ; see figure 6. The body is divided into linked compartments that can be associated with black boxes. Inputs and outputs are kinetics parameters which are most often identified by stochastic simulations (Brochot, 2006). It is therefore difficult to understand the various phenomena acting inside this boxes.

We proposed a first MIS implementation of PBPK models in (Le Yaouanq, 2010). We derived the Virtuo framework so as to be able to design chemical systems.

Each compartment is represented by an *Entity*. We linked them by *Diffusion-Phenomena* as in PBPK model. The first novelty of our model comes from the insertion of *Reaction-Phenomena* which operate between concentrations of chemical species inside the compartments. Relations between kinetics and dynamics are evidenced in this way. Our second contribution is based on a realistic identification of parameters of the model. This is where multiscale modeling gets involved. The idea is to simulate redundantly some phenomena in a microscale in order to parameter the macroscale. For the sake of clarity, we only outline our problems on the diffusion rate example.

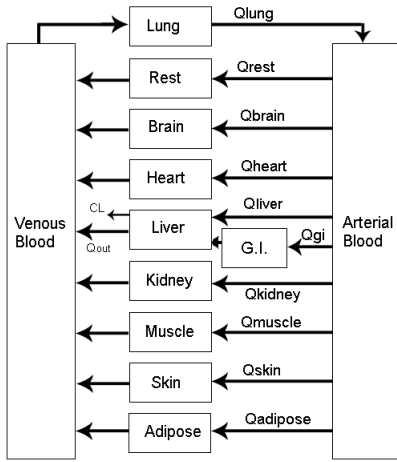

Figure 6: PBPK model (Igari et al., 1983)

**Theoretical elements** Diffusion phenomenon is described by the Fick's laws of diffusion in macroscale (Fick, 1855).

#### Fick's first law

Fick's first law relates the diffusive flux to the concentration, by postulating that the flux goes from regions of high concentration to regions of low concentration, with a magnitude that is proportional to the concentration gradient. In the one dimension case we can write

$$J = -D \frac{\partial C}{\partial x} \quad (4)$$

where :

- $J$  is the diffusion flux,
- $D$  is the diffusion coefficient,
- $C$  is the concentration,
- $x$  is the position.

#### Fick's second law

Fick's second law predicts how diffusion causes the concentration to change with time, on the hypothesis of the matter conservation. Thus the diffused concentration can be computed with :

$$\frac{\partial C}{\partial t}(x, t) = D \frac{\partial^2 C}{\partial x^2}(x, t) \quad (5)$$

This gives rise to the following formula, in the biology perspective, considering two compartments separated by a membrane :

$$\frac{\partial C}{\partial t}(x, t) = \frac{D \cdot S}{L} \cdot \Delta C \quad (6)$$

where :

- $D$  is the diffusion coefficient of a given chemical species at a given temperature,
- $S$  is the surface area over which diffusion is taking place,
- $\Delta C$  is the difference of concentration across the membrane,
- $L$  is the membrane thickness.

**Implementation** A *Diffusion-Interaction*, manifestation of a *Diffusion-Phenomenon*, operates between two compartments. It computes on each time step the diffused concentration from a compartment to the other and applies the modifications.

Let us consider two compartments  $A$  and  $B$  with the diffusion of a chemical species  $C$  from  $A$  to  $B$ . The concentrations of  $C$  in  $A$  and  $B$  from a given instant  $t$  to the instant  $t + 1$  will be altered in this way (using an explicit Euler method for numerical integration)

$$\begin{cases} [C]_A^{t+1} = [C]_A^t - d \cdot \delta t \\ [C]_B^{t+1} = [C]_B^t + d \cdot \delta t \end{cases} \quad (7)$$

where

$$d = \frac{D \cdot S}{L} \cdot ([C]_A^t - [C]_B^t) \quad (8)$$

is the diffused concentration. The figure 7 illustrates this simulation in the context of VKA diffusion.

Figure 7: Physiologically-based simulation of VKA diffusion. Colors represent the medicine's concentration and goes from blue (lower) to red (higher).

In this equation, all the parameters can be measured in the simulation except the diffusion coefficient. This piece of data is generally determined with *in vivo* or *in vitro* experimentations for a given temperature and fixed conditions. It is therefore often a missing value in our models. That is why we would like to define this parameter automatically *in virtuo* by the use of a microscale simulation.

## Microscopic model

Diffusion phenomenon at microscale is generally described with the help of stochastic processes (Karatzas and Shreve, 2000). There exist several methods more accurate than the one we expose in the following, but we chose to focus on the principle. We remind in this section some theoretical elements about the Brownian motion and how it is implemented in the Virtuo framework.

**Theoretical elements** Brownian motion, first observed by Robert Brown in 1827, is the random movement of particles suspended in a fluid. It is provoked by collisions of the considered particles with the molecules of fluid which are exposed to thermal agitation.

This random movement leads to a diffusion process which coefficient is given by the Stokes - Einstein law, in case of spherical particles :

$$D = \frac{k_B T}{6\pi\eta R} \quad (9)$$

where :

- $k_B$  is the Boltzmann constant,
- $T$  is the temperature,
- $\eta$  is the fluid viscosity,
- $R$  is the particle radius.

Thus the quadratic displacement of a particle on a  $x$  axis during a time interval  $\Delta t$  is denoted by :

$$\sqrt{\Delta x^2} = \sqrt{2D\Delta t} \quad (10)$$

**Implementation** The *Brownian-Interaction* takes place within a fluid in which particles are immersed. We consider spherical *Entities* which are moveable. The interaction uses then a Gaussian distribution, with a null average and a variance  $\sigma^2 = 2D\Delta t$ , to randomly compute their displacement on each time step (Coulon, 2010).

## Scale interaction

We now have two different levels of description of the diffusion phenomenon. Our aim is to observe the microscale in order to deduce the value of the diffusion coefficient we need in the macroscale. Here's how we proceed.

We introduce a new microscale, based on the state of the macroscale. We arrange randomly particles in a volume according to their concentration in the macroscale. It is the HMM reconstruction operator. We place side by side an empty volume. We add a *Scale-Interaction* agent between the two scales. It counts how many particles crossed from the first to the second compartment, estimates then a diffusion coefficient and sends it to the macroscale ; see figure 8. This is the HMM compression operator. We stop the microscale simulation and continue the macroscale's simulation with the new parameter.

Figure 8: Microscale simulation of diffusion phenomenon using Brownian motion

## Conclusions

We use *in virtuo* experimentation and multi-interactions systems, in the context of complex systems simulation. They enable us to describe phenomena and their actions on the entities composing the system always keeping interactivity with the simulation. This phenomenological approach induces the use of parametric models which parameters are often partially available. This assessment leads us to use multiple levels of description for the phenomena. Thus we simulate redundantly some phenomena at different scales in order to identify the missing parameters.

We propose to implement heterogeneous multiscale methods into the MIS by the introduction of a *Scale-Interaction* agent which plays the role of a translator between the simulated scales.

We illustrate our modeling method through a pharmacokinetics application and a diffusion coefficient identification process. This example points up some remarks and questions we have to answer more precisely in a future work.

Firstly, our will is to parameter a model from observations made on another model. Nevertheless, models aren't perfect by definition. Thus we should keep in mind that what we observe could be imperfect as well.

We can do the same comment about the observation method and data estimation. We inject the macroscale with estimated parameters which could introduce instabilities into the simulation. We need then to define a control mechanism or / and a more developed method to apply observation results.

Secondly, observations are made in the microscale on a very short time window. Indeed, it is generally impossible to run a microscale as fast as a macroscale due to the huge time step difference. But we need results almost immediately to meet the requirements of interactivity with the system. So we are often forced to infer that the observation remains valid for a larger period. It would be satisfactory for

some phenomena but we need to define another observation methodology to be more accurate. For instance, we could try to detect equilibrium states and organizations of *Entities* into the microscale (Ferber et al., 2003). Thus we should be able to partially generalize the observation process even if it seems difficult to define a totally generic method because of the nature of modeling.

## Abstract

We propose a motifs seeding method to encourage the emergence of modular structure during network evolution. Previous studies fail to trigger modularity on freeform evolving ANNs either when varying environmental factors or the evolutionary process itself. We extracted statistical profiles of 3-node and 4-node motifs from evolved networks, and then generated new networks by seeding the most useful 3-node motif (feed-forward loop, ID:38). A series of retina recognition experiments was conducted using the seeded networks. The performance of different algorithms was measured. Our results indicate that modularity could be encouraged under certain conditions. We were able to build networks meeting a desired Z-score.

## Introduction

Modularity is a common property of natural and artificial complex systems. Networked modular structures commonly arise in biology, computer science, social sciences as well as many other disciplines. One can recognize modularity by the presence of clusters of highly interconnected nodes that are sparsely connected to the remaining ensembles of a networked structure (Newman, 2006). Although it is known that modularity is beneficial for the evolvability and robustness of complex systems, its origin remains to be uncovered. The questions of how modularity emerges in complex systems and how it affects the system's performance during development have been frequently addressed (Wagner and Altenberg, 1996).

Artificial evolution provides an excellent platform for exploring the above questions. A variety of systems have been evolved, including simple equational models, expressed by linear matrix transformations, artificial neural networks (ANNs) (Haykin, 1994), representing complex nonlinear phenomena (Yao, 1999), physical simulations involving complex machines and even real robotic systems (Lipson, 2000).

It is generally believed that modularity should be an outcome of an evolutionary process itself. Some experiments have shown that modularity might speed up an evolutionary process (Lipson et al., 2002). Apparently the mechanisms of selection (adequate choice of fitness function), environment variation and noise generation might play a key role in the emergence of modular structures.

Most of previous models used in artificial evolution are relatively simple. Linear models have been used to simplify

the simulations; the nonlinear ANNs models have also been constrained by predefined structures or given building rules. Such limitations could significantly decrease the space of evolutionary search, and simulation results consequently lack of generality.

Freeform ANNs have been employed to increase the generality of systems, but modular networks have not been found under similar experimental conditions at all. Fortunately, further experiments show that the modularity has no conflicts with the evolution of these complex networks (Li and Yuan, 2011). Therefore more effective and general methods have to be designed to encourage the emergence of modularity.

Network motifs are small-scale sub-networks which frequently appear in complex networks, and they have been found in many systems. A network motif can be understood as a pattern or unit of a particular information-processing task. It has been suggested that in many systems the motifs and modularity emerge spontaneously and simultaneously during evolution (Kashtan and Alon, 2005).

Based on these results, we are interested in making use of the coupled mechanism between motifs and modularity, more specifically, in this study we attempt to trigger the appearance of modularity by seeding motifs into ANNs. At first, the motifs' characteristics are extracted from well evolved modular ANNs, and then a series of algorithms is proposed to construct networks with those characteristics. In addition, the well studied retina recognition experiment is conducted in order to make comparisons with previous work.

## Background and Previous Work

A common approach to investigate modularity and its effects on complex systems is to use a computer based simulation of an adaptive system. A model represents the system-environment interplay and a fitness function governs species survival. This computer based method can be seen as a simulation of natural evolution.

Lipson et al. presented a linear matrix abstraction of an adaptive system (Lipson et al., 2002). The linear system represents the transformation of resources and functional requirements for the survival of certain life-form. By randomly varying the elements of a matrix representing the environment, it was possible to observe an increase in the system's modularity. The relation between varying rate and modularity has also been studied by experiments. The authors

claimed that modularity arises in evolutionary systems in response to variation.

Following previous suggestions, research on environment variation was further pursued in (Kashtan and Alon, 2005). A simple feed-forward ANN was used to perform the retina pattern classification task, which had limited connections and a small range of weights. The general structural constraints for evolving the networks were also given. The results show that modularity and motifs spontaneously evolved in networks when the goals were switched in a modular manner during evolution. Their later work also suggested that varying environment could speed up the evolution under certain conditions (Kashtan et al., 2007).

To validate whether HyperNEAT could evolve modular neural networks, Clune et al. investigated a series of retina recognition experiments (Clune et al., 2010), which were similar to those used in previous studies (Kashtan and Alon, 2005). Their results show that HyperNEAT has the potential to produce modular structures in some simple cases, but unfortunately it was unsuccessful in more complex problems. In order to enable HyperNEAT to foster modular networks Verbancsics and Stanley presented a seeding method toward local connectivity, which successfully encouraged the natural emergence of modular structures accelerating the simulations as well (Verbancsics and Stanley, 2010).

Instead of changing the environment, HØerstad proposed the method of adding noise to the genotype-phenotype (G-P) mapping (HØerstad, 2010). He used the same retina recognition experiments to test the noised based methods. The ANNs and their encoding method were similar to those used by Kashtan and Alon (2005). Based on a large amount of simulation experiments, he gave a statistical result, showing that the novel method could trigger the appearance of modularity and finally speed up evolution, however, the switch-goal method does not show the same abilities, which are totally against the conclusions of previous study (Kashtan and Alon, 2005).

Recently, a freeform ANN model has been proposed to investigate the mechanism of modularity and their responses to the variation of environment and evolutionary process. Varying scenarios have been experimented, the results show that the evolution performance has been improved in most cases, however, the modularity never appeared among those scenarios. Further experiments show that the proposed networks have the potential to produce modular networks but more advanced methods are still needed to encourage the emergence of modularity on complex networks (Li and Yuan, 2011).

## Models, Algorithms and Tools

### The ANN Model and Evolutionary Algorithms

To better understand the geometrical properties of complex networks, such as modularity and motifs, we have presented a pure topological ANN (Li et al., 2010), which has binary connection weights and free form directed connections at the hidden layer (Fig. 1). As the architecture shows (Fig. 1), there are three groups of neurons: input neurons, hidden neurons and output neurons, represented as  $I$ ,  $H$  and  $O$  respectively.

Figure 1: Pure topological neural networks

Therefore, all hidden neurons' and output neurons' values are updated by equation (1) and (2) respectively. The overall model can be given as:

$$H_i(t) = \sin\left(\sum_{j>i} H_j(t-1) + \sum_{f<i} H_f(t) + \sum_r I_r(t)\right) \quad (1)$$

$$O_k(t) = (1 + \exp(-\sum_i H_i(t)))^{-1} \quad (2)$$

where  $H_i$  denotes the current state of the  $i^{\text{th}}$  hidden neuron, which is relative to the other hidden neurons ( $H_j$  and  $H_f$ ) and the input neurons ( $I_r$ ) that connect to  $H_i$ .  $O_k$  is the  $k^{\text{th}}$  neuron's state of all  $n$  output neurons. Due to the characteristics of activation functions, we need to normalize all input raw data into range of  $[0, 2\pi]$  before computation. Accordingly, we have to scale the output value from  $[0, 1]$  to the target range as a final step.

We use the graph encoding method, which directly encodes connections between two nodes in a "from-to" fashion, and then organize all those connections as a graph vector structure. Five evolutionary operators, elitist replication, roulette wheel selection, sub-graph crossover connection mutation and transposing mutation have been used to evolve our networks.

### Modularity Measurement by Artificial Tracer

We measured the modularity of our ANNs using the artificial tracer method (Li and Yuan, 2011), which is inspired by the chemical, isotopic and radioactive tracers. We created the

Figure 2: Artificial tracer method

digital tracer elements using different markers, such as positive and negative tracers. To measure the modularity, we first injected the different tracers into each input node of network according to their attributes. All tracers are then passed through other nodes along the directions of information flow. The output connection will pass a tracer to next node with the same marker as the parent node. Annihilation takes place if two tracers with different markers meet at one node. Then we could roughly calculate the modularity using the following equation:

$$M = \frac{\sum_{i=0}^n R_i}{C_i} \quad (3)$$

where  $M$  represents the degree of network modularity, ranging from 0 to 1. Larger values are assigned to networks with higher degree of modularity.  $R_i$  denotes the number of remaining tracers at the  $i^{\text{th}}$  node after annihilations. We summarize their values as the equivalent of total amount of remaining connections. One should notice that the  $R_i$  does not include all input nodes, since the index  $i$  starts counting from the first hidden node.  $C_i$  is the total number of connections within this network. This computation shows the essence of modularity, which is defined as a relation between the inter-connections and intra-connections of elemental modules. An illustration of this procedure is shown in Fig. 2. It should be noted that this method has a limitation for measuring the feedback loop structure.

### The Retina Pattern Recognition Task

We investigated all the scenarios using a classic retina pattern recognition test. The retina pattern recognition experiment has been frequently used in previous studies as a challenging benchmark. Usually, ANNs have been evolved to recognize and classify an artificial retina. Each retina consists of eight pixels (4-pixel wide by 2-pixel height), equally divided into left and right sides, four pixels per side. The goal is to use an ANN to recognize objects in the left and right sides of this retina (Fig.3). As defined in (Kashtan and Alon, 2005), a left object is defined by three or more black pixels or one or two

Figure 3: Retina recognition mission

black pixels in the left column only. A right object is defined in a similar way, with one or two black pixels in the right column only. Those eight pixels each could be abstracted as 1 or 0, then those eight binary values could be treated as a group of input signals for the ANN. Finally, the single output (0 or 1) of the ANN is used to decide whether the retina fits the given Boolean logic questions “L AND R”, or “L OR R”. The “L AND R” is true only if the object exists at both sides of the retina, whereas if the object appears in left side or right side or even both sides, the “L OR R” function is then true.

### Motifs Analysis and Seeding

We used the software tools Mfinder (Kashtan et al., 2004) and Fanmod (Wernicke and Rasche, 2006) for extracting the motif’s feature from evolved networks. MDRAW (Kashtan et al., 2004) was used to display the global network topological architecture. As we know (Kashtan and Alon, 2005), a motif’s statistical significance can be described quantitatively using the Z-score.

$$Z_{score} = (N_{real} - N_{rand}) / STD \quad (4)$$

where  $N_{real}$  is the number of times the sub-graph appears in the original network, and  $N_{rand}$  and  $STD$  are the mean and standard deviation of its frequency of appearances in the randomized networks respectively.

---

#### Algorithm 1:

SeedMotifs (Motif\_ID, Target\_Z-score, Net\_size, Max\_refine\_times)

---

```

1: Net_pop ← RandomNetworks(Pop_size)
2: for each Net_i ∈ Net_pop do
3:   App_i ← EnumerateMotifs(Net_i, Motif_ID)
4: end for
5: Mean_app ← Average of App_i in Net_pop
6: STD_app ← Standard deviation of App_i in Net_pop
7: Target_app ← Target_Z-score*STD_app + Mean_app
8: Seeding_model ← Initial
9: Net ← ∅; Current_links ← 0; Current_app ← 0
10: while Current_links < Net_size do
11:   if Seeding_model = Initial then
12:     Net ← MotifSeedInitial (Net, Motif_ID)
13:   else
14:     Net ← MotifSeedRefine (Net, Motif_ID)
15:     Refine_count ← Refine_count + 1
16:   end if
17:   if Current_links ≥ Net_size then
18:     if Refine_count > Max_refine_times then
19:       return Net
20:     else
21:       Current_app ← EnumerateMotifs (Net, Motif_ID)
22:       if Current_app < Target_app then
23:         Reduce_ratio ← 1 - Current_app / Target_app
24:         Net ← ReduceLinks (Net, Reduce_ratio)
25:         Seeding_model ← Refine
26:       else
27:         return Net
28:       end if
29:     end if
30:   end if
31:   Current_links ← LinksCount(Net).
32: end while
33: return Net

```

---

Here we propose a series of algorithms to seed motifs into ANNs and then construct the whole network with expected characteristics. We define the network as  $Net(N, E)$ , where  $N(n_i, i \in [1, Net\_size])$  is the set of all nodes in this network and  $E(e_t, t \in [1, Net\_links])$  represents the set of edges. Each edge  $e_t \{From\_node, To\_node\}$  consists of a connection between two nodes.  $Net\_pop$  is defined as a group of  $Net$ . The  $App$  indicates the appearance time of specific motifs in network. As the algorithm 1 shows, given the motifs' ID and expected Z-score, the function  $SeedMotifs()$  is able to construct a network by repeatedly seeding single type motifs. The feedback of current network's motifs could be obtained by calling the function  $EnumerateMotifs()$ , which will return the appearance time of the motifs, the details of this function are given in algorithm 2. Two types of seeding operators have been designed, which will be used in different stages of seeding. The  $MotifSeedInitial()$  starts at the beginning of the process, whereas, the refining model  $MotifSeedRefine()$  will be executed after reducing the relatively useless links by the  $ReduceLinks()$ . It should be noted that the Algorithm 2 shown here is just for enumerating 3-node motifs, but it can be easily adapted for detecting other motifs. Other major algorithms could be found at the end of this paper.

**Algorithm 2:** EnumerateMotifs( $Net, Motif\_ID$ )

```

1:  $Net\_size \leftarrow$  the size of current  $Net$ 
2:  $En \leftarrow$  the edge number of current  $Motif$ 
3:  $E \leftarrow \emptyset$ 
4:  $Motif\_app \leftarrow 0$ 
5: for each  $Ce \in Net.E$  do
6:    $Ce.degree \leftarrow 0$ 
7: end for
8: for  $i=1$  to  $En$  do
9:    $Em_i \leftarrow false$ 
10: end for
11: for  $a=1$  to  $Net\_size-2$  do
12:   for  $b=a+1$  to  $Net\_size-1$  do
13:     for  $c=b+1$  to  $Net\_size$  do
14:        $E \leftarrow MotifExample(Motif\_ID, n_a, n_b, n_c)$ 
15:       for  $t=1$  to  $En$  do
16:          $Em_t = EdgeMatch(Net, Me_t)$ 
17:       end for
18:       if all  $Em_t = true$  then
19:          $Motif\_app \leftarrow Motif\_app + 1$ 
20:         for each  $Ce \in Net.E$  do
21:            $Ce.degree \leftarrow Ce.degree + 1$ 
22:         end for
23:       end if
24:     end for
25:   end for
26: end for
27: return  $Motif\_app$ 

```

## Experiments and Results

### Experiments on Performances of Algorithms

In order to assess the performance of motifs seeding method, we pursued a group of experiments. We used target networks having 30 nodes and 120 links. We focus our study on seeding 3-node motifs, especially the feed-forward loop motif (ID:38). Given a target Z-score of 10 we have executed 10 independent tests to see the capabilities of seeding speed and convergence, the average Z-score and its standard deviation are shown in Fig.4 (a). It is easy to observe that under limited refining times (10), the Z-score mean rapidly approaches to 10 with a small standard deviation. Furthermore, different Z-score requirements have also been tested, and the 10-times average results are compared with other motif detecting tools as shown in Fig.4 (b). As it can be seen the algorithms perform better on the larger Z-score (5 and 10) targets.

### Experiments on Motifs Extraction

Before seeding the motifs, we have analyzed the modular ANNs by the Fanmod software. All networks were evolved from our previous experiments (Li and Yuan, 2011), resulting in high values of modularity. We extracted all 3-node motifs and some significant 4-node motifs from 10 networks, the statistical results are shown in Fig. 5 and Table.1. From these results, we could observe some simply statistical attributes among all networks. As for 3-node motifs, the motifs with ID of 38 have a mean Z-score of about 20. This means that motif 38 appears significantly more times than others, whereas the motifs 6, 12 and 36 detected from modular ANNs are less than

Figure 4: Performances of algorithms: (a) speed and convergence; (b) accuracy

Fig.5. The 3-node motifs' significance profile of networks

	Top two 4-node motifs				Last two 4-node motifs			
Network ID	Motif ID	Z-score	Motif ID	Z-score	Motif ID	Z-score	Motif ID	Z-score
1	2254	9	2252	9.02	2124	-6.73	140	-9.65
2	2254	37.35	2252	20.65	392	-6.71	140	-15.99

10	2254	71.7	2252	38.67	2184	-8.49	140	-17.84
Probability	P(2254) = 100%		P(2252) = 100%		P(2124) = 60%		P(140) = 100%	
Average Z-score	 ID:2254 A(2254) = 30.58		 ID:2252 A(2252) = 21.64		 ID:2124 A(2124) = -6.67		 ID:140 A(140) = -13.66	

Table 2: The 4-node Motifs' Significance Profile of Networks

in random networks, we name those 3-node motifs as binary tree motif (ID:6), three-chain motif (ID:12) and reverse binary tree motif (ID:36) respectively. Moreover, the 4-node motifs also show very interesting features. The motifs 2254 (tetrad-feedforward loops motif) and 2252 (bi-feedforward loops motif) appear with highest Z-score among all networks. In contrast, the motif 140 (counter-links four-chain motif) seems to emerge much less than others with a smaller mean Z-score of about -13.66

### Experiments on Retina Recognition

As for the evolutionary simulation, we first constructed a population of 600 candidate networks by seeding the motifs 38 with a target Z-score of 10 and number of links limited to 120. To reduce the computational complexity, we also constrained the network size to 30 nodes from which 8 nodes were assigned as input pixels' values. One node defined as

output, and the remaining nodes (up to 21) were free to build any structures through evolution towards a given task. We set the maximum generation as 5,000 then the modularity was estimated as well as the fitness, and the best networks' structures of each generation were recorded also. In most of our retina recognition experiments, the data set used for training consisted of 100 independent retina patterns which were randomly generated at startup. The general fitness was designed to reflect the ratio of correct recognition over all 100 samples. We evolved the ANNs under a group of different regimes, and we run each test 10 times independently for various experimental scenarios, a list of experiments is shown in Table 1.

We first evolved the networks to recognize the patterns of "L AND R" from the predefined data set. Then, similarly as in previous work, we pursued an interesting MVG regime, in which the recognition goal switched between "L AND R" and

“L OR R” every 50 generations. A varying environment regime (VE) was also tested. We temporally changed the dimension of the data set as a practical method to introduce environment change. Additionally, following the suggestions of (Lipson et al., 2002), we designed the VS scenario as the

Experiment	Description
FG-AND	Evolving networks to solve the fixed goal L AND R
MVG	The goal switched between “L AND R” and “L OR R” every 50 generations.
MVE	The data set changed between 100 samples and randomly selected 50 samples every 50 generations.
VS	The selection mechanism alternated between proportion-based roulette selection and random selection.
VM	The order of mutation operation and selection operation reverse d every 50 generations.
FG-M	Same as FG-AND, but the fitness function coupled with the value of modularity

Table 2: The List of Experiments

variations of selection process, the proportion-based roulette selection mechanism sometimes got a failure during evolution, and then the random selection played a key role for producing offspring. The VM scheme temporally applied the mutational operators after the performance evaluation; it thus reversed the traditional sequence between the selection/replication and the mutation every 50 generations.

The comparisons of results on different regimes are shown in Fig.6, results correspond to the average values over 10 runs. Fig.6 (a) shows the best networks’ fitness records over all regimes, as we can see, the MVE exhibit a significant higher fitness than others, and it approaches 0.95 within 4,000 generations, whereas the MVG does not show any advantages either in fitness value or evolution speed, its fitness value stays under 0.9.

Fig.6 (b) presents the resulting modularity estimation results for the best evolved networks of all regimes. The figure shows a result that a highly modular structure ( $>0.8$ ) which never arose among all previous tests. For most of regimes, the modularity values keep under a low level of 0.5.

Although the mean values of VM cases do not show much advance than others, one of VM tests evolved a highly modular structure and with a high correct ratio about 0.9, the correct ratio and modularity are shown in Fig.6 (c).

Figure 6: Results of different experiments

As for the FG-M cases, the comparison between random based evolution and motifs-seeding based evolution is shown in Fig.6 (d). It could be easily found that the correction ratio and modularity, they both approach a relative high level at 0.9 and 0.95 respectively. More importantly, these results indicate that the motifs seeding method brings an improvement on the speed of evolution for both correct ratio and modularity.

## Discussion

We have proposed a novel method to construct networks by seeding single type motifs. The performances have been tested by two experiments. Compared to other motifs-detecting tools, our method is able to construct networks with predefined Z-score. The seeding algorithms seem relatively accurate for a higher Z-score ( $\geq 5$ ) and the target Z-score could be quickly achieved within limited iterations. This is mainly attributed to the operators of refining, after reducing the lowest-degree edges, the remaining edges have the opportunities to be reused in new motifs, and then the density of motifs becomes higher. Since we are aiming at seeding a large population, thus the current method is accurate enough, however, we have to admit that the seeding method still have space to be improved on its accuracy, a real-time feedback mechanism might be useful for a more precise seeding.

After analyzing the well evolved modular networks, we have found that for 3-node motifs, the feed-forward loop motif (ID:38) seems very useful for constructing a modular architecture, but the binary tree motif (ID:6), three-chain motif (ID:12) and reverse binary tree motif (ID:36) conflict with modularity. Similar phenomenon was also found for 4-node motifs, where the tetrad-feedforward loops motif (ID:2254) and bi-feedforward loops motif (ID:2252) always appear much more times than others but the counter-links four-chain motif (ID:140) is useless for a modular structure. These results match with previous work very well, it again validates the idea that motifs could emerge spontaneously as the modularity arises, but the hidden mechanism between them still unrevealed. These phenomena are probably due to the natural feed-forward information processing of retina recognition tests, and the inherited relations between full-loop structures (motifs) and their sub-structures (motifs).

According to the analysis of our results, we ran various tests after seeding the feed-forward loop motifs into networks, however in most of cases, the modularity of networks have no improvement compared to our previous work. Fortunately, one of the VM tests has evolved a relatively higher modularity than others. As for all the FG-M cases, the performance of modularity and correct ratio have been both improved, the evolved network (Fig.6(d)) presents a nearly perfect modular structure with a high correct ratio. It is obvious that the emergence speed of modular structures is higher than previous results. These results might be attributed to the motifs seeding mechanism, which offers well organized networks for evolution.

Could the motifs seeding method generate highly modular networks regardless the objective of evolution? Since we just simply seed single motif type into a network, the side-effects of seeding have been ignored, however they might be essential for global performances of networks. Based on this

hypothesis, the multiple-types or hybrid motifs seeding method is needed in the future study.

## Conclusion and Future Work

It is still an open question whether the modularity of ANNs could be encouraged by varying the environment or the evolution process, however, previous work has experimented that the freeform ANNs have difficulty to evolve modular structure under simple variation of external environment.

In this study we try to encourage the networks' modularity by seeding motifs into networks. The motifs statistical features have been extracted from a group of well evolved modular networks. The motif seeding algorithms are proposed and the performances have been evaluated by experiments. We then seeded the network populations by the feed-forward loop motifs and conducted classic retina recognition tests by proposed evolutionary simulation. The modular networks have been discovered during one of tests under varying mutation scenarios. By introducing modularity into fitness function, the modular structures have emerged during evolution; experimental results show that after seeding motifs to initial networks, this emergence process could be accelerated further. These results open the door for triggering modular structure through seeding motifs.

In future, the statistical result will be given based on more experiments under different scenarios. The hybrid motifs seeding algorithms are expected to further encourage the appearance of modularity with a higher success ratio.

## Appendices

## Abstract

We discuss an ensemble investigation of the computational capabilities of small-world networks as compared to ordered and random topologies, using random Boolean functions to provide dynamics of the nodes. We find that the ordered phase of the dynamics (low activity in dynamics) and topologies with low randomness are dominated by information storage, while the chaotic phase (high activity in dynamics) and topologies with high randomness are dominated by information transfer. Information storage and information transfer are somewhat balanced near the small-world regime, providing quantitative evidence that small-world networks do indeed have a propensity to “combine” comparably large information storage and transfer capacity.

## Introduction

It is often suggested that the prevalence of small-world networks in nature is due to an inherent capability to store and transfer information efficiently (Watts and Strogatz, 1998; Latora and Marchiori, 2001). Yet while these claims are all based on quantitative results, they are not based on direct measurement of the relevant dynamic information quantities, either relying on measurements of topological features or on equating perturbation or damage-spreading type results to information transfer. A recently published framework (Lizier et al., 2008, 2010) affords the opportunity to directly measure these computational properties or *information dynamics*.

We discuss our previously published ensemble investigation (Lizier et al., 2011) of the *information dynamics* of small-world Boolean networks, from the perspective of the distributed computation undertaken by the nodes of the network in the transient computation of their attractor. We show that small-world networks exhibit something of a balance between information storage and transfer capabilities, with the capability for apparent (or coherent) information transfer being maximized near the small-world state.

## Small-world Boolean Networks

The small-world network model (Watts and Strogatz, 1998) specifies how to tune networks with  $N$  nodes (with  $\bar{K}$  nearest neighbors each) from ordered, lattice-like structures, to

fully-random topologies using a level of random rewiring of edges  $\gamma$ . There is a significant intermediate range of values  $\gamma$  for which networks exhibit both high clustering (typical of ordered networks) and small average path length (typical of randomized networks); networks in this range are labeled *small-world networks*.

We generate time-series activity for the networks by assigning synchronous random Boolean functions to the nodes (with a bias probability  $r$  for each input configuration of each node to produce a “1” output). This equates to combining *random Boolean networks* (RBNs) (Kauffman, 1993; Gershenson, 2004) with small-world topologies. We select RBNs due to the very large sample space they provide, and their use as models of Gene Regulatory Networks (GRNs). They display a well-known phase transition from *ordered dynamics* (at low connectivity  $\bar{K}$  and activity  $r$ ) to *chaotic dynamics* (at high connectivity and activity), as measured by damage spreading with the normalized Hamming distance  $\delta$  (Gershenson, 2004). We identify the critical state in *finite* networks where the standard deviation  $\sigma_\delta$  of  $\delta$  is maximized. Finally, other recent studies combine RBNs with small-world topologies, e.g. (Lu and Teuscher, 2009).

## Information dynamics

The *active information storage* (Lizier et al., 2010) for a node  $X$  is defined as the average mutual information (MI) between its semi-infinite past  $x_n^{(k)}$  (as  $k \rightarrow \infty$ ) and its next state  $x_{n+1}$  at time step  $n + 1$ :  $A_X(k) = \langle i(x_n^{(k)}; x_{n+1}) \rangle$ .

We note that the local entropy for  $X$  is the sum of  $A_X(k)$  and the local entropy rate  $H_{\mu X}(k) = \langle h(x_{n+1} | x_n^{(k)}) \rangle$ ; i.e.  $H_X = A_X(k) + H_{\mu X}(k)$ . In a deterministic system such as RBNs, there is no intrinsic uncertainty in  $H_{\mu X}(k)$  so it represents the *joint* contribution or transfer from the causal information sources to the destination (Lizier et al., 2010).

The *information transfer* (formulated in the *apparent transfer entropy* (Schreiber, 2000; Lizier et al., 2008)) from *one* source  $Y$  to a destination  $X$  is the average MI between the previous source state  $y_n$  and the next destination state  $x_{n+1}$ , *conditioned* on the semi-infinite past of the destination  $x_n^{(k)}$  (as  $k \rightarrow \infty$ ):  $T_{Y \rightarrow X}(k) = \langle i(y_n; x_{n+1} | x_n^{(k)}) \rangle$ .

Figure 1: Measures of dynamics versus  $r$  and  $\gamma$  for  $K = 4$  (color online). Ordered dynamics occur for low  $r$  and  $\gamma$  (bottom left), and chaotic dynamics for high  $r$  and  $\gamma$  (top right); the critical regime at the maxima in (a) separates these.

## Results and discussion

We examine ensembles of networks of size  $N = 264$  as a function of  $\bar{K}$ ,  $r$  and  $\gamma$  (sources of links only rewired; other details in (Lizier et al., 2011)) using extensions to RBNLab (Gershenson, 2003). We use  $\bar{K} = 4$ : the small-world region then occurs approximately for  $0.03 \leq \gamma \leq 0.1$ .

Using  $\sigma$  (not shown) and  $\sigma_\delta$  (Fig. 1a, Fig. 2) we see that (i) for fixed  $\gamma$  an ordered phase exists for low  $r$ , with the chaotic phase for large  $r$ . Crucially, a similar transition occurs (ii) with respect to  $\gamma$  for fixed  $r$ , with ordered dynamics for small  $\gamma$  (more ordered networks), and chaotic dynamics for large  $\gamma$  (more randomized networks). The critical region in dynamics has much similarity to the small-world regions of  $\gamma$  (however this is highly dependent on activity  $r$ ).

The ordered phase of these dynamics (low  $r$  and  $\gamma$ ) is dominated by information storage  $A_X$  (Fig. 1b), while the chaotic phase of the dynamics (high  $r$  and  $\gamma$ ) is dominated by information transfer (captured in total in  $H_{\mu X}$  in Fig. 1c). The critical regime exhibited a balance between these two operations (Fig. 2), and since this was near to the small-world topology regime, it could be said that **small-world networks have a propensity to combine comparably large information storage and transfer capabilities**.

This balance can be explained by considering how the topological features related to the information dynamics. Information storage is strongly correlated to the clustering coefficient: locally clustered structure appears to strongly support storage operations. In contrast, information transfer was anti-correlated with average path length: long links appear to be a crucial facilitator of transfer across the network.

Figure 2: Measures of dynamics versus  $\gamma$ , for  $K = 4$  and  $r = 0.36$ .  $\sigma_\delta$  is plotted against the right y-axis. Error bars indicate *standard deviation* across 250 sampled networks.

Additionally, Fig. 1d shows apparent information transfer  $T_{Y \rightarrow X}$  is maximized slightly inside the chaotic phase of dynamics (near to the small-world regime). The capacity for coherent computation is eroded as too many random links promote interactions and make the dynamics more chaotic.

These results add evidence that small-world networks hold computational advantages over other topologies.

## Abstract

Artificial biochemical networks (ABNs) are computational architectures motivated by the organisation of cells and tissues at a biochemical level. In previous work, we have shown how artificial biochemical networks can be used to control trajectories in discrete and continuous dynamical systems. In this work, we extend the approach to the control of a hybrid dynamical system: a legged robot. Taking inspiration from biological cells, in which complex behaviours come about through the interaction of different classes of biochemical network, we develop the notion of a coupled artificial biochemical network, in which an artificial genetic network controls the configuration of an artificial metabolic network. Using a higher-level robotic control task, we show how the coupled network finds solutions which can not be readily expressed using the artificial genetic network or artificial metabolic network alone. Our results also show the important role that non-linear maps can play as a natural source of complex dynamics.

## Introduction

The structure and function of biological organisms emerges from the action and interaction of biochemical networks operating within cells. There are three main types of biochemical network: the *metabolic network*, comprising the protein-mediated chemical reactions that take place within the cell; the *signalling network*, composed of the protein-mediated responses to chemical messengers received by the cell; and the *genetic network*, which emerges from the regulatory interactions between genes.

From a computational perspective, biochemical networks are interesting for a number of reasons. This includes their ability to express complex behaviours, their compactness, their ability to adapt to changing environments, their robustness to environmental perturbation and—from the perspective of evolutionary computation—their evolvability. Such reasoning has motivated a host of computational models whose architectures are based upon the structure and function of biochemical networks. We refer to these collectively as *artificial biochemical networks*, or ABNs (Lones et al., 2010).

Perhaps best known of these are Boolean networks (Kauffman, 1969) and other kinds of *artificial genetic networks* (e.g. Reil, 1999; Banzhaf, 2003). By modelling the regulatory interactions which occur between genes, these models attempt to capture the dynamics of genetic networks, using these to generate complex, robust, behaviour. Another class of models, which includes P Systems (Păun, 2000) and artificial chemistries (e.g. Fontana, 1992; Banzhaf, 2004), can be categorised as *artificial metabolic networks*. These mimic the self-organising behaviour of biological metabolisms, and attempt to capture the manner in which complex behaviour can emerge from interactions between simple computational components. There has also been some work on *artificial signalling networks*, including early work on perceptron-like feed-forward networks (Bray, 1995) and more recent work on signalling-based classifier systems (Decraene et al., 2007).

ABNs have been used to implement a range of computational behaviours, including those required for robotic navigation (Ziegler and Banzhaf, 2001; Taylor, 2004), classification (Banzhaf and Lasarczyk, 2005), pole balancing (Nicolau et al., 2010) and image compression (Trefzer et al., 2010). In our research, we are interested in the ability of ABNs to control the kind of dynamics found in complex real world systems. In (Lones et al., 2010), we applied ABNs to the control of two numerical dynamical systems: the Lorenz equations, a continuous-time dissipative dynamical system; and Chirikov's standard map, a discrete-time conservative dynamical system. These both model complex dynamics found within real world systems, and also lie at opposite ends of the dynamical systems spectrum. In both cases, we were able to evolve ABNs capable of controlling trajectories in a prescribed manner.

However, many real world systems do not have purely continuous or discrete dynamics, but rather a hybrid of the two (Branicky, 2005). These often occur on different time scales, such that continuous state flow is occasionally interrupted by jump discontinuities caused by the occurrence of discrete events. Two common examples of this are physical systems with impact, such as a bouncing ball, and switched

systems, where a signal change causes a discrete change in behaviour. In this paper, we consider a problem which combines both of these: controlling the gait and direction of movement of a simulated legged robot.

Coupling between different classes of biochemical network plays an important part in the functioning of biological cells. The coupling between a genetic network and a metabolic network, in particular, is central to a cell's ability to both specialise and adapt to a changing environment. Taking inspiration from this biological behaviour, we investigate a hybrid ABN architecture, in which an artificial genetic network controls the expression of an artificial metabolic network. Results on the robot locomotion tasks suggest that such an architecture is particularly suited to problems that require reconfigurable dynamical behaviour.

The paper is structured as follows: We first introduce the ABN models used in this work. We then describe how these models are evolved. Finally, we introduce the robotic locomotion tasks to which they were applied, and present results and conclusions.

## Artificial Biochemical Network Models

In this section, we describe the three ABN models used in this work: an artificial genetic network (AGN), an artificial metabolic network (AMN), and a hybrid ABN formed from the coupling of an AGN and an AMN. In addition to expressiveness and evolvability, our choice of models is also influenced by a desire for efficiency and simplicity. For this reason, the models use discrete-time rather than continuous-time updates (unlike, for instance, Banzhaf, 2003). Since continuous-time dynamical systems can often be reduced to discrete-time equivalents by taking Poincaré sections (Kantz and Schreiber, 2004), this arguably makes little difference in terms of expressiveness, but does considerably reduce execution time.

### Artificial Genetic Network (AGN)

In general, the complex behaviour of biological genetic networks stems not from the complexity of their component parts, but from the complexity of their dynamics. Hence, a simple abstraction such as the Boolean network can display complex behaviour without the need to model biological details such as continuous-valued expression, asynchronous updates, continuous-time, and the presence of transcription factors. Nevertheless, there are advantages to using more complicated models, and in this work we use a continuous-valued generalisation of the Boolean network.

Continuous values have two main advantages. First, they make it easier to interface with external systems, since inputs and outputs do not need to be encoded in binary. Second, the size of the state space is not limited by the number of genes in the network. In a Boolean network, the number of possible states is  $2^N$ , where  $N$  is the number of genes, meaning that small networks are always attracted to a limit

cycle. When continuous values are used, the state space is infinite (within the limits of representation), meaning that small networks have the potential to exhibit more complex behaviours.

Formally, an AGN consists of an indexed set of genes,  $G$ . Each  $g_i \in G$  has an expression level  $\lambda_i$ , an indexed set of regulatory inputs  $R_i$ , and a regulatory function  $f_i$ , which maps the expression levels of its regulatory inputs to its own expression level. The first time the AGN is executed, its expression levels are initialised from an indexed set of initial values,  $L_G$ . External inputs can be delivered to the network either by explicitly setting the expression levels of certain genes, or by introducing new regulatory inputs with fixed values. After iterating the network a specified number of times,  $t_G$ , outputs are captured from the final expression levels of designated genes.

### Artificial Metabolic Network (AMN)

The artificial metabolic network complements the AGN described in the previous section. It is a simple artificial chemistry with continuous-valued chemicals and continuous-valued reactions. Formally, it consists of an indexed set of enzyme-analogous elements  $E$  which transform the concentrations of an indexed set of real-valued chemicals  $C$ . Each enzyme has a set of substrates  $S_i \subseteq C$ , a set of products  $P_i \subseteq C$ , and a reaction  $m_i$  which calculates the concentrations of its products based upon the concentrations of its substrates.

The first time the AMN is executed, its chemical concentrations are initialised from an indexed set of initial values,  $L_C$ . External inputs are delivered to the network by explicitly setting the concentrations of certain chemicals. At each time step, each enzyme  $e_i$  applies its reaction  $m_i$  to the current concentrations of its substrates  $S_i$  in order to determine the new concentrations of its products  $P_i$ . Where the same chemical is produced by multiple enzymes, i.e. when  $\exists j, k : j \neq k \wedge c_i \in P_j \cap P_k$ , the new concentration is the mean output value of all contributing enzymes:  $c_i = \sum_{e_j \in E_{c_i}} c_i^{e_j} / |E_{c_i}|$  where  $E_{c_i}$  are enzymes for which  $c_i \in P_i$  and  $c_i^{e_j}$  is the output value of  $e_j$  for  $c_i$ . After iterating the network  $t_M$  times, outputs are captured from the final concentrations of designated chemicals.

### Coupled Artificial Biochemical Network (CABN)

Biological biochemical networks interact with one another in a number of ways. Perhaps most significantly, the genetic network controls when and where proteins are expressed. This determines which enzymes are present in the metabolic network, and hence which reactions can take place within a cell. In effect, the genetic network is able to reconfigure the cell's processing machinery over the course of time. This behaviour occurs extensively in both single-celled and multicellular organisms. In the former, it allows the metabolism to be changed in order to react to the presence of different

Figure 1: Coupled artificial biochemical network.

kinds of nutrients in the organism’s environment. In the latter, it underlies the processes of cell specialisation and development which are fundamental to multi-cellular organisms.

In the coupled artificial biochemical network (CABN) model, we capture this idea of a genetic network controlling the expression of a metabolic network (See Fig. 1). Formally, a CABN comprises an AGN, an AMN, and an injective coupling function  $\chi : G_C \rightarrow E$  where  $G_C \subseteq G$  is the set of enzyme coding genes, i.e. each enzyme is coupled to a single gene, and some genes may not be enzyme coding (yet are still involved in regulating other genes). Coupling is carried out by giving each enzyme an expression level,  $\xi_i$ , and setting this to the expression level of the gene to which it is coupled, i.e.  $\forall (g_i, e_j) \in \chi : \xi_j := \lambda_i$ . This expression level then determines the relative influence of each enzyme when calculating the new concentration of a chemical:

$$c_i = \sum_{e_j \in E_{c_i}} \frac{\xi_i c_i^{e_j}}{\sum_{e_j \in E_{c_i}} \xi_i} \quad (1)$$

i.e. the new concentration is the mean of each enzyme’s output value weighted by its relative expression level. This captures the idea that changes in the genetic network lead to changes in the balance between competing pathways in a metabolism.

## Regulatory functions and enzyme reactions

Table 1 lists the mathematical functions from which regulatory functions ( $f$ ) and enzyme reactions ( $m$ ) are chosen.

*Sigmoids* model the switching behaviour of many non-linear biological systems, making them a good choice for approximating the behaviours of genetic and metabolic pathways. We use the logistic function, where  $s$  determines the slope and  $b$  the slope offset (or *bias*). For multiple inputs,  $x = \sum_{j=0}^n i_j w_j$ , where  $i_0 \dots i_n$  are inputs and  $w_0 \dots w_n \in [-1, 1]$  are corresponding input weights, with negative values indicating repression.

The remaining functions, all of which are discrete non-linear maps, are motivated by our earlier work (Lones et al.,

Table 1: Mathematical functions used within ABNs.

---

Logistic (Sigmoidal) function:

$$f(x) = (1 + e^{-sx-b})^{-1}, \text{ where } s \in [0, 20], b \in [-1, 1]$$

Logistic map:

$$x_{n+1} = rx(1-x), \text{ where } r \in [0, 4]$$

Arnold’s cat map:

$$(x_{n+1}, y_{n+1}) = ([2x_n + y_n] \bmod 1, [x_n + y_n] \bmod 1)$$

Baker’s map:

$$(x_{n+1}, y_{n+1}) = \begin{cases} (2x_n, y_n/2) & 0 \leq x_n \leq \frac{1}{2} \\ (2 - 2x_n, 1 - y_n/2) & \frac{1}{2} \leq x_n < 1 \end{cases}$$

Chirikov’s standard map:

$$\begin{aligned} p_{n+1} &= (p_n + K \sin \theta_n) \bmod 2\pi, \quad K \in [0, 10] \\ \theta_{n+1} &= (\theta_n + p_{n+1}) \bmod 2\pi \end{aligned}$$

---

2010) in which we found that the use of logistic maps within ABNs could lead to the evolution of more effective controllers. We hypothesised that this was due to evolution taking advantage of the complex dynamical behaviours displayed by non-linear discrete maps.

In this work, we extend the approach by using four well-known discrete maps that capture the natural dynamics present in a range of biological and physical systems. *The logistic map* is a model of biological population growth. Depending on the value of parameter  $r$ , the system is attracted to either a fixed-point, cyclic or chaotic orbit (May, 1976). *Arnold’s cat map* (Arnold and Avez, 1968) is a geometric transformation of the unit square with interesting periodic behaviour. *The baker’s map* is an archetypal model of deterministic chaos, capturing the exponential sensitivity to initial conditions that results when kneading bread (Silva, 2008). *Chirikov’s standard map* (Chirikov, 1969) captures the behaviour of dynamical systems with co-existing ordered and chaotic regimes. Its dynamics are ordered for low values of parameter  $K$  and become increasingly chaotic for higher values. The parameterised maps (the logistic map and Chirikov’s map) can be used either with an evolved parameter value or with an extra input, whose current value is used to set the parameter. The latter is referred to as a tunable map, since its dynamics can be modified by the ABN during execution.

## Evolving Artificial Biochemical Networks

Our ABNs are evolved using a standard generational evolutionary algorithm with tournament selection (size 4), uniform crossover ( $p=0.15$ ), and point mutation ( $p=0.06$ ). Crossover points always fall between gene or enzyme boundaries. Inputs and outputs ( $R_i, S_i$  and  $P_i$ ) are represented by absolute references to indices. Function parameters (e.g. slopes, input weights) and initial values are rep-

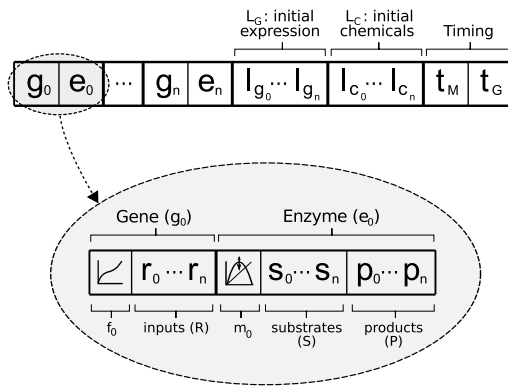

Figure 2: Genetic encoding of an artificial biochemical network.

Figure 3: Quadruped robot simulated in Open Dynamics Environment. Arrows indicate the direction of movement along the x-axis plane.

resented as floating-point values and are mutated using a Gaussian distribution centred around the current value.

We use a standardised genetic encoding for all ABN types (see Fig. 2). This represents the ABN as a sequence of genetic units, where each genetic unit has an optional regulatory region and an optional coding region. In a coupled network, the regulatory region encodes the gene and the coding region encodes the enzyme which it expresses. Where a gene does not express an enzyme (such as in an AGN), the coding region is empty. For an AMN, where there are no genes, the regulatory region is empty. The genetic encoding also includes the initial gene expression and chemical concentrations (where applicable) and timing information.

## Controlling Legged Robot Locomotion

Legged robot locomotion is a challenging problem. In (Beer and Gallagher, 1992), the authors summarised the challenge by stating “A locomotion system must simultaneously solve the two tightly coupled problems of support and progression.” In this paper, we address the locomotion of a simulated quadrupedal robot. There have been a number of previous attempts to evolve quadrupedal locomotion (e.g. Hornby et al., 2005; Kamio et al., 2003; Seo and Hyun, 2008; Clune et al., 2009). Since functional gaits can be generated by tapping sinusoidal functions at appropriate phase offsets,

a common approach is to use genetic algorithms (Hornby et al., 2005) or genetic programming (Seo and Hyun, 2008) to generate sinusoid-based controllers. Another, potentially more robust, approach is to evolve neural networks (Beer and Gallagher, 1992; Clune et al., 2009).

Since our focus is upon using legged robot locomotion as a test bed for comparing the expressiveness of different ABN models, the robot (see Fig. 3) is purposely very simple in design, comprising a square top section with four legs connected by actuators at the corners. The actuators are limited to movement in the x-axis plane, with a maximum elevation of  $60^\circ$  from vertical. The robot was simulated using the Open Dynamics Engine (ODE) physics engine, with a step size of  $\Delta_t = 0.05s$ , friction of 200N, CFM (an ODE parameter) of  $10^{-5}$ , and standard gravity. Actuators have a maximum angular velocity of 3m/s and a maximum torque of 150Nm. These values are sufficient to enable dynamic gaits, but not large enough to allow the body to be dragged by the front legs without the involvement of the rear legs. The ABN is executed every 10 simulation steps.

## Generating Quadrupedal Gaits

The first task was to evolve ABNs capable of generating quadrupedal gaits, i.e. patterns of actuator movements which would cause the robot to move away from its starting position. The aim of this task was to determine whether the different ABN types and configurations were able to generate appropriate patterns of movement.

**Experimental Settings** A controller’s fitness is the Euclidean distance moved by the robot within an evaluation period of 500 time steps. The population size is 200, with a generation limit of 100. ABNs have four inputs, corresponding to the actuator angles, and four outputs, which are used to set the torques of the actuators during the next 10 simulation steps. Note that the requirement to map angles to torques adds a degree of difficulty to this task. All inputs and outputs are linearly scaled to the interval  $[0, 1]$ . For AMNs and CABNs, inputs are delivered via initial chemical concentrations. For AGNs, inputs are delivered via initial gene expression levels.

**Results** Figure 4 compares the fitness distributions of evolved controllers. This shows that all three classes of ABN are capable of generating gaits which solve the movement task. It also indicates that there is no significant difference in the median performance of the AGN, AMN and CABN models. However, for all ABN models, the best controllers use Sigmoidal functions rather than non-linear maps. Solution length (i.e. network size) has relatively little impact. Examples of evolved behaviours are shown in Figure 5.

These results demonstrate that effective controllers can be expressed using any of the ABN models, although good controllers are more readily found when using Sigmoidal functions. It is interesting to note that there is no observable

Figure 4: Controlling legged robots using coupled and uncoupled ABNs with sigmoids (Sig) or discrete maps. Summary statistics for 50 runs are shown as notched box plots. Overlapping notches indicate that median values (thick horizontal bars) are not significantly different at the 95% confidence level. Kernel density estimates of underlying distributions are also shown (in grey), showing that some of the distributions are multimodal. The notation  $F_{n1} \mapsto F_{n2}$  denotes a genetic network with  $F_{n1}$  regulatory functions coupled to a metabolic network with  $F_{n2}$  enzyme functions. Coupled networks comprise 10 genes (expressing up to 10 enzymes) and 10 chemicals. For uncoupled genetic and metabolic networks, results are shown for solution lengths of both 10 and 20 (genes, or enzymes and chemicals, respectively), to allow fair comparison with the coupled networks.

penalty to using the structurally more complex coupled networks.

### Higher Level Control of Locomotion

The second task introduced an extra level of difficulty, requiring the ABNs to control the robot's direction of movement in addition to its gait. The aim of the task was to test not only the ABNs' abilities to express suitable patterns of movement, but also their ability to switch between different patterns as required.

**Objective function** The robot is required to change direction by  $180^\circ$  when signalled to do so, whilst still moving as far as possible in the given direction. Controller fitness is measured over a sequence of epochs  $\langle e_0, \dots, e_{N-1} \rangle$ , each with a random duration between 300 and 600 time steps, with the required direction of movement reversing during subsequent epochs. The fitness function  $f$  is defined:

$$f = \frac{t_{\max} - t_{\min}}{N} \min \left\{ \sum_{n \in \mathbb{N}_{\text{even}}, n < N} p(n), \sum_{n \in \mathbb{N}_{\text{odd}}, n < N} p(n) \right\} \quad (2)$$

where  $t_{\max}$  and  $t_{\min}$  are the maximum and minimum bounds on epoch duration and  $p(n)$  is the progress made during epoch  $n$ , defined:

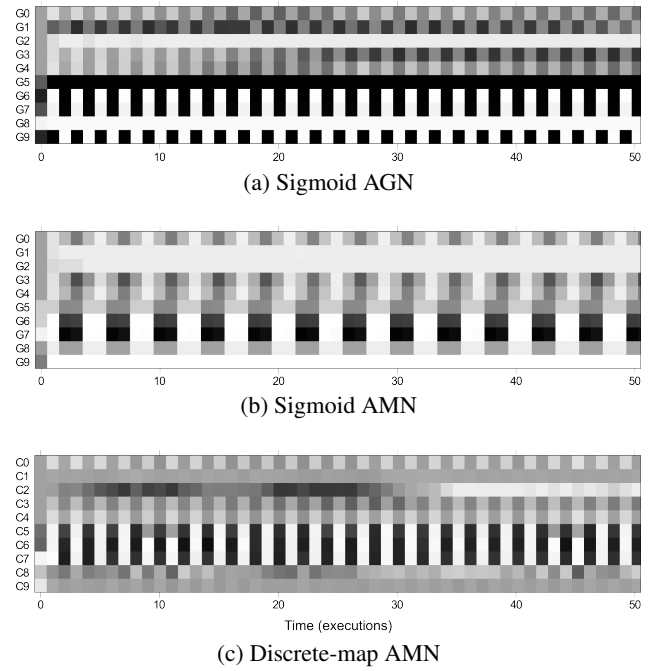

Figure 5: Time series plots of ABNs generating quadrupedal gaits. Actuator angles are input via the first four gene expression levels (G0–G3) or chemical concentrations (C0–C3), and new torque settings are read from the last four (G6–G9, C6–C9). White represents 0, black represents 1, greyscales represent intermediate values.

$$p(n) = \frac{d_n}{t_n} \left( 2 \frac{\eta_b(e_n, e_{n+1})}{\pi} - 1 \right) \left( 1 - \frac{\eta_w(e_n)}{\pi} \right) \sigma_n \quad (3)$$

where  $d_n$  is the distance travelled during epoch  $n$ ,  $t_n$  is the duration of epoch  $n$ ,  $\eta_b$  is the difference in mean heading between two epochs,  $\eta_w$  is the difference in heading within an epoch (as measured during the first and last 50 time-steps of the epoch), and  $\sigma_n$  is a penalty for non-movement: equal to 1 if the robot has not moved for 100 subsequent ABN updates in epoch  $n$ , and 0 otherwise.

In effect, progress is the mean velocity in the required direction, with penalties for turning during an epoch and for non-movement. Assuming movement in a straight-line and no stopping, fitness is equivalent to the expected distance covered during an epoch in the forward or backward direction, whichever is shortest.

**Experimental Settings** A population of 500 is used for this task, to reflect its greater difficulty. In addition to the four actuator angles, the ABN also receives a direction input. This has the value 0 during even-numbered epochs and 1 during odd-numbered epochs. In addition to delivering this signal with the actuator angles, for AGNs and CABNs we also look at the effect of delivering the signal separately through the first regulatory input of one or more genes.

Figure 6: Controlling direction and movement of legged robots. For each function set (or pair of function sets in the case of the coupled network), results for the best-performing combination of solution size and (for genetic and coupled networks) regulatory signal destination are shown. For the latter,  $g_0$  indicates that the control signal was delivered as a regulatory input to the first gene, all indicates that the control signal was delivered as a regulatory input to all genes.

Figure 7: Comparing the effect of delivering the direction signal to different locations within the Sig  $\mapsto$  Maps coupled network.  $gr_{all}$  indicates a regulatory input to all genes,  $gr_0$  is a regulatory input to the first gene,  $ge_0$  is the initial expression of the first gene, and  $c_0$  is the concentration of the first chemical.

**Results** Well-behaved controllers (i.e. those which correctly respond to the direction signal and produce effective gaits) generally have a fitness greater than about 1.5: those with lower fitnesses tend to have periodic or inconsistent behaviours.

Figure 6 compares the fitness distributions of evolved controllers, suggesting that most combinations of ABN model and function set choice do not lead to well-behaved controllers. In fact, the majority of evolved Sigmoidal AGN and AMN were only capable of movement in one direction, giving them a median fitness of zero. Discrete-map AGNs and AMNs achieved higher fitness, but generally did not respond to the direction signal, displaying a range of periodic

Table 2: Occurrence of discrete maps within final solutions from all Sig  $\mapsto$  Maps CABN runs where fitness is greater than 1.5.

Maps	In solutions	Mean occurrences per solution
Baker’s map	100%	2.3
Tunable standard map	78%	1.6
Standard map	78%	1.6
Tunable logistic map	72%	1.2
Arnold’s cat map	61%	1.5
Logistic map	50%	1.7

and aperiodic behaviours.

Notably, only coupled networks comprising a Sigmoidal AGN and a discrete-map AMN (denoted Sig  $\mapsto$  Maps) were able to consistently generate competent controllers<sup>1</sup>, and only when the direction signal was delivered as a regulatory input to each gene. Figure 7 shows the effect of delivering this signal to other locations within the Sig  $\mapsto$  Maps coupled networks; showing that delivering the direction signal via a gene’s initial expression or a chemical’s initial concentration was generally ineffective.

Figure 8 shows some representative examples of how these Sig  $\mapsto$  Maps networks control gait and respond to the direction signal. In most evolved networks, the AMN is responsible for generating appropriate patterns of actuator movements and the AGN is responsible for switching between different patterns by regulating the influence of different enzymes. It is interesting to note that their behaviour over time resemble the dynamics of biological biochemical networks, in that a slow-changing genetic network controls a fast changing metabolic network. This may also explain why Sigmoidal functions, which are more amenable to producing slow-changing dynamics, play a productive role within coupled controllers but not within the stand-alone AMN and AGN controllers.

We can hypothesise that there are two reasons why discrete maps are useful for this task. First, they can individually carry out behaviours which would require a number of interconnected Sigmoids to implement—to use a biological analogy, they are the equivalent of a whole biochemical pathway. Arguably, this entails that certain pattern generators can be evolved more readily than in a Sigmoidal network, and using fewer genes. Second, all the discrete maps we use have chaotic phases. When in this phase, their dynamics are highly sensitive to small perturbations, meaning that relatively small changes in gene expression can lead to rapid switching between different attractor states—precisely the behaviour we are looking for in many control tasks.

Table 2 lists the relative occurrence of the different dis-

<sup>1</sup> 18 of the 50 runs generated solutions with fitness greater than 1.5, compared to only a handful for all the other ABNs.

(a) In this example, the AMN generates a single cyclic pattern (C5) which is then scaled and propagated to the outputs (C6–C9). The scaling for each output (and hence the direction of the resulting gait) is determined by the current gene expression pattern.

(b) In this second example, the AMN generates two different cyclic patterns (bunny hopping and a four-legged wading movement), which the AGN switches between in response to changes in the direction signal.

Figure 8: Time series plots of Sig  $\mapsto$  Maps coupled ABNs controlling the direction and gait of a legged robot. The Signal input specifies the required direction of movement. GO–G9 are the expression levels of the genes in the AGN. C0–C9 are the concentration levels of the chemicals in the AMN.

crete maps in the final solutions of successful runs. All of the maps are used by evolution, with most of them appearing in the majority of solutions. The baker's map, in particular, appears in all of the successful controllers, and usually occurs multiple times in these solutions. Since the baker's map is a model of deterministic chaos, this supports our hypothesis that chaotic dynamics are useful. The standard map is also well-represented in evolved solutions, perhaps reflecting its relatively high degree of expressiveness and configurability. It is also notable that the tunable versions of the logistic and Chirikov's maps are often used.

## Conclusions

In this paper, we have shown that artificial biochemical networks can be evolved to control the locomotion of a simulated legged robot. We used two artificial biochemical network models—an artificial genetic network and an artificial metabolic network—and looked at how these models can be

used both individually and when coupled together.

For a simple movement task, where the robot was required to move as far as possible from its starting position, both individual and coupled networks could be evolved to generate suitable gaits. However, for a harder task, where the robot was required to reverse its direction of movement when given a signal, only coupled networks could be evolved to express suitable behaviours. Analysis of the resulting controllers suggests there is a clear separation of effort, with the artificial metabolic network generating patterns of actuator movements and the artificial genetic network switching between different patterns as appropriate.

We found that non-linear discrete maps play an important role in solving the harder of the two problems. When used as functional elements within artificial biochemical networks, these maps provide a useful source of configurable pre-packaged dynamics. Of the maps used in this study, the chaotic baker's map occurred most within evolved solutions.

This finding supports the idea that the inherent instability of chaotic maps makes them useful for rapidly switching between different behaviours.

We also found that the destination of the direction signal has a large effect upon the ability of the networks to solve the harder task. This may reflect the important role that signal recruitment plays within the evolution of biological biochemical networks. Rather than pre-specifying the destination of signals, as we have done in this work, in future work we will look at whether an artificial signalling network can be used to deliver signals to appropriate parts of the genetic and metabolic networks.

## Abstract

Although the emergence of communication has been the topic of various Artificial Life experiments, the study of underlying representational processes finds little discussion. We have previously differentiated between symbolic and indexical interpretation and proposed that symbolic interpretation may act as a shortcut to cognitive traits already acquired. Here we evaluate conditions of this acquired cognitive trait for the emergence of different modalities of sign interpretation. Results show that symbolic processes may act as a cognitive shortcut to a previous acquired cognitive competence even if minimally functional or initially not available.

## Introduction

Computational simulation approaches, such as Artificial Life experiments, are considered to have an important role in the study and modeling of general semiotic processes (see Christiansen and Kirby, 2003, Noble et al., 2010, Cangelosi and Parisi, 2001, Steels, 2003). Communication, vocabulary, grammar are among the processes that have been studied by this synthetic approach (for a review, see Nolfi and Mirolli, 2010, Wagner et al. 2003). In these experiments, semiotic processes are simulated in a social context, involving multiple agents. The process in focus is not pre-defined, but it rather emerges during and by means of agents' interactions. As the main form of interaction between agents, in most of these synthetic experiments, communication has, particularly, been a significant research subject. It depends on the production of representations (by an utterer) and the interpretation of them (by an interpreter). Nevertheless, we find little discussion around representation processes underlying communication such as the types of representations involved and how they can represent something to the agents. If agents communicate, the underlying representational processes are an essential issue to be addressed.

We have previously modeled the emergence of two different types of representational processes (symbols and indexes) and how they emerge in a community of simulated creatures (Loula et al., 2010a). We proposed that a symbolic interpretation process can act as a cognitive shortcut to a cognitive competence that is hard to acquire. Here we propose to assess further this hypothesis and evaluate

cognitive conditions to the emergence of interpretation processes, varying availability and reliability. We apply the same scenario previously used, which involves empirical constraints from studies of animal communication and also theoretical constraints from Peircean pragmatic theory of signs.

In the next section, we review related work in the context of the emergence of communication in Artificial Life research. Next, we briefly describe the theoretical principles and biological motivations that guided our experimental design. We then describe the experiment involving the emergence of different interpretational processes in communication events. Results are presented next, summarizing previous results and exhibiting news ones on the conditions for the emergence of sign interpretation. We discuss achievements and draw conclusions and future directions, in the end.

## Related work

The simulation of the emergence of communication is the topic of various works, but discussions on the underlying semiotic processes finds little space in such literature. Therefore, we will review two representative works that deals with the emergence of communication that are relevant in the context of this work.

Robots were evolved by de Greeff and Nolfi (2010) to execute a navigation task in which two robots had to exchange places in two target areas. The robots could use wireless sensors for an 'explicit signal' communication or they could use their spatial position as an 'implicit signal'. At the end of an evolution process of neural networks that control the robots, de Greeff and Nolfi (2010) described that the robots were able to use 2 or 3 explicit signals to execute the proposed task, but also used one implicit signal to achieve that. They state that explicit signals codify certain conditions in which the emitter robot finds itself and that the implicit signal is a visual perception of the position of the other robot, and that each signal produces a different reaction. Signals are said to be deictic, dependent of spatial-temporal context, but there was no further discussion on what and how robots representationally interpret such signals.

In an experiment with artificial creatures in a grid world, Cangelosi (2001) simulated the emergence of communication systems to name edible and poisonous mushrooms. He had relied on biological motivations to define a food forage goal for the creatures. He proposed the emergence of different modalities of representations in this experiment on the evolution of communication. To classify communication systems, Cangelosi (2001) differentiated signals, with direct relation with world entities, from symbols, also with relation with world entities but also related to other symbols. In his experiments, neural networks were both evolved and trained in various tasks, and, at the end, a shared communication system emerged, involving signals and symbols, according to Cangelosi. But he did not describe how these signals and symbols were interpreted by the creatures and what they actually represented.

Other works have also studied the emergence of communication traits and the acquisition of vocabulary or language among artificial agents (see Nolfi and Mirolli, 2010, Wagner et al. 2003). Nevertheless, we have not found works that have studied the emergence of different types of interpretations processes and differentiated the interpretation processes that emerged.

### Theoretical and Empirical Constraints

Synthetic experiments such as Artificial Life ones are heavily influenced by theoretical principles and biological motivations, and that such background should be an essential part of any synthetic experiment (Parisi, 2001, see also Noble 1997, Loula et al., 2010b). Theoretical principles and biological motivations act as requirements and constraints during the design of the experiments, and influences modeling on different degrees depending on how it constrains the model being built and what decisions it leaves to the experimenter.

To model the emergence of communication processes based on different types of representation, it is certainly important to look at theoretical models and principles, and also look for biological motivations, and avoid arbitrary or naïve assumptions about the underlying processes.

Sign-mediated processes, such as the interpretation of representations in communicative contexts, show a remarkable variety. A basic typology (and the most fundamental one), proposed by Peirce (1958; see Short 2007), differentiates between iconic, indexical, and symbolic processes. Icons are signs that stand for their objects by a similarity or resemblance, no matter if they show any spatio-temporal physical correlation with an existent object. In this case, a sign refers to an object in virtue of a certain quality which is shared between them. Indexes are signs which refer to their objects due to a direct physical connection between them. Since (in this case) the sign should be determined by the object (e.g. by means of a causal relationship) both must exist as actual events. Spatio-temporal co-variation is the most characteristic property of indexical processes. Symbols are signs that are related to their object through a determinative

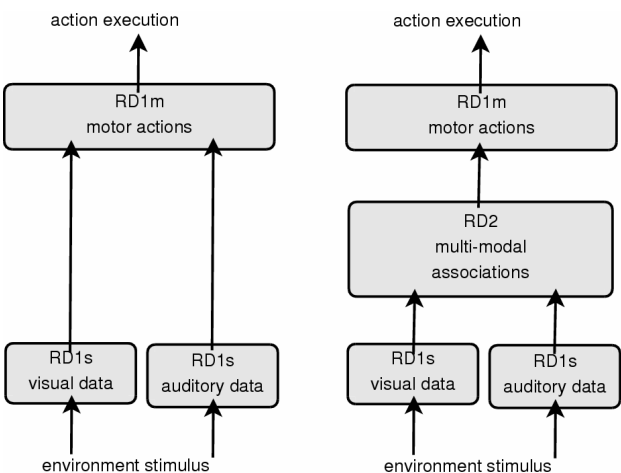

Figure 1: Cognitive architectures for representations interpretations. Left: Type 1 architecture, RD1s are connected directly to RD1m. Right: Type 2 architecture, data from visual RD1s and auditory RD1s can be associated in RD2 before connecting to RD1m.

relation of law, rule or convention<sup>1</sup>. A symbol becomes a sign of some object merely or mainly by the fact that it is used and understood as such by the interpreter, who establishes this connection.

Communication is a process that occurs among natural systems and as such we can employ empirical evidences on building our synthetic experiment. Animals communicate in various situations, from courtship and dominance to predator warning and food calls (see Hauser, 1997). And following Peirce’s definition of symbols, many animals can actually be capable of communicating by means of symbols (Ribeiro et al., 2007).

To further explore the mechanisms behind communication, a minimum brain model can be useful to understand what cognitive resources might be available and process underlining certain behaviors. Queiroz and Ribeiro (2002) described a minimum vertebrate brain for vervet monkeys predator warning vocalization behavior (Seyfarth et al 1980). It was modeled as being composed by three major representational relays or domains: the sensory, the associative and the motor. According to such minimalist design, different first-order sensory representational domains (RD1s) receive unimodal stimuli, which are then associated in a second-order multi-modal representation domain (RD2) so as to elicit symbolic responses to alarm-calls by means of a first-order motor representation domain (RD1m).

Our objective is to model the emergence of indexical and symbolic interpretation competences, so the first step is to specify the requirements for each and also how to recognize each of them in the experiment. Indexical interpretation is a reactive interpretation of signs, such that the interpreter is directed by the sign to recognize its object as something spatio-temporally connected to it, so for our creatures to have

<sup>1</sup> Differently from Cangelosi’s (2001) definition of symbol, based on Deacon’s approach (1997), Peirce (1958) did not require symbols to be related to each other to be called symbols.

this competence, they must be able to reactively respond to sensory stimulus with prompt motor answer. In the minimum brain model, this corresponds to an individual capable of connecting RD1s to RD1m without the need for RD2. But a symbolic interpretation undergoes the mediation of the interpreter to connect the sign to its object, in such a way that a habit (either inborn or acquired) must be present to establish this association. Thus, in symbolic interpretation, RD2 must be present once it is the only domain able to establish connections between different representation modes. Thus, our artificial creatures must be able to receive sensory data, both visual and auditory, in its respective RD1s, that can be connected directly to RD1m, defining motor actions (Type 1 architecture), or connected to RD1m indirectly, through the mediation of RD2, that associates auditory stimulus to visual stimulus acting as an associative memory module (Type 2 architecture) (see figure 1). To evaluate what conditions might elicit each response type – indexical or symbolic –, we implemented these two possible cognitive processing paths as mutually exclusive paths: either the creature responds to auditory events indexically and reactively responds with motor actions, or the creatures responds to auditory events symbolically and associates them with a visual stimulus and responds as if that was really seen. For an external observer, who only watches the information available to the creature and its motor responses, it may not be possible to see changes in the interpretation process. But the underlying mechanisms behind each semiotic process are qualitatively different.

### The experiment

The scenario to test the conditions for the emergence of semiotic processes is inspired by food foraging behavior of animals. One way animals cooperate in such task is by vocalizing for food quality, recruiting other group members to feed. Inspired by such biological motivation, we simulate a scenario of artificial creatures evolved to collect resources in a virtual environment.

Lower quality resources are scattered throughout the environment and a single location receives highest quality resources. One creature (vocalizer) is placed in this high quality resource position, vocalizing a sign continuously. At the start of simulation, the other creatures (interpreters) do not know how to respond appropriately to sensory inputs and neither recognizes the sign vocalized as a sign. But an evolutionary process of variation and selection is applied, allowing the evolution of individuals to better accomplish the task of resource foraging. During the evolutionary process, for each start-up conditions, we observe the emergence of indexical or symbolic interpretation for the vocalizations.

The environment is a 50 by 50 grid world (figure 2) and there are 20 random positions with only one resource unit each. There is also one position with 500 resource units, where an immovable vocalizer creature is placed. The vocalizer's sole behavior is to produce a single vocal sign, reproduced at every instant. Fifty interpreter creatures are randomly placed in this grid.

Interpreter creatures are capable of visually sensing food up to a distance of 4 positions and sensing vocalizations up to a distance of 25 positions. This sensory range difference models

Figure 2: The grid environment. Creatures are blue circles, low quality resource positions are in green cells, and high quality one in the cyan cell in the center.

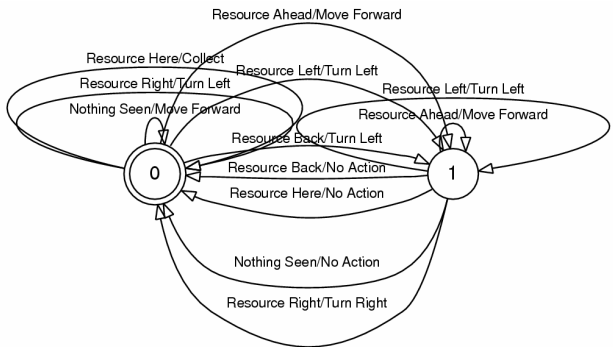

Figure 3: State diagram of a sample FSM that controls the creatures. The circles are states and a double circle marks the start state. Arches represent transitions and are labeled according to the sensory event and the action to take over when that event occurs. This FSM has only visual inputs and 2 states to simplify the diagram, but there can be more arches for auditory inputs (vocalization and its position) and up to 4 states.

an environment where vision is limited by the presence of other elements such as vegetation, restraining far vision such as in an open field. These creatures can either see a resource and its position or hear a vocalization and its position, if any of them is within range.

Interpreters are controlled by finite state machines (FSM), with up to 4 states (see figure 3). An FSM was chosen as the control architecture because the analysis of how it is functioning is quite simple and direct, permitting direct identification of the processes underlying the creatures' cognition. Input events to the FSM include 5 visual events for resource in 5 different positions (ahead, left, right, back, or same position), 4 auditory events for vocalization in 4 positions (ahead, left, right, back), and 1 event for nothing seen or heard. Outputs from FSM can be one of the 5 motor

actions for creatures: move forward, turn left, turn right, collect resource, or do nothing.

The creatures can respond to visual inputs with one of the motor actions, and can also respond to auditory input with a direct motor action (a reactive, indexical process) (Type 1 architecture). Alternatively, before an input is sent to the FSM, they can also choose to establish an internal association between the heard stimulus and the visual representation domain (Type 2 architecture). This internal association links what is heard with the view of a collectible resource, i.e. the creature can interpret the sign heard as a resource and act as if the resource was seen. As a result, an auditory input is exchanged by an equivalent visual input and the FSM is executed with that input. Additionally, the creature may also ignore the sign heard, interpreting it as nothing and acting as if no sensory data was received.

At start, creatures are controlled by randomly constructed FSMs, and are all placed at random in the environment. They are allowed to collect resources for 10 trials of 100 iterations each trial. Creatures collect resources by executing the specific action, removing one unit from the resource at each time step. When no more units are available at the resource, it disappears.

### Creatures evolution

At the all trials, the 10 best creatures in the foraging task (those that collected the most resource units) are selected to create next generation. These 10 individuals are copied to the next population and the 40 remaining individuals are a product of mutations and crossovers of the FSMs of the best individuals.

The mutations can be of changing an action in transition, changing the next state after a transition, changing the start state, add a state and remove a state. There can also be a mutation of the cognitive architecture type, as described below. The number of mutations is selected from a Poisson probability distribution with an expected value of 3. The crossover has a 50% chance of occurring and it exchanges states and transitions originating from the selected states between two FSM in a uniform way. All FSM undergo a correction process to fix error that might occur during these operations, such as a transition pointing to a non-existing state.

The experiment runs for 500 generations, normally with two distinct moments. In the first 200 generations (cycle 1), the vocalizer creature is not present and interpreters do not have an auditory sensor, but this first cycle will be omitted in one of the simulation scenarios. In the 300 subsequent generations the vocalizer creature is present and interpreters are able to hear (cycle 2).

At the start of cycle 2, all creatures are set to ignore the vocalizations, as if it was not relevant, however, there is also a small mutation probability for changing the type of response to vocalizations. These can be of reacting to them by moving towards the resource, or to linking it with the view of a resource. This corresponds to a change to a Type 1 cognitive architecture (indexical) or to a Type 2 cognitive architecture

(symbolic). The probability of going from Type 1 architecture to Type 2 architecture is lower than the other way around to simulate the fact that such a significant cognitive change is not that easy to happen.

We expect that creatures adapt to the foraging task by responding to the auditory input of vocalizations. Since they can not see the high quality resource position, they must rely on the vocalization to guide their movements in this direction. We are interested in observing the overall adaptation process to the foraging task, and are specially focused on the type of interpretation process, related to the cognitive architecture type, that might result.

## Results

In previous work, we have run two initial experiments to evaluate the emergence of either an indexical interpretation or a symbolic interpretation of vocalizations (Loula et al., 2010a). Such experiments involved 2 cycles as described above, varying the way motor actions needed to be coordinated. In the first experiment, creatures just had to have the specified action as output of the FSM to execute that action. In this scenario, we observed that indexical interpretation was the competence acquired by creatures to deal with communication, with direct association between auditory signs and motor actions. But in a second experiment, for motor actions to be executed, the creatures needed to first output a null action before any movement action, that way it would be harder to learn motor coordination. In this alternative scenario, symbolic interpretation was the emerging competence, instead of an indexical one like it happened in the previous case. We made the hypothesis that acquiring symbolic competence would act as a *cognitive shortcut*, by reusing a previously acquired ability in cycle 1: to appropriately respond to visual data with motor actions. We proposed that a symbolic interpretation process can happen if a cognitive trait is hard to be acquired and the symbolic interpretation of a sign will connect it with another sign for which the creature already has an appropriate response.

### Single cycle scenario

In face of the fact that there should be a previously acquired competence for symbolic interpretation to benefit from, a subsequent question is to ask what would happen to sign interpretation if such previous competence is not present. If the creature does not respond in a proper manner to visual input, a cognitive shortcut to this uncoordinated competence would not help the foraging success. As cycle 1 acts as a first step in which creatures are dedicated to learn visual-motor coordination, we removed this cycle in a new scenario, in which the simulation begins in cycle 2 with the vocalizer at the center and interpreter creatures able to hear but starting with random FSMs. The need to first output a null action before any movement action remains, so it is hard to learn motor coordination. Figure 4 shows the performance of creatures in foraging and the type of interpretation used.

Figure 4: Evaluation of foraging task and type of response to vocalizations along the generations for the one cycle only experiment.

Figure 5: Evaluation of foraging task and type of response to vocalizations along the generations for the 20% failure experiment.

Figure 6: Evaluation of foraging task and type of response to vocalizations along the generations for the 50% failure experiment.

As we can see from the graphs, the experiment had three phases. At first, no resources were collected and creatures opted to ignore signs produced by the vocalizer. Then there was a transition phase, where the amounts of resources increased rapidly along generations and creatures gave up ignoring signs and started an indexical interpretation of them. Then creatures turn to a symbolic interpretation of sign and the amount of resources collected further increases and then stabilizes. To better understand what happened in such transitions, the FSMs of creatures have to be further detailed.

From the first generation until generation 25, creatures did not demonstrate any motor coordination and were not able to collect resources, and *most creatures just ignored signs*. In generation 26, one creature was able to move forward and collect when a resource was in front of it, but it still ignored signs.

This remained the same until generation 39, where one creature was able to turn right when a resource was seen at right side, and this creature was also *responding indexically to signs*, by going towards the vocalizer when a sign was heard in front of it. By generation 40, half of the population is interpreting signs indexically and the other half is ignoring it. Most of the creatures could move towards a seen resource, but there were still some useless outputs from the FSM, state/transition combinations that would make a creature stop responding effectively, and they still would not move when nothing is seen.

At generation 44, one creature starts *interpreting signs as symbols*, relating the sign heard with the view of a resource, able to collect 67 resource units, while the best performing creature collected 77, but interpreting signs as index. Nevertheless, creatures still had problems in motor coordination. By generation 46, half of the creatures were symbolically interpreting signs, and by generation 50, almost all of them did so. From there on, all 10 best performing creatures used symbolic interpretations (and most of the others too), and the number of collected resources increased rapidly as creatures acquired a best performing FSM, that would always respond effectively to the inputs received.

So even though, there was no cycle dedicated to acquire a previous competence that could be re-used by a symbolic interpretation, the evolution process allowed first for visual-motor coordination to appear before sign interpretation (either as index or symbol) started. Thus, there was at least a little visual-motor competence to be re-used by symbolic interpretation.

### Cognitive module malfunction scenario

To further evaluate the way symbolic interpretation acts as a cognitive shortcut, we set up one more scenario. Since there is re-use of a previous acquired cognitive competence, we tested how reliable should this competence be for this new symbolic process to connect to it. The scenario is similar to the one above, but we brought back cycle 1 before cycle 2, so the creatures had time to acquire visual-motor coordination. However, in this reliability test, we introduced a failure chance in the visual-motor coordination after cycle 1, simulating a malfunctioning cognitive module. Given an output from the FSM in response to a visual input, this output (an action) would have a chance of changing to a different

one. If the input is 'Resource Left' and the output from the FSM is 'Turn Left', for example, it could be changed to 'Turn Right'. Outputs that are responses to auditory inputs are not subject to such changes. This way visual-motor coordination would be defective and processes relying on it would be jeopardized.

The first simulation of this malfunctioning in visual-motor coordination applied a 20% chance of output change. The results are presented in figure 5. Compared to a previous experiment with 2 cycles but no malfunction (Loula et al., 2010a), it is possible to notice that the number of collected resources during cycle 1 is similar in both experiments, but in the second cycle it is quite different: while in the previous experiment the best creature collected between 500 and 600 units, in this unreliable module experiment, the best creature collect only around 300 units. This shows that the foraging efficiency has dropped down with the imposed malfunctioning. Looking at the type of response, signs ended up having a *symbolic interpretation*, thus the unreliable visual-motor connections were in fact reused, despite the fact that it was not an efficient module. Comparing with the cited previous experiment, the interpretation type graph is quite similar.

Taking a closer look at simulation outcome, results show that from generation 200 to 210 the foraging performance did not improve. Initially creatures ignored signs, but by generation 202, a few creatures start trying to respond to signs in an indexical manner. These creatures with type 1 architecture, nevertheless, are not able to move towards the vocalizer and still rely in the defective visual-motor coordination. In generation 208, almost all creatures are ignoring signs again.

By generation 210, a symbolic interpreter appeared and it was able to collect more than 200 resource units. Even though visual-motor coordination was degraded, it still performed better than the random actions of a creature trying an indexical response. From this generation on, the number of creatures *interpreting signs symbolically* increased and, by generation 218, almost all creatures followed this type of interpretation.

To further test the effects of a malfunctioning of a cognitive module, the chance of changing actions was increased to 50% in a new simulation, with the expected effect of turning the visual-motor coordination so unreliable that its reuse would be not be possible. Results of this simulation are shown in figure 6.

In this new simulation run, we observe that after cycle 1 the number of collected resources dropped considerably more, to about half of the amount at the end of cycle 1. This was expected since the creatures are using a quite defective control model that is not able to cope with the task of foraging resources efficiently anymore.

Until around generation 250, creatures had this bad performance, but in the meanwhile sign interpretation was varying from ignoring signs to indexical response. The best performing creatures were most ignoring sign, though, indicating that indexical interpreters were not able to successfully respond to signs. One or two creatures with symbolic response were created but disappear right after as its performance was not consistent, due to the dependence on visual-motor coordination.

At generation 258, there appeared a creature with *indexical interpretation*, able to collect 210 resource units. This creature was able to effectively respond to signs by going towards the vocalizer when it was located ahead or to the left. Therefore, this indexical interpreter was able to rely on a direct connection between auditory input and motor actions, and avoided using the faulty cognitive module. The number of collected resource units along generations increased fast, and the best creature (an indexical interpreter) on generation 270 was collecting almost 600 resource units and this performance was consistently kept until the end of simulation. Notice that if we compare the efficiency of creatures in the 20% failure chance simulation with this 50% failure chance simulation, it is clear that even though the second simulation had a worst damage to the visual-motor module, it was able to achieve better performance at the end.

## Discussion

In this paper, we continue investigating conditions for qualitative different interpretation processes to emerge in a communicational context. Previous results showed that symbolic interpretation can emerge when the appropriate motor coordination is a hard skill to acquire, and therefore symbolic processes can act as a cognitive shortcut, mapping auditory signs to visual input and reusing visual module mapping to motor actions. Here we test other conditions for this cognitive shortcut to be established.

First we removed the first cycle, when creatures were allowed to acquire visual-motor coordination, which could be reused through a cognitive shortcut. Consequently, adequate auditory and visual responses needed to be acquired at the same time. From this single cycle experiment, it is possible to observe that even though the vocalizer and the hearing sensor were available from start, creatures did not use signs at all in a first moment. It was necessary to first have minimum visual-motor coordination for signs to start being interpreted by creatures. Indexical interpretation was the first attempt as a response to signs. As trying to acquire visual-motor coordination and also a sign-motor coordination is a tough route, the symbolic interpretation diminished this effort and became the dominant strategy.

To further evaluate the cognitive shortcut stability, we imposed a variable malfunctioning to the visual-motor connections. At first, a 20% of changing actions specified by the visual module still conducted to the establishment of symbolic processes, with reuse of a degraded module, but that still allowed a relative increase in foraging efficiency. A higher failure of 50% proved to worsen the performance of the visual control module considerably more, and allowed indexical interpretation of sign to be established, as a way to avoid reusing it. And, even though symbolic processes were established in the 20% failure scenario, it seems that creatures got trapped in a 'local maximum' performance, as the foraging efficacy of creatures in the 50% failure scenario was much better.

## Conclusion

Communication necessarily involves an utterer, who produces a sign, conveyed to an interpreter, in whom the sign produces its effect. And signs can be of different types according to the way it is connected during interpretation process to its referent. We proposed that, for two types of signs – indexes and symbols – to be interpreted, different cognitive paths had to be followed, one with direct mapping of signs to motor actions (indexical interpretation) and another one with a mapping of signs into another representation form (symbolic interpretation) and then to motor actions.

We proposed that a cognitive shortcut can be established by symbolic interpretation processes, by establishing bridges to reuse previous acquired competences. We confirmed here that the cognitive module to which the symbolic interpretation is connecting to must be already established, otherwise there is no advantage in such connection. But it does need to be fully functional, as minimal visual-motor coordination is sufficient to begin a symbolic interpretation process, according to the single cycle experiment, and even a moderately damaged module can also be reused as a cognitive shortcut.

Even further investigations on differentiating indexical and symbolic processes have to be done. Other aspects and conditions should be tested to better understand what leads sign interpreters to each of them, for example, how can an agent handle both of them at the same time or how does other cognitive competences influence this process. We expect that the discrimination of these semiotic processes and the cognitive apparatus necessary for each of them will bring forth more discussion on representation process in experiments on the emergence of communication and language.

## Abstract

As part of our research on <programmed self-decomposition>, we formed the hypothesis that originally immortal terrestrial organisms evolve into ones that are programmed for autonomous death. We then conducted simulation experiments in which we examined this hypothesis using an artificial ecosystem that we designed to refer to a terrestrial ecosystem endowed with Artificial Chemistry (ACChem). Our findings suggest that, in the case of a mortal organism appearing among a population of immortal organisms as a mutant which evolutionarily acquires a genetic program for death by means of self-decomposition, this organism and its surviving offspring surpass immortal organisms and eventually prosper with adaptive divergence under various environmental conditions within a certain probability.

## Introduction

We modeled autonomous death, which is the significant and universal attribute of terrestrial life, as <programmed self-decomposition> (Oohashi, et al. 1987, 2009). Our research has proceeded through a series of studies that look into the existence of autonomous death by means of experiments in the field of molecular cell biology with existing living organisms as subjects; concurrently, by means of evolutionary simulations of Artificial Life (ALife), we raise the possibility that mortal organisms having autonomous death are superior to immortal organisms (Oohashi, et al. 1987, 1996, 1999, 2001, 2009, 2011).

Throughout this study, we take note of the fact that mortal organisms endowed with programmed self-decomposition are more complex than immortal organisms in both structural and functional aspects, and that the former can better increase the prosperity of their offspring than the latter can. Therefore, we formed the hypothesis that [originally immortal terrestrial organisms evolved into ones capable of autonomous death.] We then conducted a preliminary investigation using an artificial ecosystem SIVA-III (Oohashi et al. 1996) of our own design and obtained results that suggest the robustness of our hypothesis (Oohashi et al. 2001).

Thereupon, we constructed a more sophisticated model for a more detailed investigation making use of an artificial <ACChem> ecosystem SIVA-T05. The essential questions we sought to answer are as follows: Would an individual mortal organism, overwhelmed by immortal organisms, become extinct, or could such an individual survive and produce

offspring? If it survived and produced offspring, what kind of power relationships would be established between such mortal organisms and the immortal ones?

Our findings suggest that a mortal organism, born among a population of immortal organisms, cannot reproduce and becomes extinct in many cases. Nonetheless, a number of mortal organisms did manage to survive at a small but significant rate. Moreover, once a mortal organism survives, it extends its habitation area, surpasses immortal organisms and prospers without exception. This paper provides details of the above findings.

## Methods

### 1) Programmed Self-Decomposition Model

We previously designed “Programmed Self-Decomposition (PSD) Model” (Oohashi, et al. 1987, 2009) based on a hypothesis concerning death universally observed in terrestrial life. This hypothesis is summarized below since it constitutes the framework of the current study, which examines the acquisition of death. The terrestrial ecosystem forms a nearly closed system in that both its space and substance are limited. Accordingly, to maintain the stability of terrestrial life activities, the space and substance of the environment used by life activities have to be returned to the environment. That is to say, the ecosystem must return to its original state. The mechanism for restoring the terrestrial ecosystem has conventionally been explained by the principle of biological circulation called the food chain (Odum, 1971), which is a biomolecular recycling mechanism for terrestrial life. We set forth a new hypothesis complementary to that of the food chain. In our view of the terrestrial ecosystem, besides the restoration of the environment due to the food chain, another hidden mechanism is fundamentally built into every life individual, by which it autonomously decomposes itself so as to contribute to the restoration of the environment. We regard the phenomenon of decomposition based on the life individual’s own effort, called self-decomposition, to be a controlled biochemical process of returning the substance and space that that individual possesses to the environment for the purpose of restoring the environment to its original state. We call this programmed self-decomposition (PSD) (Oohashi, et al. 1987, 2009). We posit that the effect of the mechanism of self-decomposition does not directly accord benefits to the

Figure 1. Von Neumann's self-reproductive automaton and Oohashi's self-reproductive, self-decomposable automaton.

(A) Von Neumann's self-reproductive automaton model. This is an immortal type model without an autonomous mechanism for the restoration of the environment to its original state. (B) Oohashi's self-reproductive, self-decomposable (SRSD) automaton model. This model uses von Neumann's self-reproductive automaton model as its prototype. It has a programmed mechanism contributing to the restoration of the environment to its original state through autonomous individual death with self-decomposition, which is an essential feature of terrestrial life. Two activation modes are defined for the self-decomposition automaton FZ. The first one is activated by a signal input from outside, indicating unconformity between the life and its habitation environment. The second mode constitutes the end of the life span.

decomposing individual itself, but rather it enhances benefit to the species sharing its genetic lineage as well as to the ecosystem as a whole. It is necessary to conduct experiments to determine whether such a phenomenon is evolutionarily selected or not. We have developed a self-reproductive, self-decomposable (SRSD) automaton, on the basis of which we have been examining the PSD model, using von Neumann's self-reproductive automaton model (Neumann, 1951) as a prototype (Figure 1) (Oohashi et al., 1987, 2009).

## 2) Architecture of SIVA-T05

We developed a virtual ecosystem series SIVA (Oohashi, et al. 1996, 2001, 2009) configured with Oohashi's SRSD automaton installed in a finite, heterogeneous environment consisting of virtual biomolecules having chemical reactivity. Since constructing SIVA-III, a pioneering prototype for an AChem system, in 1996 (Oohashi et al. 1996), we have continued to develop SIVA as a virtual ecosystem based on AChem. To promote the main purpose of AChem, namely, the achievement of a closer relationship with existent terrestrial life, SIVA-T05, a new version of SIVA, has been developed to have a biomolecular hierarchy, as put forth in Network Artificial Chemistry (Suzuki, 2004), which is an AChem system that succeeds in simulating molecular conformation and reactivity by arranging the strength of cohesion between elements into a hierarchy. SIVA-T05 was adopted as a simulator in this paper.

**A) Environmental Design of SIVA-T05.** To simulate the characteristics of a terrestrial environment with limited amounts of materials and energy distributed in a finite space, the virtual space of SIVA-T05 is designed to be a two-dimensional lattice consisting of 16 x 16 (= 256) spatial blocks. A single spatial block is defined as 8 x 8 (= 64) pixels for habitation points. One habitation point is occupied by one virtual life individual (VLI) and vice versa [Figure 2(A)]. Environmental conditions can be independently defined for each spatial block, and those of the 64 habitation points in the same spatial block are configured to always be homogeneous. VLIs change the quantity of available substances in the environment by importing them into their bodies as materials for self-reproduction and by exporting them through self-decomposition. Since all VLIs in one spatial block share the same environmental conditions, the population of VLIs in that block significantly affects local conditions. Consequently the divergence of local environmental conditions across the whole ecosystem is gradually emphasized along with the proliferation of VLIs, as would also occur in a terrestrial ecosystem.

The temperature gradient and the initial distribution of virtual energy and four kinds of virtual inorganic biomaterials (see the next section) consisting of VLIs are heterogeneous across the whole ecosystem as shown in Figure 2 (B). No substances other than virtual inorganic biomaterials exist in the initial environment. To simulate the effects of solar energy and its

Figure 2. Environmental conditions of the virtual ecosystem SIVA-T05 are designed to be finite and heterogeneous. (A) Spatial design. The virtual space of SIVA-T05 is a two-dimensional lattice (B) Spatial distribution of environmental conditions. Left: Distribution of environmental temperature. Initial distribution of energy stocked in each spatial block. Right: Initial distribution of four kinds of virtual inorganic biomaterials (VI). Each substance flows between adjacent spatial blocks to restore the environment to the initial condition when the amount of a substance goes above or below that of the predetermined level.

diffusion and radiation in the terrestrial ecosystem, a predefined amount of energy per time unit is refilled, and the total amount of energy in each spatial block must not exceed a predetermined threshold. The amount of refilled energy and the upper limit of total energy are set at appropriate levels so that a simulation does not become meaningless, that is, not so small that no VLI can live stably and not so large that all VLIs can always live without any failure.

**B) Design of Virtual Life in SIVA-T05.** In SIVA-T05, we have designed a new type of virtual life based on the hierarchical biomolecular covalent bond (HBCB) model (Oohashi et al. 2009). Table 1 shows the design of the hierarchical structure of virtual biomolecules based on the complexity of the interatomic network of actual biomolecules that compose terrestrial life.

Virtual biological polymers (VPs) and virtual biological monomers (VMs) are categorized into two groups: the functional module group and the constitutive information group, which in terrestrial life correspond to the phenotype and the genotype respectively.

Basically each substance in a certain class consists of several elements belonging to the next lower class. For example, a virtual organic biomaterial (VO) consists of several virtual inorganic biomaterials (VIs), and a VM consists of several VOs. Several VMs constitute a functional unit, which is a subclass of its VP class, and several functional units constitute a larger VP. In the present simulation experiments, we designed five VMs as a single functional unit. A functional unit serves as one word in the SIVA language in the functional module group and also constitutes a virtual codon (Vcodon) in the constitutive information group. Oohashi's SRSD automaton is installed as an artificial life form in SIVA-T05 (Figure 3). The VLI consists of a virtual genome and functional automata. The virtual genome is a VP of the constitutive information group and corresponds to instruction

tape I in Figure 3, whereas the functional automata are VPs belonging to the functional module group and correspond to automata A, B, C, and FZ in Figure 3. The virtual genome encompasses the functions of preservation, replication, and transcription of structural and functional information about a VLI, while the functional automaton encompasses various life activities of the VLI, such as synthesis, decomposition, and reproduction.

The virtual genome consists of a sequence of four kinds of VM (W, X, Y, Z in Table 1) corresponding to the nucleotide in terrestrial life (Figure 3). In the virtual genome, five VMs constitute a functional unit, which serves as a Vcodon. Namely, each Vcodon is defined as corresponding to one of 18 kinds of VM (I, J, K, L; O, P, Q, R; 0–9 in Table 1) of the functional module group (i.e., virtual amino acid: VAA). The sequence of Vcodons defines the sequence of the VAAs in a functional automaton. The sequence information regarding all automata is described in the virtual genome. For the reproduction of a VLI, automaton B replicates the whole virtual genome, and automaton A synthesizes a functional automaton. Mutation can occur in either of these processes.

SIVA-T05 executes the functions of the automata described by the SIVA language as an interpreter by which life activities of VLIs are expressed. First, a functional unit consisting of a sequence of five VAAs serves as a <word> in the SIVA language. A <word> can be categorized as a functional word, which serves as an executable <command>, or as a temporary information word (Table 1). A <command> as a functional word covers a substantial part of the life activities of a VLI. One or more words constitute a <sentence>, which has to include zero or more <command>s and one <period> at the end. Before a <command>, a <sentence> can include one or more conditional phrases. When there is no conditional phrase in the <sentence>, <command>s are directly executed in the order described in the <sentence>. If a <sentence> includes any conditional phrases, a <command> is executed only when

Table1: Hierarchization of virtual biomolecules composing virtual life based on the complexity of the inter-atomic network.

Class name	Functional module group		Constitutive information group
Virtual biological polymer (VP)	Polymerized functional units		
<i>Functional unit</i>	Functional word (command)	Temporary information word (variable, relational operator etc.)	Virtual codon
Virtual biological monomer (VM)	O P Q R(4 kinds)	I J K L 0 1 2 3 4 5 6 7 8 9 (14 kinds)	W X Y Z(4 kinds)
Virtual organic biomaterial (VO)	A B C D (4 kinds/upper-case letter)		
Virtual inorganic biomaterial (VI)	a b c d (4 kinds/lower-case letter)		

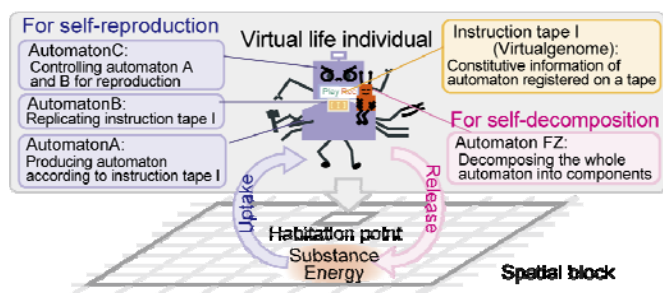

Figure 3. Relationship between life activities of virtual life individuals (VLIs) and the environment in SIVA-T05. Oohashi's SRSD automaton is implemented in the VLI in SIVA-T05. Each VLI consists of functional automata for self-reproduction [D (=A+B+C)], those for self-decomposition [FZ], and an instruction tape [ID+FZ] (i.e., a virtual genome) that is a blueprint of all the automata. Automaton A produces all the functional automata described in the virtual genome. Automaton B replicates the virtual genome. Automaton C constitutes a daughter VLI, combining the automata newly synthesized by automaton A and the virtual genome replicated by automaton B, and divides it from the parental VLI. Automaton FZ decomposes a VLI when the VLI encounters environmental conditions unsuitable for survival or when it lives out its life span. A VLI can reproduce itself by the uptake of substances and energy existing in the spatial block to which its habitation point belongs. During self-decomposition, the substances and the energy generated by the decomposition of virtual biomolecules constituting the VLI are restored to the spatial block. The occupied space is also released for utilization by another VLI.

all the conditional phrases are true but not when any of the conditional phrases is false. On the basis of these rules, a VLI can be programmed to undergo individual division when all conditions are satisfied, and to decompose itself when unfitness for its environment exceeds threshold level, etc.

Each VLI expresses its life activities by executing all <sentence>s during one time count (TC), the unit of virtual time in SIVA-T05. The order in which a VLI in the virtual ecosystem expresses its life activities within one TC is randomly determined at every TC. It takes at least 5 TCs for a newborn individual to reproduce itself in our current simulation experiments. Therefore, we use <passage duration> as a virtual time unit, which corresponds to the value of TC divided by 5.

When a VLI reproduces itself, it chooses a habitation point for a newborn VLI adjacent to its own habitation point. If the life activities of a newborn VLI fit the environmental conditions in the habitation point, it can also reproduce itself. If such activities do not do so, the newborn VLI decomposes itself prior to reproduction. Since certain mutations may accumulate as generation changes recur, certain offspring may emerge whose life activities fit environmental conditions differing slightly from those existing for their parents. Consequently, VLIs increase or decrease the size of their habitation point. (Oohashi et. al., 2009)

### 3) Experimental conditions

First, we designed a VLI of a mortal organism with a genetic program for death. This VLI has Automaton A, B, C and FZ as described in Figure 1 and 3, an initialization Automaton that produces the initial setting of the VLI, and a virtual genome corresponding to these Automata. On the basis of the PSD model (see Figure 1), the Automaton FZ, the mechanism for death, was designed to be activated when either of the following conditions is true: (1) unconformity between the VLI and its habitation environment or (2) the end of the life span of the VLI. We took advantage of this mechanism to design a VLI of an immortal organism, of which the value of both the conditional phrases of SIVA language for Automaton FZ were kept unchangeable at a false value and accordingly the functional words in SIVA language for self-decomposition in the FZ automaton were kept unchangeable at an inactivated state. If a mutation occurs in one of these conditional phrases and the value of either conditional phrase becomes changeable, it means that a mortal VLI is evolutionarily born. The functional words in SIVA language for self-decomposition of the mutant VLI will become activated, and the VLI will decompose itself when the above conditions become satisfied during the life of the VLI.

We seeded a single VLI that possessed this precursor of a genetic program for death in the center habitation point of the ecosystem with suitable environmental conditions and then conducted simulations of reproduction and evolution.

In the present simulation experiments, mutation of virtual genomes randomly occurs at the probability predetermined as a mutation rate. We investigated three mutation rates as follows: 0.005, 0.002 and 0.001. Mutation rates of the existing terrestrial lives are distributed from 10<sup>-4</sup> to 10<sup>-10</sup>. There is a tendency for a living organism with a small genome to exhibit a large mutation rate. For example, an organism with a genome of 104 molecules has a 10<sup>-4</sup> mutation rate. Virtual genomes of the VLIs in the present simulation experiments consist of 1275 molecules of VM, so we think the above configured mutation rates are within an appropriate range.

Consequently, we conducted 200, 500 and 800 simulations at mutation rates of 0.005, 0.002 and 0.001, respectively. The simulations were of 800 passage durations. Changes in size of the habitation area, number of individuals, and frequency of mutation were observed.

## Results

The rates at which mortal organisms evolutionarily emerged and survived are shown in Table 2. The denominators are the number of simulation trials including many cases in which no valid mutation occurred or no VLI of a mortal organism emerged within the 800 passage durations. The rates are 3.5%, 1.4%, and 0.25% for mutation rates of 0.005, 0.002, and 0.001, respectively. That is to say, when the genetic program for death was evolutionarily acquired, the individual possessing the program and its offspring did not always become extinct and survived within a certain probability.

When a VLI of a mortal organism survived, it and its offspring surpassed VLIs of an immortal organism and became prosperous without exception. Figure 4 shows successive changes of VLI distribution, number of

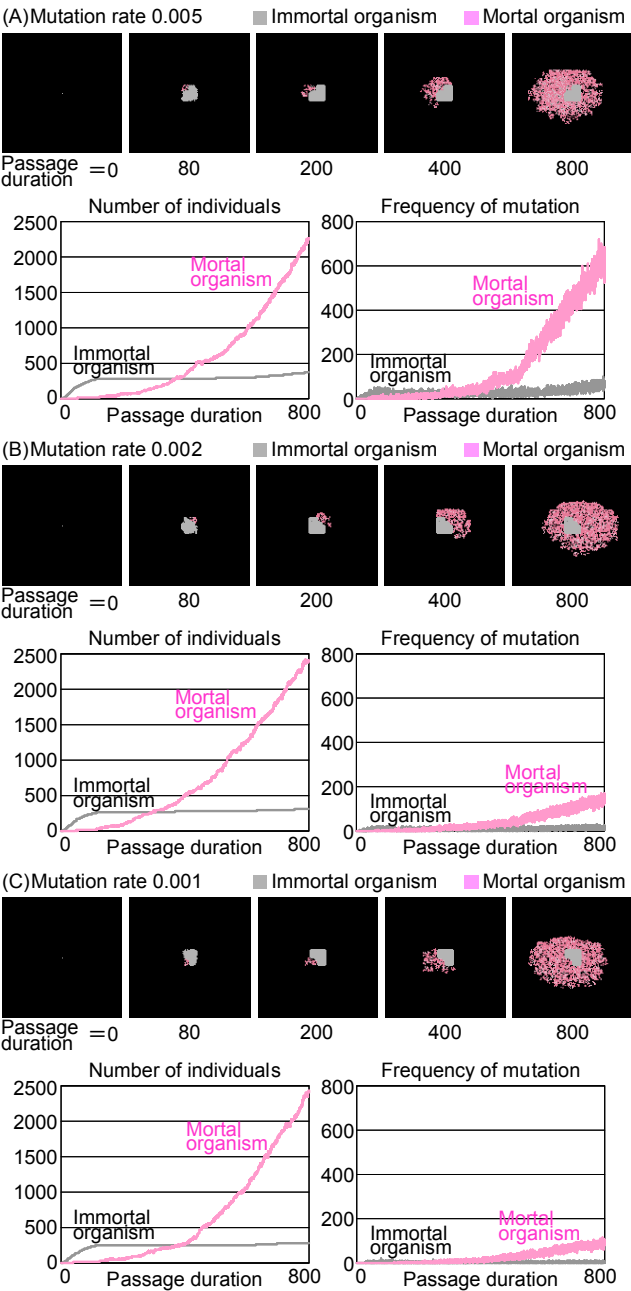

Figure 4. Evolutionarily emerging and surviving VLI of mortal organism certainly surpassed VLIs of immortal organism and became prosperous with adaptive divergence under various environmental conditions. Successive changes of individual distribution, the number of individual, and the frequency of mutation were illustrated. (A) 0.005 of mutation rate. (B) 0.002 of mutation rate. (C) 0.001 of mutation rate.

individuals, and frequency of mutation for each mutation rate. For example, for the mutation rate of 0.005 [Figure 4 (A)], a VLI with a genetic program for death emerged at the 30 passage durations' mark and produced offspring without extinction. In the case of 0.002 and 0.001 mutation rates

[Figure 4 (B), (C)], a VLI with a genetic program for death emerged at 11 and 29 passage durations respectively. Both produced offspring without extinction. Successive changes in the number of individuals and the frequency of mutation shown in Figure 4 demonstrate massive activities of mortal organisms compared to those of immortal organisms. The number of VLIs of a mortal organism grew at a sluggish pace shortly after emergence. However the mortal organisms extended their habitation area by degree, moved ahead of immortal organisms around the 300 or 400 passage duration mark, and then continued to extend their habitation area. There was no difference observed in the number of VLIs of a mortal organism introduced by the difference in mutation rate. We think the difference in the frequency of mutation of mortal organisms is reasonable because it may be introduced by the difference in mutation rates.

Table2: Probability of evolutionary emergence and survival of mortal organism

Mutation rate	Evolutionary emergence and survival	
	Frequency	Probability
0.005	7 times per 200 trial	3.5%
0.002	7 times per 500 trial	1.4%
0.001	2 times per 800 trial	0.25%

Discussion

1) Mortal organism survived and prospered within a certain probability

We carried out an evolutionary simulation experiment using our artificial ecosystem SIVA-T05, modeled for a finite, heterogeneous terrestrial environment and arranged in a biomolecular hierarchy. In many cases, we observed that when a mortal organism endowed with an evolutionarily acquired genetic program for death was born in a place in which immortal organisms already existed, the mortal organism, instead reproducing, became extinct by means of self-decomposition, overwhelmed by the indigenous immortal organisms. Nonetheless, our simulation process also demonstrated that some mortal organisms were evolutionarily appeared and managed to survive at a probability of 0.25% to 3.5% in accordance with mutation rates (Table 2). Furthermore, without exception, the mortal organisms that could overcome extinction thereafter prospered to the extent that they surpassed immortal organisms and continued to prosper, thanks to adaptive divergence under various environmental conditions. Although the probability of the survival and prosperity of the mortal organisms as shown in our simulations was low, it was, nonetheless, significant. Thus we can expect that mortal organisms might evolutionarily emerge, survive and prosper with adaptive divergence in other ecosystems under various environmental conditions while various ecosystems would repeatedly receive not a few opportunities for mutation. Considering the result of the experiment that a 0.25-to-3.5% probability for simulated ecosystems in which mortal

organisms prosper within a short duration of 800 passage durations applied to the terrestrial ecosystem, we believe that scale and heterogeneity of the earth's environment and length of time having elapsed during the evolution of terrestrial life and its concomitant ecosystem constitute sufficient probability for the possibility that mortal organisms could be evolutionarily selected and prosper terrestrially. Hence no inconsistency exists between our results and the experimental results described in our previous report (Oohashi et al. 2001).

## 2) Explanation of the superiority of mortal organisms

The transition of a number of individual organisms (Figure 4) indicates that the number of mortal organisms surpasses that of immortal organisms at the point in time after which 300-to 400 passage durations has elapsed, and that mortal organisms continue to prosper thereafter. How do mortal organisms overwhelm immortal organisms in this process? One interpretation of this phenomenon is as follows:

Immortal organisms dominate space and materials once they have been secured while the volume of resources to sustain life activities monotonically decreases. With less chance of reproduction in association with decrease of resources, chances for mutation as well as those for evolutionary adaptation are likewise reduced without limit.

On the other hand, mortal organisms release space for other organisms and return optimum parts for them to reutilize through self-decomposition upon termination of their mortal life. By doing so, equally benign or enhanced habitat environmental conditions can thus be secured for the all organisms including their own offspring in the ecosystem, which, in turn, will repeat the alternation of generation by utilizing finite space and materials. It is conceivable that due to accumulated mutations through the alternation of generations, new organisms emerge as a result of accelerated evolutionary adaptation in neighboring areas under environmental conditions that had not previously permitted the existence of earlier generations.

Independent of the studies that we have undertaken since 1987 (Oohashi et al., 1987, 1996, 1999, 2001, 2009, 2011), Todd implemented artificial death in his ALife system (Todd, 1993, 1994), and those experiments supported the recognition shared with us that death affords another entity its space in which to exist, and that death, accordingly, is essential throughout the ongoing evolutionary process. Nevertheless, the model of death constructed by Todd differs from our model of death in two patently obvious respects. First, death in Todd's model affords no process by which the organism might decompose itself into constituent parts for the efficient and collective reutilization of other organisms, which is an essential feature of our model. Second, the death of an individual in Todd's model appears as a probabilistic phenomenon, or as a given result controlled by the simulation system, in sharp contrast to the activation of death in our model, which is a process genetically regulated in the individual that starts from detection either of the end of its life span or of excess unconformity with the environment. Consequently, it would be difficult to use the ALife system as constructed by Todd to investigate the evolutionary emergence of death itself.

It is noteworthy that the mechanism of programmed self-decomposition, observed as being evolutionarily selected in this study, accords benefits not only to direct offspring but

also to all organisms of the entire ecosystem. It is difficult to produce a tenable explanation for this phenomenon based only on the "selfish gene" paradigm.

Programmed self-decomposition has been observed as a life phenomenon of existent terrestrial life as previously reported (Oohashi et al, 1987, 2009). The gradual consolidation of these complementary approaches—ALife simulations and biological experiments—will likely throw added light on this topic in the future.

## 3) Conclusion

The evolutionary simulations using our artificial ecosystem SIVA-T05 show that, if mortal organisms evolutionarily acquire a genetic program for autonomous death and then appear among a population of immortal organisms, such mortal organisms, endowed as they are with a genetic program for autonomous death, can survive and will surpass immortal organisms lacking autonomous death and will prosper with adaptive divergence under various environmental conditions within a certain probability.

The above results thus support our hypothesis that originally immortal organisms evolve into mortal organisms by acquiring a new genetic program for autonomous death.

## Abstract

Partner selection is a mechanism that promotes sustainability of cooperators in cooperative dilemmas. In this paper we investigate the conditions that favour the evolution of a particular partner selection model that can be applied to any  $n$ -player game. The model allows a player to select partner combinations that satisfy his preferences. A limit case of the model is random choice of partners. Model parameters are under evolutionary control. We present simulations of our model that show evidence of the evolution of partner selection instead of random choice.

## Introduction

In social interactions one of the main sources of distress is the proliferation of non-cooperative elements. A small percentage of unsocial behaviour is well accepted or even beneficial (Semmann et al., 2003). However, an unlimited growth of the percentage of free-riders is detrimental to cooperation and therefore to the maintenance of a society as a whole.

The study of social interactions has been modelled by several games presenting social dilemmas. For instance we have Iterated Prisoner's Dilemma (IPD), Ultimatum, Investment, Centipede, Public Good Provision (PGP) and Give-Take (Gintis, 2000; Fudenberg and Tirole, 1991; Axelrod, 1997; Mariano and Correia, 2002). Theoretical analysis of these games predicts the prevalence of exploiters or non-social behaviour in general (Gintis, 2000).

Several approaches have been developed in order to limit proliferation of free-riders. Some of them use game specific strategies while others fall into mechanism design. In the former category, we have tit-for-tat as an example of a strategy to play IPD that in a variety of conditions is able to resist non-cooperative players. In the latter we have the possibility of partner selection (Izquierdo et al., 2010; Santos et al., 2006; Aktipis, 2004).

In this paper we investigate the conditions that favour the evolution of partner selection in any symmetrical  $n$ -player game. In particular, we examine the model proposed in Mariano and Correia (2010). That model assigns probabilities to combinations of partners that are updated in a process similar to Hebbian learning. The process motivation is that, in the

long run, cooperative players mostly select partners among themselves. When a positive interaction occurs, instead of reinforcing probabilities of combinations, probabilities remain unchanged. When a negative interaction occurs, the combination is replaced and its probability is decreased. As a result probabilities of combinations with positive interactions absorb decreasing probabilities. By positive interaction we mean that a player considers the result as acceptable or the interaction as cooperative. The model can be applied to any  $n$ -player game with any type of strategy (deterministic or stochastic).

## Related Work

It has been reported in human experiments (Barclay and Willer, 2007; Coricelli et al., 2004; Ehrhart and Keser, 1999) that if players are able to select their partners they will seek cooperative partners while escaping free riders. In Price (2006) the author refers that in experiments involving human subjects, people tend to cooperate more when they can choose their interaction partners and, in that case, they cooperate when they perceive altruistic behaviour.

There is research on partner selection (Izquierdo et al., 2010; Pacheco et al., 2006; Santos et al., 2006; Zimmermann and Eguíluz, 2005; Aktipis, 2004; Semmann et al., 2003; Hauert et al., 2002; Stanley et al., 1995; Orbell and Dawes, 1993; Vanberg and Congleton, 1992) but this characteristic is granted in the model, i.e. players cannot choose between random partner allocation (Suzuki and Akiyama, 2008; Axelrod and Hamilton, 1981) or having the possibility to select with whom they will play. Moreover, these models are often tailored for a specific game such as PGP or IPD (Izquierdo et al., 2010; Aktipis, 2004).

Research similar to ours is Santos et al. (2006) and Pacheco et al. (2006) where population structure is able to evolve. Players are embedded in a network. If a player can change his links, selection favours cooperators that prefer to maintain links with their kin and to drop links with defectors. However, their findings were done in 2-player games and they only considered two types of strategies.

## Model Description

The model of partner selection presented in Mariano and Correia (2010) is characterised by two vectors. One,  $\mathbf{p}$ , contains combinations of  $n - 1$  partners drawn from a set of candidate partners, which constitute the player's neighbourhood  $\mathcal{N}$ . Each combination is assigned a probability stored in vector,  $\mathbf{c}$ . In that paper three update policies of the above vectors are compared. In the present paper, we use the policy that has given the best results. In this policy, after a player plays a game with a combination drawn from vector  $\mathbf{c}$  it compares the utility obtained  $u$  with parameter  $u_T$  and updates vector  $\mathbf{p}$ . The probability of the selected combination,  $k$ , is updated as follows:

$$p_k^{t+1} = \begin{cases} \delta p_k^t & \text{if } u < u_T \\ p_k^t & \text{if } u \geq u_T \end{cases} . \quad (1)$$

The probabilities of other combinations are updated as follows:

$$p_i^{t+1} = \begin{cases} p_i^t + \frac{(1 - \delta)p_k^t}{l - 1} & \text{if } u < u_T \\ p_i^t & \text{if } u \geq u_T \end{cases} , \quad (2)$$

where  $i \neq k$ , in order to maintain sum to unit and  $\delta$  represents the probability decrease factor.

If the utility is lower than threshold  $u_T$ , slot  $k$  of vector  $\mathbf{c}$  is replaced by a randomly generated combination, different from the ones in the other slots. Players of the new combination are randomly selected from  $\mathcal{N}$ .

Both vectors  $\mathbf{c}$  and  $\mathbf{p}$  have the same length represented by parameter  $l$ . This model has two particular cases of partner selection. When  $l = 0$  the player randomly picks  $n - 1$  partners from  $\mathcal{N}$  to play a game. The specific case of  $l = 1$  is similar to the model presented in Aktipis (2004) and Izquierdo et al. (2010). In these works, which only consider IPD (a game with two players) if a player is not happy, he moves away seeking a new partner. In our case, a new random combination of partners is selected.

## Player Chromosome

The description of the model has shown that it can handle random partner allocation as well as selection of best partner combinations. As we are using an evolutionary algorithm, the model parameters, namely  $l$ ,  $\delta$  and  $u_T$ , are part of the player's chromosome. In our simulations the domain of  $l$  is  $\{0, 1, \dots, \bar{l}\}$ , where  $\bar{l}$  represents the maximum value of  $l$  and the domain of  $\delta$  is  $[0, 1]$ . The update policy is based on private information, namely the utility the player assigns to a specific partner combination. In this paper we simplify and assume  $u = \pi$ , the utility is equal to the payoff  $\pi$  ascribed by the specific game used. Therefore the domain of  $u_T$  is  $[\underline{\pi}, \bar{\pi}]$ , where  $\underline{\pi}$  and  $\bar{\pi}$  are, respectively, the lowest and highest payoff of the game. Besides these three parameters, the chromosome also contains the strategy,  $s$ , used to play the

$s$	strategy
$l$	size of vectors $\mathbf{p}$ and $\mathbf{c}$
$u_T$	utility threshold
$\delta$	probability decrease factor

Table 1: Player's chromosome

game. When talking about the chromosome we may designate the coded parameters as variables or genes. Table 1 summarises player's chromosome.

## Evolutionary Setup

A plain genetic algorithm (Holland, 1975) with players' fitness as the total payoff obtained by a player favours players that are selected more often, typically cooperators. On the other hand, if we average players' payoffs other types of players are favoured. For instance, an exploiter that played a single game and obtained the highest payoff is favoured compared to cooperative players that played more games among themselves, which produces a lower average.

Artificial Life systems such as AVida (Misevic et al., 2006), Tierra (Ray, 1992) or Polyworld (Yaeger, 1994) do not have an explicit fitness function. These systems are considered when the goal is the simulation of open-ended evolution (Chaumont and Adami, 2010). Individuals must continuously adapt their strategy to the environment they are faced with. Typically, individuals must manage their energy in order to survive and pass their genes to their offspring.

Here we use a similar model but we frame it in the context of game theory. We consider that players obtain energy by playing some game  $\mathcal{G}$ . A player reproduces when his energy reaches some threshold. Every newborn player starts with zero energy. A player's energy is incremented by the payoff  $\pi$  he obtains. In order to avoid negative energies due to negative payoffs, we adjust the payoff by the lowest payoff obtained in the game,  $\underline{\pi}$ . Summing up, the energy,  $e$ , of a player is updated as:

$$e^{t+1} = e^t + \pi - \underline{\pi} . \quad (3)$$

Whenever a player's energy reaches the reproduction threshold,  $e_R$ , he produces an offspring. Reproduction is asexual and the offspring is a clone of the parent subject to mutation. The parent's energy goes back to zero.

The mutation operator is similar for all genes. Parameter  $l$  is perturbed by a discretized normal distribution with mean zero and standard deviation  $\bar{l}/2$ . Parameter  $u_T$  is modified by a normal distribution with mean zero and standard deviation  $(\bar{\pi} - \underline{\pi})/2$ . Parameter  $\delta$  is perturbed by a normal distribution with zero mean and standard deviation 0.5.

Summarising, a player's phenotype is characterised by his strategy, the probability and combination vectors, his neighbourhood and his energy. We also record a player's age. Table 2 shows these parameters. When a player is born, vector

$a$	age
$s$	strategy
$\mathbf{p}$	probability vector
$\mathbf{c}$	combination vector
$\mathcal{N}$	neighbourhood
$e$	energy

Table 2: Player’s phenotype

$\mathbf{c}$  is initialised with  $l$  random combinations of partners and vector  $\mathbf{p}$  is initialised with constant value  $l^{-1}$ .

## Environment

There are different artificial environments that influence how players interact. Research on cooperation uses toroidal lattices (Nowak et al., 2004), well-mixed populations (Pacheco et al., 2006), or small-world networks. Population structure influences the evolution and stability of cooperation. We opted for a well-mixed population, which means that a player can draw a combination from all the other players. Formally, for every player  $\alpha$  in population  $\mathcal{P}$  we have  $\{\alpha\} \cup \mathcal{N}_\alpha = \mathcal{P}$ . This is a typical structure in small communities (Price, 2006).

A simulation is composed of several rounds,  $N_R$ . In each round, all players select a combination of partners from their combination vector  $\mathbf{c}$  using their probability vector  $\mathbf{p}$ . They play the game  $\mathcal{G}$ . For each played game, all participants update their energy as defined by equation (3). The player that selected the partners is the only one that updates his probability and combination vectors, according to equations (1) and (2). The other players may not know all their partners. Only the selecting player has all the players in his combination vector. This approach prevents players from copying others’ combinations vectors.

The next step in a round is reproduction. All players that have reached the reproduction threshold generate one offspring. These players have their energy reset to zero.

Since reproduction increments population size, we need a mechanism to avoid an infinite growth of players. In the end of each round, a player may die with a probability given by the following sigmoid function:

$$P(\text{player dies}) = \frac{1}{1 + e^{B - |\mathcal{P}| - a}} \quad (4)$$

where  $B$  represents the carrying capacity,  $|\mathcal{P}|$  is the population size and  $a$  is the player’s age. Not only a player dies from overcrowding, but also he dies from old age. This implies that set  $\mathcal{N}$  may vary from round to round with a strong dependency on  $B$ . Since we considered a well-mixed population,  $\mathcal{N}$  is virtually the size of the population. Parameters that describe the overall behaviour of a simulation are presented in table 3.

$\mathcal{G}$	$n$ -player game
$B$	carrying capacity
$e_R$	reproduction threshold
$\mathcal{P}^0$	initial population
$N_R$	number of rounds

Table 3: Simulation parameters

## Comments

Players that are only exploited and cannot find sufficient co-operators, will not be able to reproduce. Also a population composed of a majority of exploiters may go extinct if the reproduction threshold is high.

The ratio  $R_1 = e_R / (\bar{\pi} - \pi)$  represents the minimum number of games a player has to play to reproduce. The higher the former value, the more pronounced the effect of partner selection. It takes some time for the probability vector to converge to a situation where only cooperators are present in the best combinations of the combination vector. This was observed in a situation where set  $\mathcal{N}$  is static (Mariano and Correia, 2010). In this paper we show that this may also happen in dynamic populations, meaning with variable  $\mathcal{N}$ . Notice that a cooperator will reproduce increasingly faster until the convergence of the probability vector.

An Evolutionary Stable Strategy (ESS) of some game  $\mathcal{G}$  depends on the evolutionary mechanism. For instance, in a context of infinite populations where players play infinitely often (Hofbauer and Sigmund, 1998), defection is the ESS of the PGP game.

Using the energy model that we presented without partner selection (partners randomly picked) all players will play approximately the same number of games. If the game  $\mathcal{G}$  is symmetric, its Nash Equilibrium (NE) will be maintained with this energy model. If some player deviates from the NE, energy obtained per game diminishes and consequently he will take longer to reach the reproduction threshold. This means that he will produce less offspring compared to those that stick to the NE. Due to the carrying capacity, the deviating player and his offspring have more chances of disappearing. The bottom line, is that in PGP with our energy model defection is still the ESS. However, with partner selection this may change. If a player can choose his partners, there may exist other ESS, namely cooperation, in the PGP game. This results from cooperators selecting preferably among themselves.

We have used a well-mixed population. Even in this case, since players select their partners, they are effectively constructing a network of contacts. The minimum and maximum number of contacts a player may have depend on  $n$  and  $l$ . The combination vector  $\mathbf{c}$  can have  $l$  distinct combinations differing in a single partner, yielding a minimum value of  $n + l - 2$  contacts. On the other end, all players in every combination may be unique, yielding a maximum

$n$	3	4	5	6	7	
$B$	100	110	120	130	140	150
$e_R$	50	60	70	80	90	100

Table 4: Parameters values used in the simulations.

value of  $(n - 1)l$  contacts.

This contrasts with recent work that considered other types of population structure such as small-world and scale-free (Pacheco and Santos, 2005). With structure the contact limits above defined may be further reduced.

## Experimental Analysis

The capability of the model we present to evolve partner selection can be assessed by tracking parameters  $l$ ,  $u_T$  and  $\delta$ . On the other hand, sustainability of cooperation can be measured by counting the number of cooperators that appear in a simulation.

### Game

We have performed simulations using the PGP game (Boyd et al., 2003; Hauert et al., 2002). This game is commonly studied to analyse cooperative dilemmas. Moreover, it is a  $n$ -player game. It is considered a generalisation of the Prisoner's Dilemma (PD) game to  $n$  players. In the PGP game, a player that contributes to the good, incurs a cost  $c$ . The good is worth  $g$  for each player. Let  $x$  be the proportion of players that provide the good. The payoff of a player that provides the good is  $gx - c$  while players that defect get  $gx$ . The game has a single iteration. The strategy used by a player is probabilistic and is defined by probability  $s$  to provide the good. We assume that the utility of a player is equal to its payoff. In the simulations we set  $g = 1$  and  $c = 0.4$ . The number of players in a game varied between three and seven. In this game, defection is the Nash Equilibrium and it is also the unique ESS.

### Tested Parameters

We have varied the carrying capacity and some parameters that influence the number of games a player has to play in order to reproduce. The latter is directly influenced by the reproduction threshold  $e_R$  but also by the number of players per game,  $n$ . Table 4 shows the values of the tested parameters thus giving an overview of the conditions where the evolution of partner selection was tested.

The size of initial population is 20. Those players all have the same chromosome: ( $s = 1, l = 0, u_T = \pi, \delta = 0$ ), i.e. players are cooperative but perform random selection of partners. Whenever a new offspring is born, mutation occurs with probability 0.1. Mutation of genes  $l$ ,  $u_T$  and  $\delta$  has already been described. The maximum value of gene  $l$  was 10. Gene  $s$  is altered by a normal distribution with mean zero and standard deviation 0.1. Each simulation run

(a) 3-player PGP.

(b) 4-player PGP.

Figure 1: Average number of cooperators in the last round.  $e_R$  is the energy required for reproduction and  $B$  is the carrying capacity.

consists of  $N_R = 10^5$  rounds. For statistical purposes, each result was taken from 30 independent runs, except otherwise noted.

## Results

One major outcome was the identification of conditions for the survival of cooperators. This is important because in the plain PGP defection is the ESS. The use of partner selection modified this situation. Since we are using probabilistic strategies, we classified a strategy as cooperating if it cooperates more than 90% of the time. This is a strict threshold and results could improve if it was lower.

The survival of cooperators depends mostly on the number of players in a game. With 3-player PGP cooperators survive, but not with 4 or more players per game (see figure 1). It has been shown in Mariano and Correia (2010) that the number of possible combinations of partners grows exponentially with the number of players per game,  $n$ , and the number of candidate partners,  $\mathcal{N}$ , which is the size of the neighbourhood. Now, in a well-mixed population ( $\mathcal{N}$  is the size of the population) with  $n = 4$ , the difficulty to find a favourable combination is already too high for cooperators to survive. In general, if the set of candidate partners is big and the number of players in a game is high, there are more

The last three columns contain the energy obtained by a cooperator, represented by letter C, and by a defector, represented by letter D. In the first situation (#C=  $n$  column) all  $n$  players cooperate, while in the second (last two columns) all but one player cooperate.

combinations of players to explore. In these cases, the partner selection model requires more time to find the correct partner combination, which may not be available even with large life span and low reproduction threshold.

Results also show that there are conditions where the population decreases until there are not enough players to play a game. Such occurrence of extinctions depends on the number of players, energy required to reproduce and parameter  $B$ , as shown in figure 2. Extinctions increase with increasing  $e_R$  and decreasing  $B$ . While parameter  $B$  can be interpreted as a carrying capacity, it can also be interpreted as a player’s average life span (see equation (4)). With low  $B$  values, high  $e_R$  and small  $n$  it is improbable that a player can attain sufficient energy to reproduce during his life span. This situation leads to high extinction rates.

We have already seen that 3-player PGP is the only case where cooperators survive. When we go to 4-or-more-player PGP the only survivors are defectors. In 4-player PGP, cooperators are early on wiped out by exploiters and the remaining exploiters cannot obtain sufficient energy to reproduce and die of old age. However, with growing  $n$  the probability of extinctions diminishes. This is due to the fact that each player is chosen more often to play by his neighbours. Therefore he may be able to attain the reproduction threshold,  $e_R$ , even when parameter  $B$  is low. In a population composed of only defectors, the payoff obtained by each one is zero. However, even in this situation, due to how energy is calculated (see equation (3)), defectors gain some energy. The more players in a game the more energy defectors obtain. Table 5 shows minimum and maximum payoff values for the tested number of players.

In the case of 3-player PGP, we analysed the evolution of the other three variables (genes) of the partner selection model, see figure 3. The pool size,  $l$ , increases from zero and stabilises around five. Variable  $\delta$  also increases from zero and stabilises around 0.5. As for  $u_T$  it increases, stabilising just under the Pareto payoff obtained by a cooperator playing with only cooperators. The fact that these pa-

Figure 2: Percentage of simulations without extinctions.  $e_R$  is the energy required for reproduction and  $B$  is the carrying capacity.

Figure 3: Example of a single simulation run (3-player PGP, carrying capacity  $B$  is 150, reproduction threshold  $e_R$  is 50) where cooperators are able to persist. In the cooperators plot, red solid line is population size and blue dashed line is number of cooperators (which fluctuates significantly without a corresponding influence on the average). In the plot of  $u_T$  the horizontal dashed line corresponds to the Pareto payoff. Results are plotted every 50 rounds.

rameters stabilise around some values means that there is no random drift. We confirmed such finding by measuring the variables under different  $e_R$  and  $B$  values, see figure 4. Remarkably, these variables are almost constant across all the values experimented for reproduction threshold,  $e_R$ , and  $B$ . Moreover, the memory length for partner combinations,  $l$ , is approximately 5, which is a quite small value. The fact these variables remain constant under different conditions reflects that a cooperator doing partner selection can find an adequate choice of partners, given time to achieve it.

## Conclusions

We have analysed the conditions for the evolution of a partner selection model. With such a model, the average number of games played by some player depends on his characteristic. Cooperators that select among themselves play more often compared to defectors. Reproduction was based on an energy model. Players reproduce when they attain some reproduction threshold. In order to contain the population under some limits, players die from overcrowding and old age.

The results show that cooperators are able to persist in a population even if with low percentages. These results were only possible due to partner selection. Cooperators persistence was only observed in some conditions, namely, 3-player PGP, high carrying capacity and small reproduction

threshold. In other conditions, we observed that defection, which is the ESS, was the sole strategy present in the population. The evolutionary dynamics of partner selection did not show any random drift in its variables. In fact the model is quite robust since the memory of partner combinations,  $l$ , the probability decrease factor,  $\delta$ , and the utility threshold,  $u_T$ , are virtually independent of the carrying capacity,  $B$ , and the reproduction threshold,  $e_R$ .

We have shown the evolution of cooperators in the PGP. In contrast with others, (Izquierdo et al., 2010; Pacheco et al., 2006; Santos et al., 2006; Aktipis, 2004), this was obtained with stochastic strategies. Previous work has focused in specific games with only two strategies.

We are currently investigating how cooperators can persist in games with more than three players. Preliminary results show that with increasing carrying capacity cooperators live longer. Another possibility is to decouple the chance of player survival in two events: one for overcrowding and another for old age.

The fact that players are able to select with whom they play means that this model is suitable to study the emergence of niches. Suppose a game has multiple strategies to cooperate. This model of partner selection may favour the emergence of groups of players, where each group uses one of the different cooperating strategies available.

We have used a well-mixed population. However, this

does not preclude the appearance of a network of players. With partner selection, a player is restricted to interact only with the partners in his combination vector. The use of another population structure, such as small-world, for instance, reduces the number of players available to form partner combinations. Consequently the number of partner combinations will be more limited. If we take into consideration the results with 3-player PGP partner selection may not evolve in some situations. This occurs specially for small populations (small  $B$ ) and high reproduction energy,  $e_R$ . However, this is one avenue for future work.

## Abstract

A metabolism-first scenario for the origin of life entails that as early as replicating entities have emerged prebiotically, they must have constituted relatively complex molecular networks, arising via spontaneous accretion of assemblies of simpler organic molecules. While it is widely accepted that self-catalysis is a prerequisite for life, considerably less attention has been devoted to network-based mutual-catalysis and its effect on evolution. To remedy this, we have used the graded autocatalytic replication domain (GARD) model, previously shown to capture essential features of reproduction, mutation and evolution in compositional molecular assemblies. We simulated a large ensemble of GARD rate-enhancement networks, thus allowing one to better study the crucial network properties of the implicated molecular assemblies. We found, with high statistical power, that high prevalence of mutual-catalysis is required for the emergence of appreciable diversity and evolvability of the assemblies, as well as for them to have significant selection attributes. We suggest that only minimal self-catalysis capabilities are needed to facilitate evolution-like behavior, and that excess self-catalysis may drive a population towards an evolutionary 'dead-end'.

## Introduction

A metabolism-first scenario for the origin of life entails that as early as replicating entities have emerged in the prebiotic soup, they must have constituted relatively complex molecular networks, arising via spontaneous accretion of early assemblies of simpler organic molecules (Dyson 1982; Bachmann et al. 1992; Kauffman 1993; Segre et al. 1998a; Luisi et al. 1999; Szathmáry 2000; Segre et al. 2001a; Shapiro 2006; Barandiaran and Ruiz-Mirazo 2008). In this scenario it is further proposed that faithful assembly reproduction directly stems from certain network attributes. To provide support for this scenario one must better understand the network properties of the implicated molecular assemblies. The GARD kinetic model for origin of life describes the homeostatic growth and evolution of an assembly composed out of a repertoire of  $N_G$  simple organic molecules (Segre et al. 1998a; Segre et al. 1998b; Segre et al. 2000; Segre et al. 2001a; Segre et al. 2001b; Shenhav et al. 2003; Shenhav et al. 2005; Hunding et al. 2006; Lancet et al. 2006) typically assumed to consist of amphiphilic molecules, e.g. lipids, and suggests a possible pathway to the formation of a minimal protocell (Shenhav et al. 2003; Szathmáry et al. 2005; Lancet et al. 2006; Thomas and Rana 2007; Chen and Walde 2010). The model is based on a catalytic network,  $\beta$ , usually presented in the form of a non-symmetric  $N_G \times N_G$  matrix, and

the system is kept away from equilibrium by imposing a fission action once an assembly reaches a size of  $N_{\max}$ . Key in GARD are compotypes – clusters of replication-prone quasi-stationary states (composomes) appearing during GARD dynamics – that make the compositional-genome (Segre et al. 2000; Segre et al. 2001b; Lancet et al. 2002; Shenhav et al. 2007) – and take an essential role in evolutionary processes related to GARD. Here, we used GARD simulations to ask how attributes of the mutually catalytic network embodied in the  $\beta$  matrix govern the evolution-related dynamics of compositional assemblies. We further report that GARD compotypes may display appreciable selection, contrary to a recent report (Vasas et al. 2010).

## Simulations

The model is subjected to a kinetic Monte-Carlo simulation based on Gillespie's algorithm (Gillespie 1976; Gillespie 1977; Segre et al. 1998a; Segre et al. 1998b), using parameter values similar to those typically employed in previous studies. A set of 10,000 GARD instances is generated, each with the same parameters and a different  $\beta$  matrix generated by a randomization of the same lognormal distribution (with a mean value of -4 and standard deviation of 4). Such random sampling of the  $\beta$  mutual catalysis network may be perceived as representing different possible GARD environmental chemistries.

## Compotypal diversity

Fig. 1 shows the correlation between the number of compotypes and the self-catalysis power (Eq. 1). As the propensity of self-catalysis increases, the probability of networks exhibiting a higher number of compotypes ( $>3$ ) is dramatically reduced,

$$p_{SC} = \frac{\sum_{q=1}^{N_G} \beta_{qq}}{\sum_{i=1}^{N_G} \sum_{j=1}^{N_G} \beta_{ij}} \quad (1)$$

Figure 1: A density plot for the correlation between the number of composites and the self-catalysis power, obtained from 10,000 GARD instances.

meaning fewer possible targets for selection and therefore possibly hindering the selection response. Curiously, even among the majority of simulations that show only one composite, a large portion has low self-catalysis strength, suggesting that low self-catalysis strength is a necessary but not sufficient condition for high number of composites.

## Selection in GARD

In order to assess the selection response of GARD assemblies, a 'selection-GARD' simulation is performed by choosing a target composite and then running the simulation while temporarily biasing the growth of assemblies towards that target, based on a slight fitness gain and level of compositional similarity between an assembly and the target. A 'selection excess' (SE) parameter is subsequently defined, by comparing the frequencies of the target composite before and after selection. An increase in the target frequency as a response to selection pressure means positive selection and is represented by  $SE > 1$ . Similarly  $SE < 1$  and  $SE = 1$  represents negative and no selection, respectively.

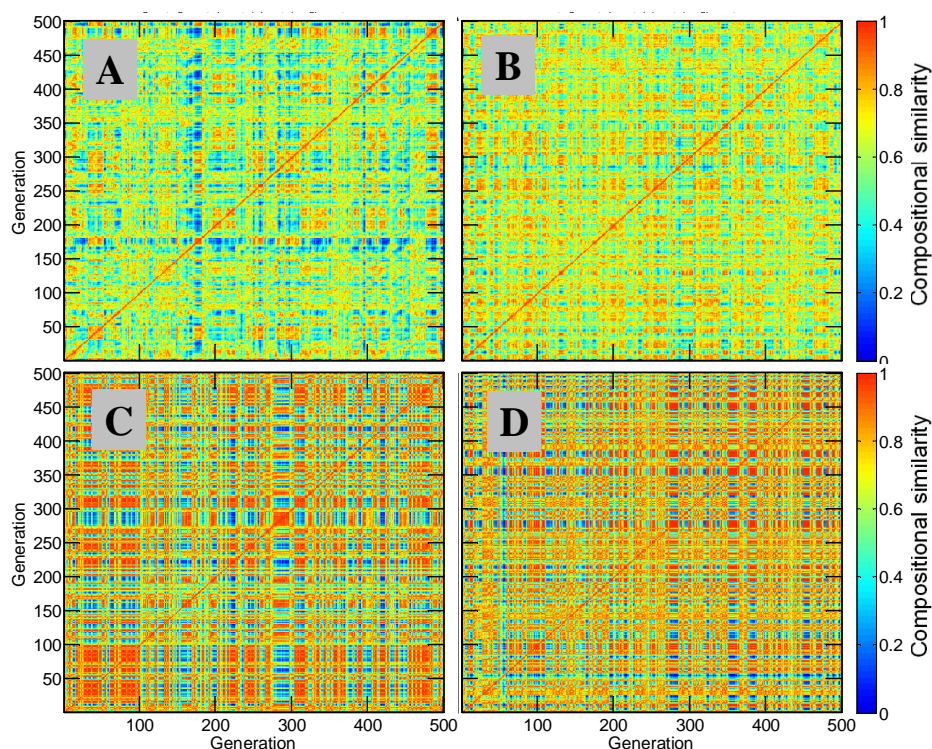

Figure 2: Examples of 'similarity carpet' before (A, C) and after (B, D) selection. The first example (A, B) is of a simulation positively responding to selection, as seen by the frequency of the target composite increasing by 75% ( $SE = 1.75$ ) in response to the selection pressure, seen as higher preponderance of large overall compositional similarity. The second example (C, D) is of negative selection. The frequency of the target is diminished ( $SE = 0.83$ ) seen as lower preponderance of large overall compositional similarity

We used the parameter SE to assess the capacity of GARD assemblies to undergo a process akin to Darwinian selection. Figs. 2 show examples of how GARD assemblies positively and negatively respond to selection pressure. Analysis of the entire 10,000 simulation instances reveals that a considerable percentage (~30%) of the networks show positive response to selection ( $SE > 1$ , and as large as  $SE = 2$ ). The mean SE value in this range is found to be about 1.4.

Such observations are contrary to a recent report (Vasas et al. 2010), where a claim has been made that specific GARD compositions show a negligible capacity to respond to selective pressure. Moreover, we interestingly find that networks with strong self-catalytic power exhibit practically no selection, and that the same range of low self-catalysis power that allows for high compotypal diversity also displays selection (both positive and negative), suggesting that GARD  $\beta$  networks must have an optimal ratio of self- to mutual-catalysis to manifest effective evolution-like behavior.

## Abstract

We explore self-organizing strategies for role assignment and strategy selection in a foraging task carried out by a colony of artificial agents. Foraging strategies are selected by strategies inspired by various mechanisms of division of labor (polyethism) observed in eusocial insects like ants, termites, or bees. Specifically we instantiate models of *caste polyethism* and *age* or *temporal polyethism* to evaluate the benefits to foraging in a dynamic or unknown environment. We focus on the ability of division of labor mechanisms to self-organize individual strategy selection based on the environment.

## Introduction

The self-organizing strategies of eusocial insects are now well known and well studied in biology (Beckers et al. (1989); Traniello (1989); Robinson (1992); Theraulaz et al. (1998); Theraulaz and Bonabeau (1999); Gautrais et al. (2002); Roulston and Silverman (2002); Merkle and Middendorf (2004); Garnier et al. (2007)) and applications to computation are abundant (Bonabeau et al. (1999); Panait and Luke (2004b,a); Schmickl and Crailsheim (2008); Gershenson (2010); Ducatelle et al. (2010)). One of the more remarkable behaviors observed is the ability of rather simple, unintelligent agents (individual insects) to coordinate their behavior to establish a rather fluid and adaptive behavior on the colony level. The phenomenon of *stigmergy* (communication via the environment) has now been modeled and applied in artificial simulations to achieve similar results among rather simple artificial agents (Theraulaz and Bonabeau (1999); Bonabeau et al. (1999); Panait and Luke (2004b,a); Schmickl and Crailsheim (2008)) cooperating in multi-agent systems.

However, many of these applications focus on homogeneous colonies, where each agent has the same behavioral capabilities. Nonetheless, observations of insects show that in many colonies the individuals are not always homogeneous. Colonies consist of heterogeneous agents, whether these agents display morphological differences (i.e. distinct castes) or merely behavioral differences. The effects of this

stratification of agents in a colony is referred to as division of labor (DOL) or by the term *polyethism* (Robinson (1992); Traniello and Rosengaus (1997); Theraulaz et al. (1998); Gautrais et al. (2002); Gordon (2003); Merkle and Middendorf (2004)). As artificial multi-agents systems grow larger and involve agents with different roles the problem of assigning roles to agents becomes increasingly important (Campbell and Wu (2010); dos Santos and Bazzan (2009)).

Biologists differentiate between at least two means of dividing roles amongst workers in natural insect colonies. The means we select for study are called *caste polyethism* and *age polyethism*. Other types of polyethism are also observed (e.g. *elitism*) and the two above types have many possible underlying mechanisms though these additional types and subtypes will not be explored in detail in this article. Simulations have just begun exploring task assignment and heterogeneous agent populations (e.g. Schmickl and Crailsheim (2008); Ducatelle et al. (2010)). Our experiment differs from these in that our agents are assigned the same task (foraging), but must decide which strategy to adopt to solve the task (between an individual exploratory strategy and a cooperative exploitative strategy). Other experiments focus on simulations of actual natural colony behavior in an attempt to assess models of those behaviors, whereas while we are inspired by these models our focus is on polyethism as a self-organizing strategy selection mechanism.

## Polyethism

*Caste polyethism* occurs when distinct types of individuals are bred by the colony. An individual is effectively born into its role, often times displaying morphological differences from individuals from other castes. The clearest example of castes is the division between the reproductive caste and the worker caste in eusocial insects. A single or small group of reproductive females (called queens) are responsible for all reproductive tasks in the colony while non-reproductive workers carry out all other tasks required by the colony (brood care, nest constructions and maintenance, waste removal, foraging, and defense). In some species workers are further divided into sub-castes. Differences among workers

from different castes are particular to the worker's role. For instance in some species of ants the workers can be divided into *majors* and *minors* (occasionally with an intermediate caste as well) where the majors are larger than the minors, this size being helpful in the task they carry out (primarily colony defense). Minors are smaller, making them more energy efficient, and they are relegated to less dangerous tasks like foraging and nest maintenance. Only in rare occasions will a worker do a task that is typically assigned to a different caste.

*Age* or *temporal polyethism* is a type of division of labor where the worker's role is correlated with its age or changes over time. Age polyethism is more common than caste polyethism in natural insect colonies. In colonies displaying age polyethism younger workers commonly carry out less risky tasks (nursing or nest maintenance allowing them to stay in the nest) whereas older workers carry out more dangerous tasks (foraging, defense, or raiding where the agent must leave the nest). It is hypothesized that this division of labor allows the colony to maximize the work carried out by each individual worker (i.e. young workers will be less likely to die and thus can live longer to carry out more work). This will be beneficial to the colony since it will have to breed fewer workers if each worker's longevity (and thus productivity) is maximized (Tofilski (2002, 2009)). In certain cases this progressive role assignment may also allow younger and less experienced workers to gain the experience necessary to carry out more difficult tasks (say at the very least allowing them to become familiar with the layout of the nest and surrounding environment before having to venture far from the nest) (Tofts and Franks (1992); Tofts (1993); Franks and Tofts (1994)). Many mechanisms have been suggested as the underlying reason for observed age polyethism. The mechanism we employ is similar to the response threshold model commonly studied (see e.g. Theraulaz et al. (1998); Garnier et al. (2007)).

## Artificial Ants

The experiment detailed below involves a colony of artificial ants engaged in a foraging task. The colony level task is to maximize the food intake of the colony (allowing colony sustenance and growth). On the individual worker level the task is to explore the environment, find a food object, and return to the nest with the object.

We consider two different strategies for individual workers inspired by natural ant populations. The first, and simpler, strategy is for workers to forage for the most part *individually*. We say "for the most part" here since individual foragers cooperate at least insofar as they attempt to divide the environment to be explored equally among them (see Figure 1). We implement this strategy by having ants leave a "seeker" trail as they leave the nest. While "seeking" the ants will avoid other seeker trails, meaning they will travel away from the nest while avoiding the trail they leave be-

hind them, but they will also avoid trails left by other ants, helping to divide the area somewhat evenly. Other than this simple cooperation, workers leave the nest and randomly explore until they find a food object (or reach the range of their exploration) and return to the nest. We will call this strategy the "individual" or "exploratory" strategy, and ants following this strategy "explorers". The seeker path left by these ants also serves as the ants' sole means of returning to the den (i.e. they follow seeker paths back).

Ants that find a food source of sufficient size (i.e. they find at least one food morsel to carry back to the nest and at least one more food morsel they will recruit others to seek out) the ant will leave a second type of trail we call the "carrier" trail. The second strategy, which we call the "cooperative" strategy or "exploitative" strategy, involves foragers that will follow "carrier" trails to exploit food sources that were already discovered by other ants. Both explorers and exploiters will leave "carrier" trails under the conditions listed above, but only exploiters will follow them to food sources.

Trails in our simulation consist of discrete pheromones. The trail to be followed is selected randomly from observed trails with probability weighted relative to the trail's decay (newer trails more likely to be followed than older ones). Trails to be avoided are all considered in avoidance behavior, however if there is a trail to follow the avoidance behavior is suppressed.

These strategies are inspired by those found in natural populations, with a correlation of colony size to the strategy used (Beckers et al. (1989); Traniello (1989)). It has been observed that smaller colonies tend to use the exploratory strategy whereas as the larger the colony is the more likely the colony uses an exploitative strategy. Despite this correlation, upon closer examination larger colonies have foragers carrying out both strategies, that is, they engage in polyethism.

It is known (Roulston and Silverman (2002)) that these strategies fare differently depending on the environment the colony is situated in. If food objects are *uniformly* distributed around the nest then the individual strategy reaches near optimal foraging. Over time the workers will clear a disc shaped area of food around the nest, the radius of the disc being determined by the frequency of food objects and by the size of the population. This situation is presented in Figure 1.

Interestingly, in larger colony sizes the cooperative strategy also fares quite well in environments with uniform distribution of food, though the foragers carry out a more complex foraging strategy. Cooperative foragers form an "arm" leading from the nest into the environment and this arm has been observed to swing in a circle around the nest, clearing food objects as it goes, or spontaneously dissolving and reforming in a more lucrative direction. These strategies have also been observed in natural ant colonies. While the cooperative strategy seems to approach the performance of the in-

Figure 1: Explorers in a uniform environment. The den is in the center of the torus. Green squares are food. Red paths are seeker paths. Blue paths are carrier paths. Recall that explorers ignore the carrier paths.

dividual strategy in experimentation, the individual foragers have an advantage in an environment with uniformly distributed food.

A second environment type we have investigated contains food isolated in *patches*. For the sake of comparison among simulation runs our food patches are always placed equidistant from the nest, though in a random direction. In this environment the cooperative foragers have a clear advantage. Once a forager finds a patch of food it recruits other foragers to help it clear the patch and the colony quickly optimizes the path to the food patch. Figure 2 shows a typical patch environment (with 2 patches) and a colony of exploitative ants foraging from the patches.

Individual foragers are at a significant disadvantage when faced with an environment with a single patch. Many individual foragers leave the nest in the wrong direction and return empty handed.

Given the differential success of these strategies in these environments it is our hypothesis that polyethism in a colony will be beneficial if the colony is faced with either an unknown environment (of one of these two types) or with a dynamic environment consisting of either a combination of these types or shifting between these types.

## Experimental Setup

In our experiment we consider four different types of colonies that we will expose to five different types of environment. We will consider how each colony fares in each environment, as well as how the colony fares across all en-

Figure 2: Exploiters in an environment with two patches. The den is in the center of the torus. Green squares are food. Red paths are seeker paths. Blue paths are carrier paths. Exploiters use the carrier paths to cooperatively forage.

vironments.

A colony will consist of a *queen*, a population of *workers*, a population of *larvae*, and a store of food. Workers consume food at a constant rate (about 1 food every 450 simulation rounds) and larvae consume food at a constant rate (1 food for the 100 round gestation period).

The queen lives for the duration of the experiment (or until the colony dies of starvation), though workers and larvae may die. Workers die under two conditions. If they reach their maximum age (selected uniformly from the range 2750-3250 rounds), or if they run out of food energy. When a worker consumes a piece of food it gains energy that will sustain it for 450 simulation rounds. If while foraging the worker's food energy reaches 0 (i.e. after 450 rounds) then the worker attempts to return to the nest (possibly without food). Upon returning the worker will attempt to consume a unit of food from the store. If there is no food in the store the worker dies.

A larvae also consumes food, once upon creation by the queen and again upon changing into a worker. The food consumed when the larvae matures forms the initial energy store of the worker. A queen will never create a larvae in an instance where the food stores are empty, however, a larvae may mature and find the store empty. In this case the new worker dies.

Queens from different colonies have different profiles, however, they all follow the same rule when deciding to reproduce. A queen will only create a new larvae if the food store exceeds the current population of workers plus the cur-

rent population of larvae.

## Colony Types

The first two types of colony will form a control group for comparison. These two types will not use polyethism and queens in these colonies will create *only explorers* or *only exploiters* respectively. From the earlier discussion we know that these colonies will fare well in some environments but not in others and will not be adaptive to a dynamic or unknown environment.

The third colony will engage in an *adaptive caste polyethism*. Queens in this type of colony produce larvae that can mature into either an individual or cooperative worker. The queen chooses the type of worker to create in proportion to the success rate of workers of that type. (The queen keeps track of food returned by each type of forager over the last 500 rounds, and of the number of each type of forager. From this she estimates the efficiency of the average ant of each type and randomly selects to create a new ant in proportion to the ratio of success rate.) Thus if explorers are more successful at foraging than exploiters then a queen will make an explorer with higher probability (and vice versa). Queens in this type of colony will ensure there is always at least one worker of each type so success rates can be properly estimated.

The fourth colony will engage in one type of *temporal polyethism*. Workers in these colonies are homogeneous in their behavioral repertoire, in that they can act as either explorers or exploiters. Which role a worker adopts depends first on their age (for younger workers) and then on the demands of the colony (for older workers). In this colony new workers adopt an individual foraging strategy, and may switch to a cooperative strategy (or back again) after reaching a particular age (usually consisting of 1 or 2 full foraging trips). Workers of this type choose to change roles based on collective experience, that is, in proportion to the success rate of workers in the colony similar to the mechanism used in the third colony.

(The estimation of the success rate of each strategy is carried out with simple counters in our simulation, though we believe these correspond to a basic stigmergic strategy. While we do not use pheromones in our model of this behavior we believe this mechanism is closely related to response threshold models of behavior selection.)

## Environmental Types

We expose these 4 colony types to 5 distinct environments: *uniform*, *patch*, *roaming patch*, *seasonal*, and *mixed*. The rate at which food drops in each environment is the same (1 food every 5 rounds) and each food will stay in the environment for exactly 1000 rounds or until picked up by a forager. The *uniform* and *patch* environments were described above consisting of uniformly distributed food or an isolated patch of food respectively.

The *roaming patch* environment has a single patch but this patch will change location every 1000 rounds (the new location will be the same distance from the nest as the old location). This means that after the patch has moved new food will drop in the new patch location, though old food is not removed unless foraged or it reaches its 1000 round limit. As a result there will usually be two patches in the environment, one containing old food that is decaying and one containing new food. Figure 2 displays a typical scenario for this type of environment.

The *seasonal* environment is intended to simulate an environment that changes from a uniform distribution to an isolated patch with regularity possibly corresponding to the seasons. We simulate this idea by alternating between the two distributions every 1000 rounds. Again there will be a temporal overlap between these two environments meaning that the environment will typically contain food dropped uniformly and in a patch. Every time the season changes to the patch distribution a new location for the patch is selected so in this sense we see the patch as roaming as in the last environment.

The *mixed* environment includes both uniform food drops and an isolated patch at the same time, and the environment is static (in that the patch does not move). In this environment the drop rate is the same as previous environments despite there being two active food drop mechanisms operating simultaneously.

## Observations and Data

We choose to analyze the worker population data of our colonies. This data reflects the colonies' ability to forage for food efficiently. Each colony begins with an initial food store of 32 food and zero ants. The queen will use this initial food to create 16 initial workers which mature on rounds 101-116 of the simulation. At this point the initial food stores will be exhausted. Parameters of the simulation determine a maximum colony size, namely the food drop rate and the energy consumption rate of the workers (as well to a lesser extent the size of the environment). This maximum is just above 80 workers, though due to the non-linear dynamics of the simulation this maximum can be exceeded for short periods. We used these parameters to balance computational time with robust results. A single run with a higher population suggests that the results scale, but further work would need to be done to verify this.

The initial stages of the simulation are occupied by rapid growth of population as the foragers are able to bring in more food than the colony needs so new workers are created (exceptions to this are noted below). This rapid growth commonly results in too many workers and so is often followed by a large dip in population and an oscillation is observed until an equilibrium can be found. This equilibrium depends on the type of colony and environment.

Figure 3 (left column) displays the worker population data

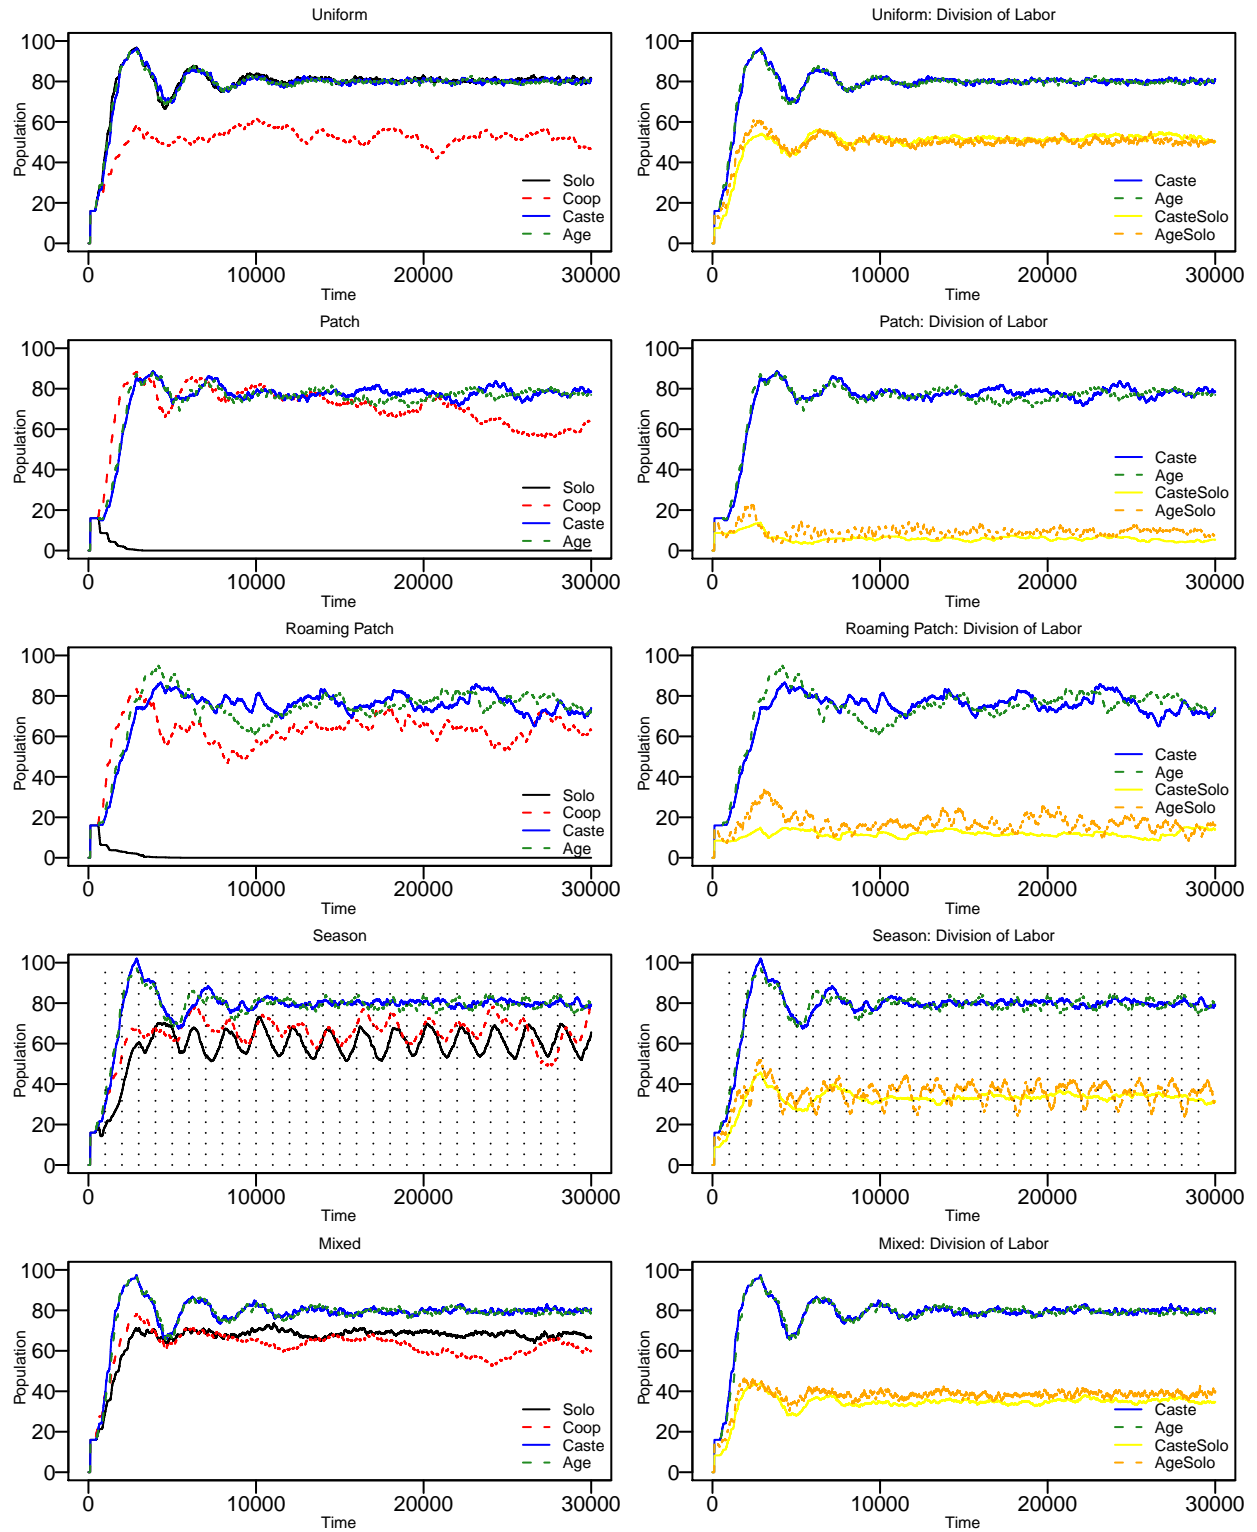

Figure 3: Worker Population Data. From the top row the data is presented for each environment: *uniform*, *patch*, *roaming patch*, *seasonal*, and *mixed*. The left column displays worker population over time for the four colony types. The right column displays the division of labor in the *Caste* and *Age* colonies. The worker population of these colonies is contrasted to the number of workers in the colony assigned to the *exploration* task. Please note we use "Solo" to indicate explorers and "Coop" to indicate exploiters in the charts.

gathered from all experimental runs. The data presented in the figure is the *average worker population* over time for  $N$  different simulation runs ( $N = 13$ ).

## Population Analysis

In the *uniform* environment the best performance is achieved by the explorers, and is closely matched by the caste and age polyethistic colonies. All three colonies settle around a population of 80 workers after initial instability. While the exploitative colony has no trouble surviving in this environment its sub-optimal foraging strategy allows it to maintain only a population of between 40-60 workers. Its population is also subject to greater instability as the foraging arm grows and shrinks in size and changes location. This is further supported by a greater average standard deviation (11.06) for exploitative population data compared to explorers, caste and age polyethistic colonies (2.37, 2.76, 2.71 respectively).

In the *patch* environment we again see expected results. The explorers are unable to maintain even the low initial colony size and the colony starves quickly. The cooperative foragers are the quickest to exploit the patch, whereas the polyethistic colonies are able to quickly adapt to the environment by producing exploiters instead of explorers. Both polyethistic colonies still maintain a small population of explorers. The dip in cooperative population observed near the end of the simulation is caused by two anomalous colonies from the simulation runs that starved to death. No such extinctions were observed among the polyethistic colonies. We observe some population instability in this environment. The average standard deviation for explorers (18.34) was about double that of the caste and age polyethistic colonies (9.13, 9.27 respectively) indicating greater stability from polyethism in this environment.

In the *roaming patch* environment we see that the polyethistic colonies are able to maintain a higher population than the purely exploitative colony (the explorers quickly starve in this environment as well). This implies a better ability to adapt to the moving patch. The exploitative colony also displays a greater instability in population though all three successful colonies have greater instability than in the stationary patch environment (supported by higher average standard deviations 22.13, 13.73, 13.25 for the exploiters, caste and age polyethistic colonies respectively) however still with greater stability in the polyethistic colonies. Also noteworthy is that all colonies have trouble maintaining an optimal population.

In the *seasonal* environment we again observe better performance from the polyethistic colonies than the purely explorer and purely exploiter colonies. Further there is greater stability of population in the polyethistic colonies (average standard deviations 7.76, 7.24 for caste and age respectively), where the pure explorer and pure exploiter colonies suffer population oscillations corresponding roughly to the

changing seasons (average standard deviations 13.77, 18.65 respectively). Note in the figures the dotted lines display the changing seasons. The polyethistic colonies manage to maintain roughly optimal populations in this environment while the explorer colony suffers the most in the seasons when food becomes isolated in a patch.

Finally, in the *mixed* environment, we again see a population advantage to polyethism. While both the purely explorer and purely exploiter colonies survive in the mixed environment they are unable to reach the optimal populations and display a slightly greater instability. The purely explorer population also maintains a slight population advantage over the purely exploiter population. Stability is highest in the explorer and polyethistic colonies (average standard deviations for this environment are 4.26, 15.74, 5.04, and 3.16 respectively).

## Division of Labor

A secondary focus of our simulations was on the division of labor in the polyethistic colonies. We gathered data on how many workers of each type were deployed at a given time by the polyethistic colonies. This data is presented in Figure 3 (right column) for each environment. We display only the number of explorer workers in the chart in contrast to the total worker population, with the number of exploitative workers being the difference. In the caste polyethism colonies this corresponded to how many workers of each caste were available. In the age polyethism colonies this corresponded to how many workers were currently assigned to each strategy during that round.

In the control environments the polyethistic colonies stabilized around a constant number of explorers. For the *uniform* environment both colonies settled at just over half of the workers (about 50 out of 80 workers) dedicated to exploring. It is worth noting that the colonies did not try to maximize the number of explorers in this environment. In the *patch* environment the caste colony settled at around 5 workers dedicated to exploring while the age colony maintained a slightly higher number of explorers, typically oscillating between 5 and 15 workers. We note that in these environments the age polyethistic colony displayed greater oscillations of worker assignments whereas the caste polyethistic colony tended to stabilize around a particular division of workers assigned to each task.

In the *roaming patch* environment more explorers were maintained than in the stationary patch environment. In the caste colony just over 10 of the workers were assigned the exploring role. The age colony still assigned more workers to exploring on average than the caste colony, typically above 15, but as high as 25. Again the age colony had greater variation in its division of labor.

The *seasonal* environment displays distinct performance differences between the two polyethistic colonies. The caste colony settles on 30 to 35 workers dedicated to exploring.

This number is stable when compared to the age colony which attempted to adjust the worker base to the current season. Thus we see the number of explorers oscillating between about 25 workers to as high as 43 workers (excepting the early spike).

In the *mixed* environment both polyethistic colonies stabilize their worker base by assigning roughly half the workers to each task. The age colony again assigns slightly more workers to exploration than the caste colony and displays slight oscillations.

## Discussion

The data presented suggests that polyethism, regardless of kind, offers benefits to the foraging task. While both of the foraging methods studied in this experiment (exploring and exploiting) can be seen as self-organizing methods, the colonies benefit if the “higher-level” self-organizing method of polyethism is applied to select which of the strategies to engage in (Gershenson (2010)). The clearest advantage shown by our experiment is the ability for these mechanisms of polyethism to *adjust the ratio* of explorers to exploiters based on the environment.

In the environments where the environment is specifically created to favor one of the two basic strategies, exploring or exploiting, we see that polyethism allows the colony to adjust the worker base to the environment. The only drawback in these environments to the polyethistic colonies is that they require some time to adjust to the environment.

In the more dynamic environments we see that polyethism is necessary to get optimal or near-optimal performance. We see that in the *roaming patch* environment, while exploiters are well suited for this environment, maintaining a small population of explorers allows the new patch location to be found quicker, and more quickly exploited (Roulston and Silverman (2002)).

In the *seasonal* and *mixed* environment polyethism is necessary to have optimal foraging. In the *seasonal* environment the non-polyethistic colonies suffer in seasons where they are not well suited. In the *mixed* environment the non-polyethistic colonies are unable to exploit all the food drops and thus cannot maintain as high a population. In the *mixed* environment the polyethistic colonies settle on a division of workers among the two strategies that allows for exploiting both food sources. It is interesting to note that the polyethistic colonies still managed to reach optimal population levels in the mixed environment, implying that the two strategies did not experience negative interference.

We also note that the polyethistic colonies adopt different approaches to the *seasonal* environment. The caste colony maintains a constant number of each worker. This can be seen as the colony being prepared for either season, but not necessarily specializing for the current season. This approach may be favored by the caste colony because the season length (1000) is short compared to the lifespan

of a worker (selected uniformly from the range 2750-3250 rounds). Thus the caste colony will not have the opportunity to adjust the balance of workers each season since workers from the previous season will still be present in the work force. The age colony *does* adjust its work force to the new season, albeit only slightly, since the workers in this colony can switch tasks every round trip which is about 300-400 rounds long, shorter than the season length. Both strategies allow the colony to maintain fairly stable and nearly optimal populations.

To test this analysis we conducted a follow up experiment where the season size was extended to 3000 rounds (see Figure 4). In this run we saw that the caste colony adopted the adjustment strategy as well, attempting to match workers to the season instead of opting for an equal distribution. We observed in this case that the age colony was able to adapt its workers more rapidly than the caste colony, and thus had a slightly more stable population. The stability of both colonies' populations suffered with the longer seasons due to more polarization of the workforce and the lag between the season change and the ability of the colony to adjust its workforce.

## Conclusion

We conclude that *division of labor* is beneficial to ant colonies in that it adds a layer of dynamism to their problem solving as well as makes the colony more robust. We suggest that the simple self-organizing methods of assigning workers to tasks can be adopted in artificial systems. These methods are simple to implement and require a minimal amount of central planning or control. The methods are reactive and dynamic and can likely be applied in a variety of situations, this being the topic of future work.

While we found little evidence favoring one of age or caste polyethism as a method of assigning workers to tasks we did find that the caste polyethism appeared to be more rigid in that it took longer for the workforce to adjust to new conditions. However, the trade off is that in the age polyethistic colonies there was a tendency to over adjust to new conditions, which may not be favorable in all situations. We believe that more work is required to determine the benefits of each of these methods, given that the distribution of these methods among natural colonies is not balanced (recall age polyethism is more common than caste polyethism). One aspect that was not considered in this experiment, and probably plays an important role in natural colonies, is the variable costs to a colony or species (genetically and in terms of energy expenditure) in producing workers that either are specialized for their task (caste polyethism) or are generalists able to take on any available task (age polyethism).

## Abstract

We propose a novel approach to learning in autonomous robots that relies on the dynamical maintenance of an actively sensitized sensorimotor loop. Very weak learning cues are sufficient to orient a robot towards the desired behavior which is then selected from the intrinsic exploratory movements rather than imposed by a control command. The learning paradigm is a form of guided self-organization and is complementary to both active and intrinsically motivated learning. We present a systematic analysis of the learning algorithm in a robot control task and demonstrate its remarkable scalability with respect to the degrees of freedom of the system.

## Introduction

Learning in autonomous agents implies an active involvement of the agent in the acquisition of new behavior. Lopez and Oudeyer (2010) ask for a unified formalism for active and intrinsically motivated exploration and observe a convergence of approaches from machine learning and developmental psychology towards a new perspective for developmental robotics. While a number of examples exist that impressively demonstrate the virtues of this view, it appears that a different sets assumptions are required that may eventually turn out to limit the possibility of on-going learning, scaling and transfer across domains. Since a more extended discussion is beyond the present scope we should mention here merely that the present approach aims at a relaxation of some of these assumptions. We will use only a local world model

While some variants of intrinsically motivated learning try to extract controllable options (Singh et al., 2004; Martius et al., 2008; Jung et al., 2011) we will use here a related approach (Martius and Herrmann, 2010) in order to improve the sensitivity with respect to given learning signals (cues). We implement in this way a form of self-organized curiosity (Schmidhuber, 1991; Herrmann, 2001) for the cues which substantially improves goal-related learning in an autonomous robot. We will show examples where the learning time within this approach scales very nicely with the complexity of the problem.

We start from an approach to self-organization of robot control (Der, 2001; Martius et al., 2011) which aims at robotic behaviors that are characterized by on-going exploration and that can be called natural for a specific robot in a particular environment (Der et al., 2006; Hesse et al., 2009). Animals, including humans, can be assumed to acquire their behavioral repertoire in a similar way: Behavioral elements are developed autonomously and are composed and refined later in order to realize more complex goals. The resulting behavior is, nevertheless, subject to an on-going developmental modulation throughout the whole life span.

In robotics, many promising examples for autonomous behavioral adaptation and generation have been studied for instance by Herrmann (2001); Tani (2003); Der et al. (2006); Nolfi (2006); Oudeyer et al. (2005). Self-organization of behavior is, nevertheless, still a field of active exploration. Further questions such as the interaction of learning by self-organization and learning by supervision or by external reinforcement are just starting to gain scientific interest.

Usually, goal-oriented behavior is achieved by direct optimization of the parameters of a control program such that the goal is approached more closely. The learning system must receive information about whether or not the behavior actually approaches the goal. This information may be available via a reward signal in reinforcement learning or by a fitness function in evolutionary algorithms. We will consider similar types of goal-related information when aiming at a combination of self-organizing control with external drives. For this combination the term *guided self-organization* (GSO) was proposed by Martius et al. (2007); Prokopenko (2009). In a general perspective, GSO is the combination of goal-oriented learning and developmental self-organization. Each of the two learning paradigms bring about their particular benefits and GSO aims at combining them in an optimal manner. For instance, self-organizing systems tend to have a high tolerance against failures and degrade gracefully, which is also desirable in task-oriented applications. when developing systems aiming to achieve tasks in practical applications. We will deal in with a specific approach to self-organizing control, namely homeokinetic learning.

*Homeokinetic learning* generates self-organized behavior which can serve as intrinsic motivation of the robot to become engaged with its environment. The robot learns to maintain an active low-level sensorimotor loop without abstract or specific information. Here we will study the possibility of including high-level information into this dynamical systems approach such that the robot can learn to reach a goal or to optimize its behavior according to external standards.

What can we expect from a *guided homeokinetic controller*? It has been shown earlier by Der et al. (2006) and Hesse et al. (2009) that a variety of behaviors can emerge from the principle of homeokinesis. The emerging behaviors show a coherent sensorimotor dynamics of the particular robot in its environment. With additional guidance the exploration of the homeokinetic controller can be channeled around desired or preferred behaviors such that control modes can be quickly found which match the given robotic task.

The behavior is essentially driven by intrinsic self-organization, while the goal is easily taken up by the system due to the optimal sensitivity of the homeokinetic control. In a sense, we are not considering here an approach to robot learning but rather an on-going dynamic realization of the (external or internal) hints as part of an exploratory regime.

In the present paper, we will advance our study of guided self-organization of behavior, presented in Martius and Hermann (2010), by an application to a high-dimensional system. In order to keep the paper self-consistent, we introduce the homeokinetic control principle in the next section and present then the guidance by supervised *teaching cues*. The latter are the basis for the guidance by cross-motor teaching that can be implemented by the specification of abstract motor relations. We will extend this framework and apply it to the locomotion of bracelet-like robots with up to 40 DoF.

## Self-Organized Closed-Loop Control

Self-organizing control for autonomous robots can be achieved by an intrinsic drive towards active and predictable behavior as described by the homeokinetic principle (Der, 2001). We assume that the dynamics of the sensor values  $x \in \mathbb{R}^n$  of the robot can be written as

$$x_{t+1} = \psi(x_t) + \xi_{t+1} \quad (1)$$

where  $\psi$  is the internal model maintained and adapted by the robot to predict future sensor values and  $\xi$  is the prediction error. The motor values (actions)  $y \in \mathbb{R}^m$  are generated by a controller implemented simply as a parametric map or one-layer neural network:

$$y_t = K(x_t, \mathcal{C}_t) = g(C_t x_t + h_t) \quad (2)$$

where  $g(\cdot)$  is a sigmoid function with  $g_i(z) = \tanh(z_i)$ . The controller parameters  $\mathcal{C}$  consist of a weight matrix  $C$  and a

bias vector  $h$ . We compose the map  $\psi$  from a forward model  $M(x, y, \mathcal{A})$  and the controller  $K(x, \mathcal{C})$  (Eq. 2) as

$$\psi(x_t) = M(x_t, y_t, \mathcal{A}_t) = M(x_t, K(x_t, \mathcal{C}_t), \mathcal{A}). \quad (3)$$

The function  $M$  is initially unknown, but the robot adapts it continuously in order to minimize the prediction error  $\xi_t$  by

$$\mathcal{A}_{t+1} = \mathcal{A}_t - \epsilon_a \frac{\partial}{\partial \mathcal{A}_t} \|\xi_t\|^2. \quad (4)$$

If the parameters  $\mathcal{C}$  were also adapted in this way then stable but typically trivial behaviors would be produced unless specific information is given to the robot.

The homeokinetic principle which we are going to use here normally does not need any specific information in order to produce a variety of elementary behaviors in a robot. We will show that this principle for the self-organization of behavior offers also a new perspective for learning in robots. That is, if additional information is available then a homeokinetically controlled robot can use this information more efficiently. This follows from the strongly enhanced sensitivity of the learning system and establishes a novel approach to learning in robots.

The homeokinetic principle suggests to use the so-called *time-loop error* (TLE) which is based on the reconstructed sensor values  $\hat{x}_t$ . Using Eq. 1 and assuming for now that  $\psi$  is invertible we define

$$\hat{x}_t = \psi^{-1}(\psi(x_t) + \xi_{t+1}) = \psi^{-1}(x_{t+1}) \quad (5)$$

which are sensor values that would have made the prediction perfect. Intuitively  $\hat{x}_t$  is obtained by going forward in time from  $x_t$  to  $x_{t+1}$  and then backward in time to  $\hat{x}_t$ . This sequence is called the time loop and thus the TLE is

$$E_{TLE} = \|v_t\|^2 \quad \text{with} \quad v_t = x_t - \hat{x}_t \quad (6)$$

which minimizes the mismatch between true sensor values  $x_t$  and their reconstruction  $\hat{x}_t$ .

In linear approximation we obtain  $v_t \approx L_t^{-1} \xi_{t+1}$ , where the matrix  $L_t = \frac{\partial \psi(x_t)}{\partial x_t}$  is the Jacobian of  $\psi$  at time  $t$ . Note that  $v_t$  can only be calculated after  $x_{t+1}$  is available. We account for non-invertible  $L$  by using a regularized inverse. The TLE

$$E_{TLE} = \|v_t\|^2 \approx \xi_{t+1}^\top (L_t L_t^\top)^{-1} \xi_{t+1}, \quad (7)$$

minimizes the norm of  $v$  (Eq. 6) and accounts for the error  $\xi$  (Eq. 1) only as much as it is transformed by the inverse dynamics of the system. This reveals another important feature of this error quantity, namely to minimize the norm of the inverse Jacobian. This results in an increase of predominantly the small eigenvalues of  $L$ . Therefore, the controller performs a destabilization in time. This eliminates the trivial fixed points (in sensor space) and enables spontaneous symmetry breaking which shows in the robot e. g. as a transition

from rest to a directed movement. Nevertheless, the system does not start to behave chaotically or enters uncontrollable oscillations because the destabilization is limited by the non-linearity  $g(\cdot)$  (Eq. 2). Intuitively, homeokinesis can be understood as the drive towards non-trivial behaviors that are still predictable by the internal model. Since the internal model is simple, smooth behaviors are preferred. Fig. 1 illustrates how the homeokinetic controller is connected to a robot.

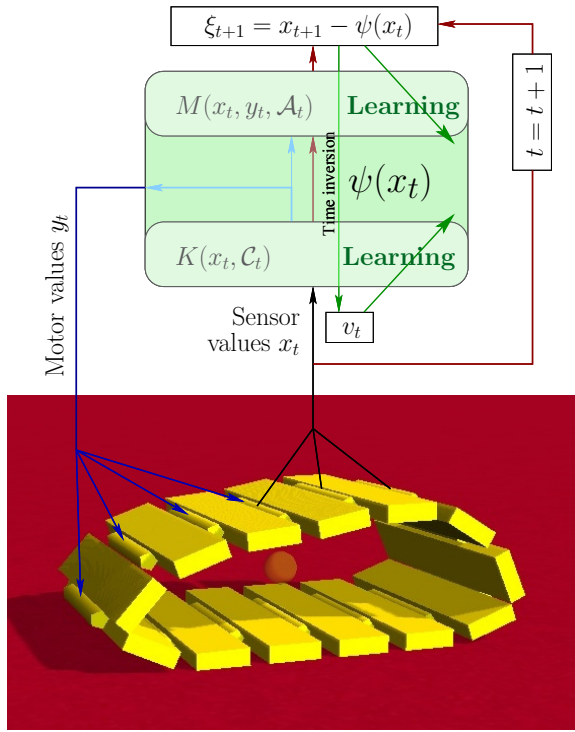

Figure 1: The homeokinetic controller connected to the ARMBAND robot. The ARMBAND consists here of  $m = 13$  flat segments that are connected by actuated joints. It receives sensory inputs  $x_i$  from the joint position sensors. The control architecture consists of the controller  $K$  and the predictor  $M$  which are combined to form  $\psi$ , see Eqs. 1 - 2. The transparent ball indicates the center of mass of the robot. It is used for evaluation of performance but not for control.

The TLE (Eq. 7) is minimized by gradient descent which gives rise to a parameter dynamics that evolves simultaneously with the state dynamics, see e. g. (Hesse et al., 2009).

$$\begin{aligned} C_{t+1} &= C_t - \epsilon_c \frac{\partial}{\partial C} E_{TLE} \\ h_{t+1} &= h_t - \epsilon_c \frac{\partial}{\partial h} E_{TLE} \end{aligned} \quad (8)$$

The learning rates  $\epsilon_c \approx \epsilon_A$  for the controller and the model are chosen such that the system adapts on the behavioral time scale. Because of unavoidable sensory noise, the TLE is never zero, neither does it have a vanishing gradient. The

rule (Eq. 8) produces therefore a continuously itinerant trajectory in the parameter space, i. e. the robot traverses a sequence of behaviors that are determined by the interaction with the environment. These behaviors are, however, waxing and waning and their transitions are hard to predict.

As an example, consider a robot with two wheels that is equipped with wheel velocity sensors. In the beginning the robot rests, but after a short time the homeokinetic learning rule initiates autonomous forward, backward or turning movements. If a wall is encountered that causes the wheels to stop, the robot will immediately reduce the motor speed and change the internal parameter to regain sensitivity. Eventually it will drive in a free direction. A more complex example for the self-organization of *natural* behaviors was provided by a spherical robot (Martius and Herrmann, 2010) that is actuated by movable internal masses. After a short time the robot starts to roll around one of its internal axes, but switches to a different axis every so often. Furthermore, high-dimensional systems such as serpentoid or catenoid robots, quadrupeds, hexapods and wheeled robots have been successfully controlled (see Martius et al. (2011)).

It is of particular interest that the control algorithm induces a preference for movements with a high degree of coordination among the various degrees of freedom. All the robotic implementations demonstrate the emergence of play-like behavior, which are characterized by coordinated whole body movements seemingly without a specific goal. The coordination among the various degrees of freedom arises from their physical coupling that is extracted and enhanced by the controller, because each motor neuron is adapted to be sensitive to coherent changes in all degrees of freedom due to Eq. 8.

## Guided Self-Organizing Control

How can we guide the joint dynamics of state (1) and parameters (8) in order to realize a given goal by the self-organizing process? One option is to modify the lifetime of the transient behaviors depending on a given reward signal, see Martius et al. (2007). A second and more stringent form of guidance was proposed by Martius and Herrmann (2010) and will be augmented and applied to a high-dimensional system in the present paper. We will formulate the problem in terms of problem-specific error functions (PSEF) that indicate an external goal by minimal values. A trivial example of such an error function is the difference between externally defined and actually executed motor actions. This is a standard control problem which, however, becomes difficult if the explorative dynamics is to be preserved.

GSO focuses on this interplay between the explorative dynamics implied by homeokinetic learning and the additional drives. The challenge in the combination of a self-organizing system with external goals becomes clear when recalling the characteristics of a self-organizing system. One important feature is the spontaneous breaking of symmetries

of the system. This is a prerequisite for spontaneous pattern formation and is usually achieved by self-amplification, i.e. small noisy perturbations cause the system to choose one of several symmetric options while the intrinsic dynamics then causes the system to settle into this asymmetric state. A nonlinear stabilization of the self-amplification forms another ingredient of self-organization. These two conditions which we will call our working regime, are to be met for a successful guidance of a self-organizing system. There are several ways to guide the homeokinetic controller which we will discuss in the following.

### Guidance by Problem-Specific Teaching

First we will describe how problem-specific error functions (PSEF) can be integrated. Recall that the adaptation of the controller parameters is done by performing a gradient descent on the time-loop error. The PSEF must depend functionally on the controller parameters in order to enable the same procedure. Unfortunately, the simple sum of both gradients (of the time-loop error and of the PSEF) is likely to steer the system out of its working regime. Furthermore, we cannot easily identify a fixed weighting between the two gradients that would satisfy an adequate pursuit of the goal while maintaining explorativity. One reason is that the non-linearity (Eq. 2) in the TLE causes the gradient to vary over orders of magnitude. A solution to this problem can be obtained by scaling the gradient of the PSEF according to the Jacobian matrix (see 7) of the sensorimotor loop such that both gradients become compatible. This transformation is essentially a natural gradient with the Jacobian matrix of the sensorimotor loop as a metrics. The update for the controller parameters  $C$  is now given by

$$\frac{1}{\epsilon_C} \Delta C_t = -\frac{\partial E_{TLE}}{\partial C} - \gamma \frac{\partial E_G}{\partial C} (L_t L_t^\top)^{-1}, \quad (9)$$

where  $E_G$  is the PSEF and  $\gamma \geq 0$  is the guidance factor deciding the strength of the guidance. For  $\gamma = 0$  there is no guidance and we re-obtain the unmodified dynamics (Eq. 8).

For clarity we will start with a very simple goal, namely we want a robot to follow predefined motor actions called *teaching signals* in addition to the homeokinetic behavior. We can define the PSEF as the mismatch  $\eta_t^G$  between motor teaching cues  $y_t^G$  and the actual motor values, thus

$$E_G = \|\eta_t^G\|^2 = \|y_t^G - y_t\|^2. \quad (10)$$

Since  $y_t$  is functionally dependent on the controller parameters (Eq. 2), the gradient descent can be performed, i.e. the derivative reads  $\frac{\partial E_G}{\partial C_{ij}} = -\eta_i^G g_i' x_j$ , where  $g_i' = \tanh' \left( \sum_{j=1}^n C_{ij} x_j + h_i \right)$  (all quantities at time  $t$ ). A similarly motivated approach is in linear systems is homeotaxis (Prokopenko et al., 2008).

An evaluation of the guidance mechanism has been performed using the TWOWHEELED robot, which was simulated in the realistic robot simulator LPZROBOTS (Martius

et al., 2011). The motor values determine the nominal wheel velocities and the sensor values report the actual wheel velocities of both wheels. We provided to both motors the same oscillating teaching signal. The resulting behavior is a mixture between the taught behavior and self-organized dynamics depending the value of  $\gamma$ . For  $\gamma = 0.01$  the teaching cues are followed most of the time but with occasional exploratory interruptions, especially when the teaching cues have a small absolute value. In this case the system is closer to the bifurcation point where the two stable fixed points for forward and backward motion meet. These interruptions cause the robot, for example, to move in curved fashion instead of strictly driving in a straight line as the teaching cue suggest. The exploration around the teaching signals might be useful in general to find modes which are better predictable or more active.

Interestingly, we can similarly define a mechanism that uses teaching cues in terms of sensor values (Martius and Herrmann, 2010).

### Guidance by Cross-Motor Teaching

Guidance mechanism can also use internal teaching signals. As an illustrative example, consider the mirror-symmetry that is preferred in many control systems. We will first follow this idea and describe a simple implementation following this example before we generalize this scheme later in order to apply it to high-dimensional systems. In either case, motor values of some motors will be used as teaching signals for other motors.

**Pairwise symmetries.** For two motors, guidance can be introduced by

$$y_{t,1}^G = y_{t,2} \quad \text{and} \quad y_{t,2}^G = y_{t,1}, \quad (11)$$

where  $y_t^G$  is the vector of nominal motor values, see (9, 10). For experimental evaluation we placed the TWOWHEELED robot in an environment cluttered with obstacles and performed many trials for different values of the guidance factor. The robot was rewarded for straight movement and was therefore expected not to get stuck at obstacles or in corners and cover substantial parts of its environment. In order to quantify the influence of the guidance we recorded the trajectory, the linear velocity, and the angular velocity of the robot. We expect an increase in linear velocity because the robot is to move straight instead of circling. For the same reason the angular velocity should be lowered. In Fig. 2 the behavioral quantification and a several sample trajectories are plotted. Additionally the relative area coverage is shown, which indicates that much more area of the environment was covered by the robot with guidance compared to freely moving robot. As expected, the robot shows a distinct decrease in mean turning velocity and a higher area coverage with increasing values of the guidance factor until the guidance becomes dominant and the performance drops. In the

Figure 2: Behavior of the TWOWHEELED robot when guided to move preferably straight. **(a)** Mean and standard deviation (of five runs each 20 min) of the area coverage (**area**), the average velocity  $\langle |v| \rangle$ , and the average angular velocity  $\langle |\omega_z| \rangle$  for different values of the guidance factor  $\gamma$ . Area coverage (box counting method with  $300 \times 300$  boxes) is given in percent relative to case  $\gamma = 0$  (**right axis**). The robot is driving straighter and its trajectory covers more area for larger  $\gamma$ . The inset shows a screenshot of the simulation. **(b)** Example trajectories for different guidance factors. Note that for  $\gamma = 0.1$  still many boxes are visited but less well spread. Parameters:  $\epsilon_c = \epsilon_a = 0.01$ , update rate 100 Hz.

normal regime the robot is still performing turns and drives both backwards and forwards and that it does not get stuck at the walls, as seen in the trajectory in Fig. 2(b), is because the sensitivity (exploration) and predictability (exploitation) of the controller remain. If the guidance is too strong the favorable properties of the self-organizing behavior are lost such that the robot stalls or performs repetitively the same motion. Note that already very small values of  $\gamma$  yield a high effect of the guidance.

**Permutation relations.** In a more general cross-motor teaching setup, each motor has one incoming and one outgoing connection, such that there is still only one teaching signal per motor. The connections can be described by a permutation  $\pi_m$  of  $m$  motors that assigns each motor a source of teaching input. The teaching signal is then given by

$$(y_t^S)_i = (y_t)_{\pi_m(i)} \quad \text{for } i = 1, \dots, m. \quad (12)$$

With a cyclic schema of connections a group of motors can be synchronized. In the following experiment we use a rotation-symmetric motor connection setting to show that a high-dimensional chain-like robot can quickly develop a locomotion behavior.

The ARMBAND robot consists of a sequence of flat segments placed in a ring-like configuration, where subsequent segments are connected by motor-operated hinge joints. As a result we obtain a robot with the appearance of a bracelet or chain, see Fig. 1. Each joint provides a sensor value of the current position. The motor values define target joint positions, which typically cannot be reached due to substantial

physical constraints and underactuation. In this way the controller obtains informative feedback from the robotic body. Since the robot is symmetric there is by construction no preferred direction of motion, meaning that the homeokinetically controller robot will move forward or backward with equal probability. The robot cannot turn or move sideways, but it can produce a variety of postures and locomotion patterns.

With the method of cross-motor teaching we can select different symmetries, such that the robot is more likely to perform a directed motion. For that we define the permutation used in Eq. 12 as

$$\pi_m(i) = (i + k + \lfloor m/2 \rfloor) \mod m, \quad (13)$$

where  $k \in \{-1, 0, 1\}$ . Coarsely speaking, this connects motors on the opposite side of the robot with a shift to one or the other side in a way that depends on  $k$ . The choice of  $k$  reflects the desired direction of motion and depends on whether the number of joints  $m$  is even or odd. If  $m$  is even then  $k = -1$  and  $k = 1$  are used for both directions (forward or backward) and  $k = 0$  represents a point symmetric connection setup. In the latter case the robot will not prefer a direction of motion and the behavior is similar to the case without guidance. For odd values of  $m$ , which is used here,  $k = 0$  and  $k = 1$  need to be used, resp., for backward and forward motion. In the following experiments the robot has  $m = 13$  motors. The motor connections for  $k = 1$  are shown in Fig. 3. Each motor connection is displayed by an arrow pointing to the receiving motor. Note that the connections are directed and a motor is not teaching the same motor from which it is receiving teaching cues. For  $k = 0$  (and  $n$

Figure 3: ARMBAND robot with cross-motor connections. Links are connected by hinge joints that are actuated by servo motors. The curved arrows indicate unidirectional cross-motor connections. For these connections the robot preferably moves leftwards. All links are identical, but four links are drawn boldly for better visibility.

odd) all arrows are inverted, meaning that for each connection the sending and receiving motors would swap roles.

## Results

To evaluate the performance we conducted for different values of the guidance factor  $\gamma_S$  five trials each 30 min long. In a first setting the cross-motor connections were fixed ( $k = 1$ ) for the entire duration of the experiment. We observed the formation of a locomotion behavior after a very short time. Note that this behavior requires all joints of the robot to be highly coordinated. As a quantitative measure of the performance we calculate the horizontal velocity  $v$  using the center of mass of the robot. Thus, the velocity is a scalar and we define forward motion if  $v > 0$  and backward motion if  $v < 0$ . In this experiment we expect the robot to move only forward, because a fixed cross-motor connection setup was used. The average velocity of the robot increased distinctively with raising guidance factors, see Fig. 4(a). For excessively large values of the guidance factor  $\gamma_S$  the velocity goes down again. This occurs for two reasons: First, the cross-motor teaching has a too strong influence on the working regime of the homeokinetic controller and second the actual motor pattern of the locomotion behavior does not perfectly obey the relations between the motor values, not all motor values are exactly equal. Again, already a small value of  $\gamma$  is sufficient to achieve the goal. It appears the self-organizing system needs only very little influence to be guided into the desired regions of the behavior space.

Without guidance the robot moves equally to both directions but with comparably low velocity. This can be seen at the mean of the absolute velocity in Fig. 4(a). If the value of the guidance factor is chosen conveniently, the robot moves in one direction with varying speed see Fig. 4(b) for 3 velocity traces. The velocity traces are seen to have a peak followed by a dip before a more steady regime is attained. It appears that the controller learning surpasses a more optimal

configuration with respect to the velocity, but there the trade-off between self-organizing and guidance is not met. Later strong fluctuations may occur that reflect the explorative nature of the homeokinetic part. The locomotive behavior can also be seen in Video 1, see Ref. (Supplement, 2011), for a low value of guidance factor ( $\gamma_s = 0.001$ ) and in Video 2 for a medium value of guidance factor ( $\gamma_s = 0.003$ ).

In a second setup, we changed the cross-motor connections every 5 min, i. e.  $k$  was changed from 0 to 1 and back. A value of  $k = 0$  should lead to a negative velocity and a  $k = 1$  to a positive velocity. To study the dependence on the guidance factor and to measure the performance we use the average absolute velocity ( $\langle |v| \rangle$ ) and the correlation of the velocity with the configuration of the connections ( $\rho(v, k)$ ), see Fig. 5(a). Without guidance ( $\gamma_S = 0$ ) there is, as expected, no correlation with the supposed direction of locomotion. For a range of values of the guidance factor we find a high total locomotion speed with a strong correlation to the supposed direction of motion. Note that the size of the correlation depends on the length of the intervals of one connection setting. For long intervals the correlation will approach one. In Fig. 5(b) the velocity of the robot is plotted for different runs with the same value of the guidance factor that was used in the previous experiment ( $\gamma_S = 0.003$ ). We observe that the robot changes the direction of motion shortly after the configuration of connections was changed, see also Video 3 at Supplement (2011).

The locomotion of the robot is essentially influenced by the number of cross-motor connections. For that we use again the fixed connectivity. In a series of simulations a number  $0 \leq l \leq m$  equally spaced cross-motor connections (Fig. 3) are used. With increasing  $l$  the robot start to locomote earlier. Full performance is reached already if 8 out of the 13 connections are used, see Fig. 6(a).

In order to study the scaling properties of the learning algorithm we varied the number of segments  $m$  of the robot and thus the dimensionality of the control problem. The results are astonishing, see Fig. 6(b): The behavior is learned with the same speed also for large number (40) of segments. There is no scaling problem here for the following reason. In the closed loop with an approximate feedback strength (self-regulated by the homeokinetic controller) the robot needs only very little influence to roll. The length of the robot can even help because other behavioral modes (e. g. wobbling) are damped increasingly due to gravitational forces. For the same reason, small robots are slower than medium ones. Large robots are again slower because the available forces at the joints become too weak. The experiment illustrates that specific behaviors can be achieved in a high-dimensional robot by using cross-motor teachings. Cross-motor connections can break the symmetry between the two directions of motion such that a locomotory behavior is produced quickly. When the connections are switched later during runtime, the behavior of the robot changes reliably.

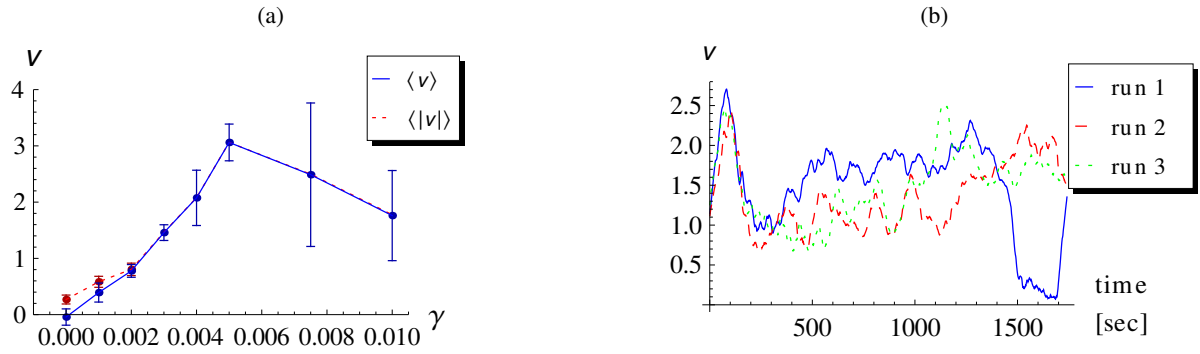

Figure 4: Performance of the ARMBAND robot with constant cross-motor teaching. **(a)** Mean and standard deviation of the average velocity  $\langle v \rangle$  and the average absolute velocity  $\langle |v| \rangle$  of five runs for different guidance factors  $\gamma_S$ . **(b)** Velocity of the robot  $\bar{v}$  (average over 1-minute sliding window) for three runs at  $\gamma_S = 0.003$ ,  $k = 1$ ,  $\epsilon_c = \epsilon_a = 0.1$ , 100 Hz update rate.

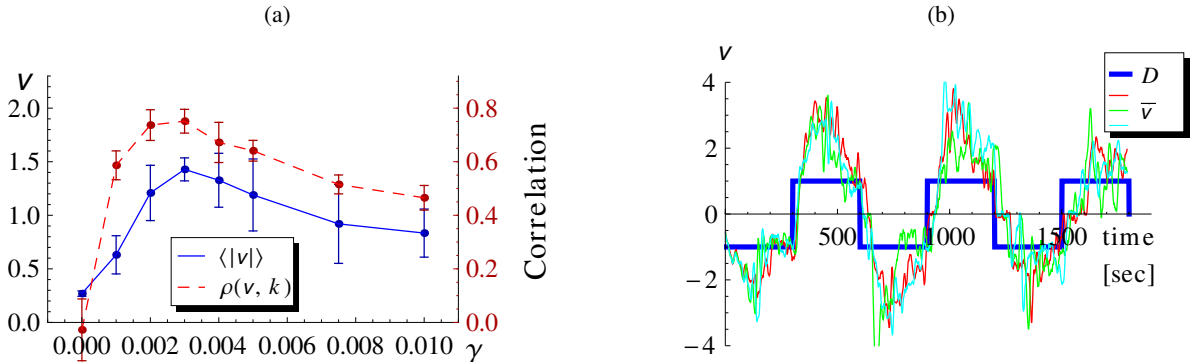

Figure 5: Performance with switching cross-motor teaching. **(a)** Mean and standard deviation of the average absolute velocity  $\langle |v| \rangle$  and the correlation  $\rho(v, k)$  of the velocity with the configuration of the connections of five runs for different guidance factors  $\gamma_S$ . **(b)** Velocity (average over 10-seconds sliding window) for three runs of the robot with a supposed direction of motion  $D$ . Parameters as in Fig. 4.

The guidance mechanism can also be transferred to sensor space using the direct sensor teaching, which was discussed above and was proposed by Martius and Herrmann (2010). One obtains a cross-sensor teaching analogously to the definitions given above. This can become useful, for example, if a certain behavior is demonstrated by a human operator by passively moving the robot. In the case of the ARMBAND robot, one can easily imagine that the robot is pushed along the ground such that a locomotion pattern is formed. Based on the sensor readings, the correlations between the sensor channels can be determined and serve as a basis for the construction of a specific cross-sensor teaching configuration.

## Discussion

We have presented here two mechanisms to guide the homeokinetic self-organization of behavior. The first one uses desired motor patterns that were introduced into the learning dynamics by means of an additional error function. The strength of guidance can be conveniently adjusted. We have considered also cross-motor teaching as a new way of using the directed teaching to select desired behaviors. The

approach introduced here is realized by a permutation of the motors signal for teaching. We applied this algorithm to a bracelet-like robot (ARMBAND) with many degrees of freedom and demonstrated the accelerated development of locomotion behavior from scratch. Even the relearning to the opposite direction of motion is possible very quickly. Since the learning is very fast and the performance changes gradually with changing  $\gamma$ , the guidance factor could be adapted automatically. Most striking is the scaling of the algorithm to higher dimensions. In the present case the performance did not decrease when the robot was enlarged to have 40 DoF. This is a result of the exploitation of the embodiment by the self-organization process.

The exploratory character of the controller is retained under guidance and helps to find a behavioral mode even if the specification of the motor teaching signals are partially contradictory. For example, the TWOWHEELED robot can choose freely between driving forward or backward, because the behavior-space is only partially constrained. Furthermore, it is evident that the robot remains sensitive to small perturbations and continues to explore its environment. The

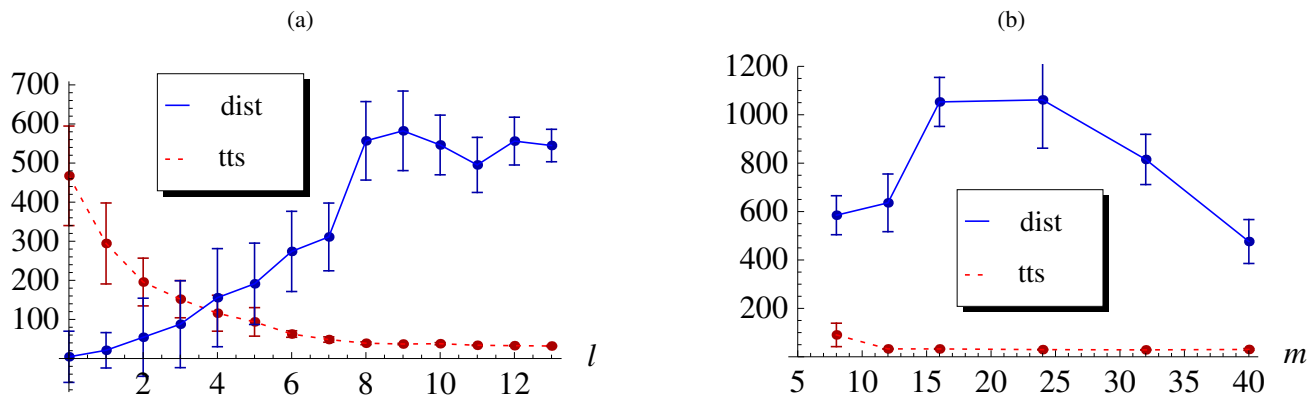

Figure 6: Scaling of learning time and performance for different robot complexity. The plots show mean and standard deviation of the distance traveled by the robot ('dist' in units of 1 segment size) and of the time-to-start ('tts' in seconds) of 20 runs à 10 min ( $\gamma = 0.003$ ). (a) Performance as a function of the number of cross-motor connections  $l$  (equally spaced around a robot with  $m = 13$  joints). (b) Performance for different numbers of segments  $m$  (DoF) with full cross-motor connectivity ( $l = m$ ).

constraints are not strictly enforced by the algorithm but the self-organization can find a mode that fits better to the particular embodiment. The presented experiments with the ARMBAND demonstrate this effect. The guidance signal alone would synchronize all motors to the same value (same phase in the oscillations) which does not lead to a locomotion behavior whereas the combined learning dynamics leads to a smooth and adaptive locomotion, see Video 3 (Supplement, 2011).

## Abstract

Vicarious trial-and-error(VTE) is a type of conflict-like behavior, observed in route selection tasks (Tolman (1939)). Studies of VTE have shown a correlation between the number of VTEs exhibited by a system with its learning efficiency. At the onset of learning a task, the number of VTEs increases, and when the learning reaches its plateau, it decreases.

The question we explore in this paper concerns the role of VTE. Basing ourselves on a model developed by Bovet and Pfeifer (2005), we ran robotic experiments to compute the number of VTEs during the learning of a T-maze task. Our results first show that what has been found in rats can be replicated in artificial systems. Furthermore, by changing the connectivity pattern of the original model, we discovered that the connection between VTEs and learning efficiency might not be necessarily true as our results show that two models exhibiting the same performance can possess a different pattern of VTEs. By comparing the robustness of the two models under varied conditions, we propose that VTEs are connected to the adaptivity of a system to environmental changes.

## Introduction

In his experiments, Tolman (1939) observed that rats are seemingly hesitating when they must choose between one of two rooms, one of which containing a reward while the other being empty. The only cue differentiating the rooms is the color of their doors. A black door indicates the room provides a reward, and a white color indicates an empty room. To reach the reward, the rats must learn the relationship between the color of the door and the presence of the reward. During the learning phase, the rats have been seen moving their head from one door to another which is referred by Tolman as a conflict-like behavior named "vicarious trial-and-error (VTE)". In his experiments, Tolman noticed that the number of VTEs increases at the onset of the learning phase to start decreasing when the performance reaches its plateau. From that observation, VTE has been connected to learning efficiency.

Following Tolman's observations, other researchers started paying attention to the presence of VTEs in their studies. Hu and Amsel (1995) showed hippocampal contribution to VTEs. Johnson and Redish (2007) reported the

presence of VTEs in experiments on rats who were shown to be simulating their next decisions internally before acting. Tarsitano (2006) found that, in a detour task, jumping spiders display two phases of action: the inspection phase, where spiders stop and inspect possible routes toward a target, and the locomotory phase, where spiders move toward a single direction. VTEs have been observed during the inspection phase. Tarsitano concluded that "one can speculate that it is a small but significant jump to use trial and error vicariously when choosing a goal to approach". Ikegami (2007) suggested the relationship between VTEs and private simulation. From these researches, VTE seems to have some essential role in internal reflection and decision making. However, the role of the VTEs has yet to be fully investigated.

The question we explore in this paper concerns the role of VTE. Using a model developed by Bovet and Pfeifer (2005) for T-maze learning experiments on robotic platforms, we study the presence of VTEs during the acquisition of the task. Our results display the same pattern of increase followed by a decrease in the number of VTEs as observed in the rat. Additionally we vary environmental parameters as well as the connectivity of the network in order to study the variations in the number of VTEs. Based on our results we hypothesize that VTEs might be connected to robustness and adaptivity. We first detail the environmental setup and the neural model in the next two sections. Then the results will be presented with a discussion of their significance.

## Methodology

Our work is based on a robotic and neural model developed by Bovet and Pfeifer. The model combines five types of modalities to control a robot in a T-maze task. The neural model is self-organized with no hierarchy between modalities, nor predetermined sensori-motor relationship. Modalities are associated through Hebbian learning only (Hebb (1949)).

Figure 1: T-maze environment used for the experiment. At the beginning of each trial, the robot is placed on the central arm of the maze. The circle at the choice point represents the tactile cue, the star at one end of the maze indicates reward, and the lightning at the other end of the maze stands for punishment. The back wall is painted black and the other walls are white, which are detected by the robot's omnidirectional camera. Walls of the T-maze are perceived by the robot's proximity sensors. The length and the width of the T-maze are denoted by 'X' and 'Y'.

### Experimental setup

The environment is a T-maze with one central arm and two side ones (see figure 1). A reward is located at the end of one arm, and a punishment is placed on the opposite one. The robot learns to reach the reward following a tactile cue placed at the end of the central arm, on the same side as the reward.

The robot is modeled following the e-puck robot (Mondada et al. (2009)) and is equipped with the following sensors and motors:

- 1) **Tactile sensors:** Tactile stimulation comes from 32 whiskers attached to the left and right sides of the robot. The signal is binary, on or off. Whisker sensors detect the tactile cue at the intersection point of the T-maze. The walls of the T-maze are low enough so that the whiskers can only detect the cue.
- 2) **Vision sensors:** Visual stimulation reflects the activity of the omnidirectional camera, which return grayscale values standardized from 0 to 1. This camera is composed of 20 pixels aligned horizontally. Everything in the T-maze is made white or transparent, except for the black back wall. In other words, the omnidirectional camera gets positive signals only from the black wall at the back of the T-maze. By this modality, the robot acquires destination information.
- 3) **Proximity sensors:** Six proximity sensors are regularly attached to the front half of the body. These sensors detect the distance from the robot to the walls of the T-maze. The values are standardized between 0 and 1. These sensors

are attached low enough to only detect the walls of the T-maze. This modality is involved in the experiment only indirectly to achieve wall avoidance.

- 4) **Reward sensitivity:** The reward sensitivity is usually set to 0. It is raised to 1 to signal a reward and lowered to -1 to indicate punishment. The value is dependent on which side of the maze is reached by the robot.

- 5) **Motors:** The forward velocity of the robot  $v_f$  is constant and positive, and the turning degree  $v_t$  is determined by the neural controller of the robot which is explained later. Both  $v_t$  and  $v_f$  are standardized between 0 and 1, and activate actual left and right wheel velocities,  $v_l, v_r$ , as following:

$$\begin{pmatrix} v_l \\ v_r \end{pmatrix} = C \cdot \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \cdot \begin{pmatrix} v_f \\ v_t \end{pmatrix} \quad (1)$$

where  $C$  is a constant for converting the standardized value to the actual motor speed. If  $v_t > 0$ , then  $v_l < v_r$ , which makes the robot turn left, and  $v_t < 0$  produces a right turn.

As a training phase, the robot runs randomly in an empty maze with no tactile cue nor reward signals. Afterward, the tactile cue and the reward are introduced into the T-maze, and the robot must complete the task. The robot learns the correlation between modalities through Hebbian learning while acquiring a reward seeking behavior (for more detailed explanations, see Bovet and Pfeifer (2005)).

### Neural Network - Bovet et al.'s Original Model

The neural network is composed of five modality modules: tactile, vision, proximity, reward, and motor (figure 2(a)). Each of them plays a separate role in treating the signals from its corresponding sensor (or motor) on the robot. Each modality has five types of neural populations, described in figure 2(b). These five populations are composed of the same number of artificial neurons, this number varying depending on the type of modality. For instance, the tactile modality has 32 neurons for each of the five populations while the motor modality has only one neuron per population. The five types of populations are described as follows:

- 1) **Current state** The current state of modality  $M$ ,  $\mathbf{x}^M(t) = (x_1^M(t), x_2^M(t), \dots, x_m^M(t))$ , receives signals from the corresponding sensors (or motors). For instance, tactile stimuli from 32 whisker sensors activate the corresponding 32 nodes of the current state.
- 2) **Delayed state** The delayed state  $\tilde{\mathbf{x}}^M(t) = \mathbf{x}^M(t - \tau)$  receives signals  $\tau$  timestep in the past.
- 3) **Current state change** The current state change  $\mathbf{y}^M(t)$  is the difference between the current and the delayed state,

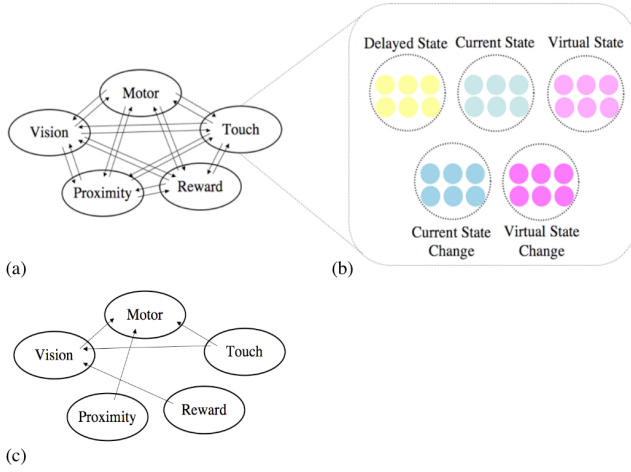

Figure 2: (a) Five sub-systems for each modalities make up the whole cognitive system of the robots. These modalities are fully connected with each other. (The original model) (b) Five types of neural populations, called the current state, the delayed state, the current state change, the virtual state, the virtual state change. (c) A new neural network where the five modalities are sparsely connected sparsely. (The minimal model)

as described below:

$$\begin{aligned} \mathbf{y}^M(t) &:= \mathbf{x}^M(t) - \tilde{\mathbf{x}}^M(t) \\ &= \mathbf{x}^M(t) - \mathbf{x}^M(t - \tau) \end{aligned} \quad (2)$$

**4) Virtual state** The virtual state of modality  $M$ ,  $\tilde{\mathbf{x}}^M(t)$ , is activated by the virtual state change of other modalities:

$$\tilde{\mathbf{x}}^M(t+1) := f(\sum_{N \neq M} W^{MN}(t) \cdot \tilde{\mathbf{y}}^N(t)) \quad (3)$$

where  $W^{MN}$  is the weight matrix connecting modality  $M$  to modality  $N$  and  $f(x)$  is a sigmoid function, written as:

$$f(x) = \frac{1.0}{1.0 + \exp(-a \cdot x)} \quad (4)$$

**5) Virtual state change** The virtual state change of modality  $M$ ,  $\tilde{\mathbf{y}}^M(t)$ , is the difference between the virtual and the current state.

$$\tilde{\mathbf{y}}^M(t) := \tilde{\mathbf{x}}^M(t) - \mathbf{x}^M(t) \quad (5)$$

The current state population, delayed state population and current state change population do not possess any in or out connections toward other modalities. All virtual state change populations are connected to virtual state populations of the other modalities. For instance, the neurons from the virtual state change population of the tactile modality

are connected to the neurons of the virtual state population of all the other modalities. Those connections are the only ones present in the model.

All the connections of the model are tuned using a modified version of Hebbian learning. The main difference between Hebb's version is that the pre and post synaptic neurons are not used to compute the change of the synaptic connections. For the learning, the neurons of the non-virtual populations are used. Instead of the virtual state population, the neurons of the current state population are used for the Hebbian learning. Similarly, the neurons of the current state change population replace the ones from the virtual state change population. Mathematically, this corresponds to the following equations:

$$\begin{aligned} \Delta W^{MN}(t) &:= l \cdot (\mathbf{x}^N(t) \mathbf{y}^M(t)^T - \alpha \mid \mathbf{y}^M(t) \mid W^{MN}(t)) \\ W^{MN}(t+1) &= W^{MN}(t) + \Delta W^{MN}(t) \end{aligned} \quad (6)$$

where  $l$  is the learning rate and  $\alpha$  is the forgetting rate. Because of the  $\alpha$ , the weight between a pair of neurons is decreased if the two neurons are not activated at the same time. It also prevents the weights from growing to infinity.

To clarify the inner algorithm of the neural model, we detail the steps leading to the generation of the outputs as follows:

1. Sensory information is transferred to the current state population.
2. The delayed state population is updated, followed by the current state change population.
3. Hebbian learning is applied on all the connections of the model.
4. The activity of the neurons from the virtual state change populations of all modalities are propagated to the neurons of the virtual state populations using a feedforward algorithm (see equation 3).
5. The activation of the single neuron of the virtual state population from the motor modality is assigned to the output  $v_t$  from equation 1.

For additional details on this model, please refer to the original paper Bovet and Pfeifer (2005).

## Neural network - Minimal model

In addition to the original neural network invented by Bovet and Pfeifer, we conducted experiments with a new neural network model. In the original model, modalities are fully connected (figure 2(a)), while our new model has only minimal connectivity among modalities. By "minimal" connectivity, we mean connections which have a specific role to solve the task. Those connections are mentioned in Bovet's

paper and stem from his analysis of the neural network, as shown in figure 2(c). We expect that the behavioral difference between the original and the minimal connectivity model will allow us to uncover the role of VTE.

### Setup of the Genetic Algorithm

Bovet and Pfeifer’s model relies on the following parameters: learning rates and forgetting rates for each modalities, update frequency of the neural network,  $\tau$  for the delayed state and constants for the sigmoid function in equation 4. Despite the authors not mentioning how to select those parameters, we found out that slight differences in their value can strongly influence the performance of the robot. This is partly due to our experiments adopting more tolerant conditions than the original experiment, like a broader T-maze. To tune these parameters and optimize the performance of the controller, we employ a genetic algorithm (GA)(Holland (1975)). Our GA possesses a population of 100 individuals to optimize 59 parameters using tournament selection, single point crossover applied with a probability of 70% and a 1% mutation rate. We also use elitism by simply copying the 5 best individuals directly to the next generation. A fitness function  $F(t)$  at generation  $t$  is calculated as:

$$F(t) = \begin{cases} +5 \text{ points, if it reaches the reward.} \\ +0.25 \text{ points, if it reaches the punishment.} \\ +0 \text{ points, if it gets timeout.} \end{cases} \quad (7)$$

The amount of points assigned is determined arbitrarily. The trials are repeated 100 times from one fixed initial position, which gives a maximum fitness value of 500. We conducted several runs of the GA for the original and the minimal model respectively.

### Results

For each model, we evolved 5 runs of GA. Figure 3 shows 2 out of 5 GA runs get the maximum fitness value (100% success) with the original model, and, in the case of the minimal model, 3 out of 5 GA runs successfully evolved. We selected one individual for each model from these evolved runs and counted the number of VTE they displayed.

It is important to notice that evolution produces different strategies for both models and that not all of them shows VTEs. For that reason we chose to work on 5 runs of GA but more have been evolved and analyzed despite not being presented here.

Our methodology to count the number of VTE in a robot is similar to the one used by Tolman. In our case, the robot does not possess a head moving independently from its body so the whole body movement has to be considered. One VTE is granted if the turning degree  $v_t$  from the equation 1 changes its sign. In order to filter small oscillations around a turning degree of 0, a VTE is only granted if the sign change is outside the range  $[-0.3; 0.3]$ .

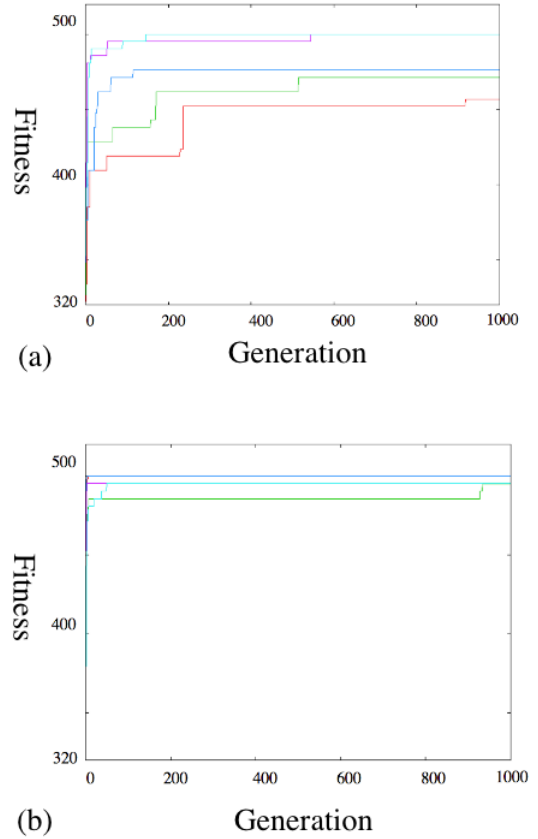

Figure 3: Fitness values of the five runs of GA. The X axis represents the number of generations, and the Y axis the fitness of the best individual in each generation. Maximum fitness value is 500. (a) In the case of the original model. Two out of five runs of GA get the maximum value. (b) In the case of the minimal model. Three out of five runs get the maximum value.

Figure 4 shows the number of VTEs observed for one evolved individual for each model. We can see from figure 4(a) that the robot evolved with the original connectivity model exhibits more VTEs at the beginning of the learning, to decrease afterward. This observation is similar to Tolman’s experiments on real rats (Tolman (1939); Muenzinger and Fletcher (1934)). On the other hand, the robot with the minimal connectivity model shows VTEs in a lower amount while remaining constant during the course of the experiment (figure 4(b)). Despite this difference in the number of VTEs, both models show a success rate of 100%. This result implies that VTEs are not directly related to performance in learning, but might have another purpose.

In order to try to understand what differentiates the two models, we looked at how the synaptic strengths are chang-

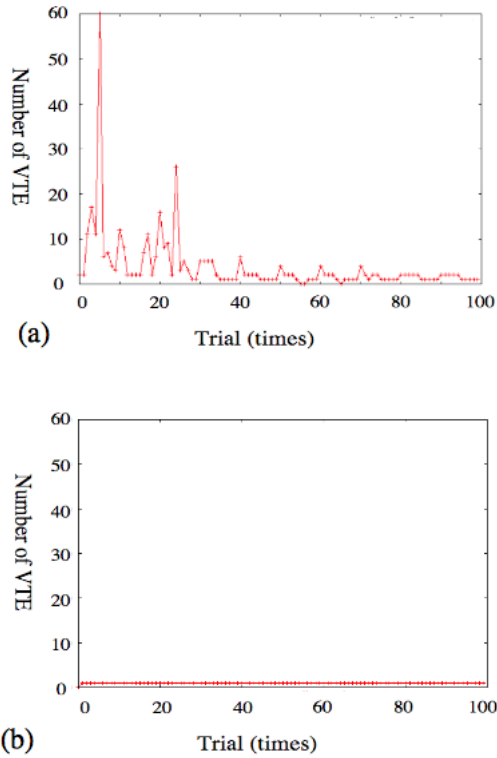

Figure 4: Change in the number of VTE during learning. (a) In the case of the original model. (b) In the case of the minimal model.

ing during 100 trials. Figure 5 presents the variation of the weights from the minimal model with their equivalent from the fully connected one. If the weights responsible for the VTEs were present among those, we would expect the strength to vary initially to stabilize toward the end of the trial as a similar observation was done on the VTEs. In the minimal connection model, no weights show such a pattern of variation. The strengths of the weights remain periodic over all the trials. In the case of the fully connected model, proximity(IR) to motor, touch to vision and vision to motor display non periodic variations, oscillating initially to stabilize later on. Proximity to motor is even more interesting as it decreases progressively over all the trials. Those variations show that the robot is changing its behavior progressively over all the trials. In the case of the minimal model, the robot does not seem to modify its strategy to reach the goal as the weights seem to be periodic. This analysis alone does not explain the source of the VTEs but it implies that the VTEs are not a random behavior and might be caused by the dynamics of the neural network.

In order to study if the presence of VTEs could imply a higher level of robustness for the robot, we analyze the

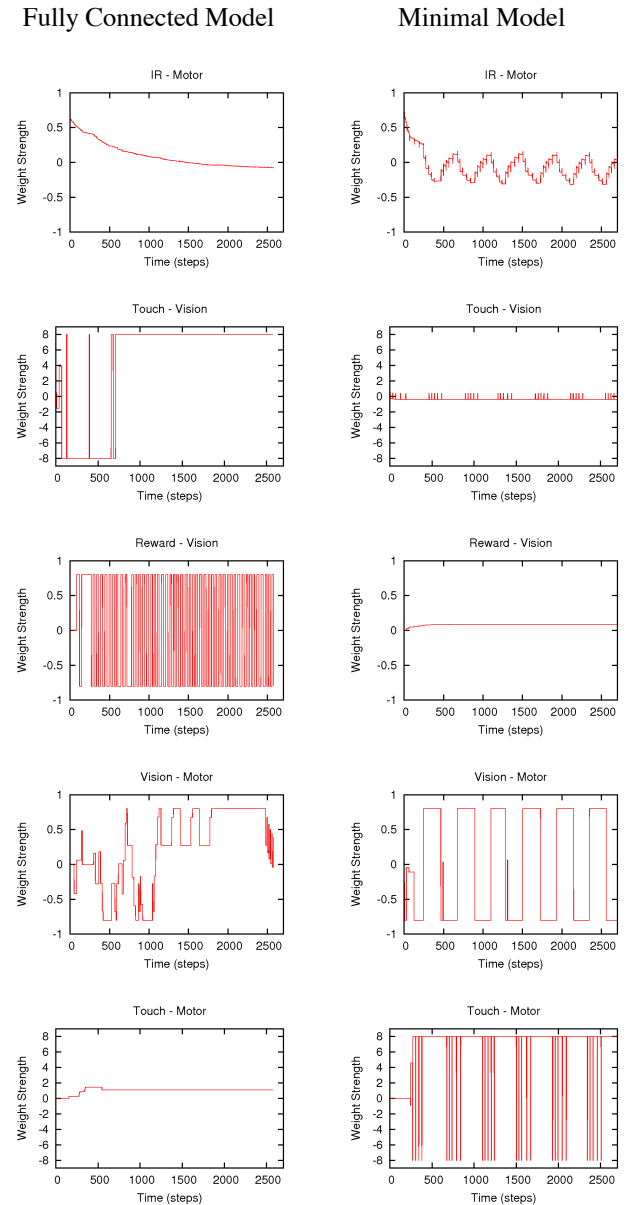

Figure 5: Comparison between the variations of the weights from the minimal model with their equivalent in the full model over 100 trials.

performance under varying initial conditions. During evolution, the starting position is  $(x, y) = (29, 20)$ . This experiment explores if the performance of the robot is affected by a change in its initial position by testing it from every other starting position inside the central arm of the T-maze. Each position has been tested 100 times to obtain the final results.

Figure 6 shows the results for each model. The first observation from this figure is that the performance is not constant over all starting positions. Some areas lead to higher performances. The second observation concerns the comparison of the variance of the performance between the two models.

In the case of the original model, the variance remains under 400 while the minimum variance of the minimal model is around 600 as seen in figure 7. This means that, despite the two models having a similar average performance, the original model seems to withstand changes in starting position. On the other hand, the minimal model is strongly affected by the initial position. This result implies that the presence of VTEs could be associated with a higher level of robustness to changes in the environment.

Based on the success rate, we observed 5 different types of behaviors:

**Going to the reward** As we described above, the robot successfully reaches the reward side. In the case of the original model, the number of VTEs becomes higher at the beginning of the learning, and decrease afterward similarly to experiments with real rats (figure 4). But with the minimal model, we only observed lower and stable VTEs.

**Going to the punishment** With about 0 % success rates, the robot learns to reach the punishment side. As the learning progresses, the number of VTE increases and afterward decreases with the original model. In the case of the minimal model, we did not observe this VTE change.

**Going to the same direction** The robot learns to go to the same fixed side (right side or left side) and gets around 50 % success rates. The number of VTE remains high during the whole experiment.

**Behavioral transition** The robot transit among the three previous behaviors - going to the reward, the punishment, and the one side - and displays success rates between 30 % and 70%. This transition might have some relationship with chaotic itinerancy where the state of a system oscillates between different attractors. However, this behavioral transition cannot be seen in the minimal model. The number of VTE remains high during the whole experiment.

**Random** The robot acts seemingly randomly and the success rate is around 50 %. The number of VTE remains high during the whole experiment.

In order to investigate further the robustness of the evolved controllers against environmental change, we carried out the same experiments with different T-maze sizes. We varied the width and the length of the T-maze, as drawn in figure 1, and calculated the average and the variance of the success rates for every initial positions. With the original model, the robot does not change its performance in respect to the average and the variance of the success rates. The robot with the minimal model gets affected by a slight change in environmental size (figure 8). This result confirms that the presence of VTE can be an indicator of the robustness of the neural system.

Figure 6: Average success rates for each starting positions. (a) In the case of the original model. (b) In the case of the minimal model.

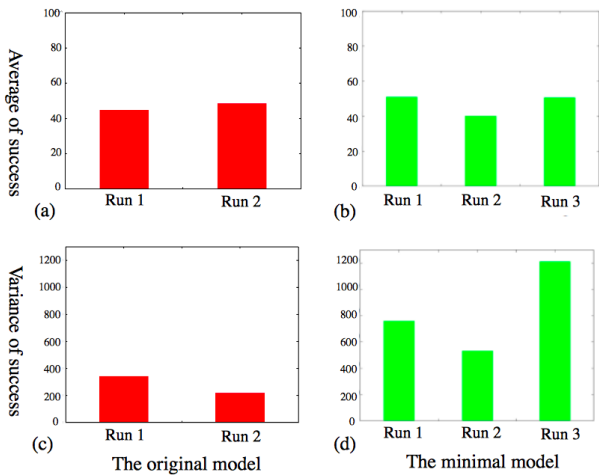

Figure 7: Average and variance of success rates per starting position. These graphs show the results of two (or three for the minimal model) GA runs of the original and the minimal model respectively. The red graphs present the results for the original model while the minimal model are in green. (a), (b) Average of success rates. (c), (d) Variance of success rates.

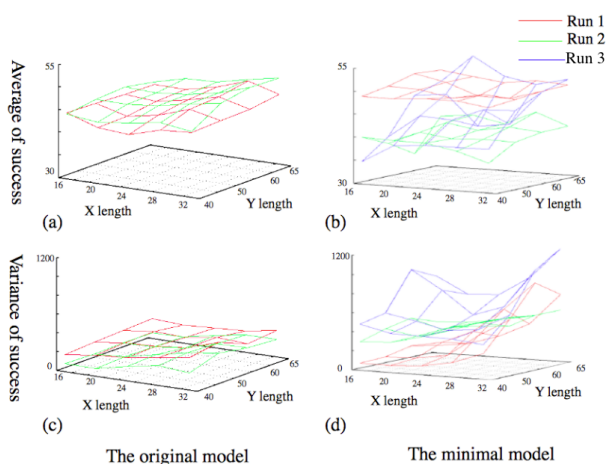

Figure 8: Average and variance of success rates per starting position, for different sizes of the T-maze. The size of the T-maze indicated by X and Y length corresponds to that of figure 1. Red and green lines corresponds to each two runs of GA. (a), (b) Average of success rates, for the original and the minimal model respectively. (c), (d) Variance of success rates.

## Conclusion

Our experiments aimed at uncovering the roles of VTEs through robotic experiments. Our work relies on a model developed by Bovet and Pfeifer where a neural network equipped with Hebbian learning commands a robot to complete a T-maze task using multiple sensory modalities (Bovet and Pfeifer (2005)). Unlike Bovet’s work, we composed the whole setup in a computer simulation, and conducted experiments under varied conditions, while optimizing the parameters of the model using a GA. This setup allows us to compute the number of VTEs during the learning of the route selection task.

We compared two models, one with full connectivity among modalities, and the other with minimal connectivity. Although both models exhibit the same performance, or 100% success, the former shows similar VTE curves to experiments with real rats, while the latter does not. This implies that VTE might not be related to performance in learning but would rather be caused by a redundant connectivity pattern.

We also noticed the original model, or the model with redundant connectivity, maintains its success rate to about 50% in most cases, regardless of perturbations to initial conditions or environmental size, which is accompanied by more VTEs. On the other hand, the model with minimal connectivity exhibits a lower robustness against perturbations. This model shows almost no VTEs. In conclusion, we offer the hypothesis that VTE might be linked to adaptivity to environmental changes.

In addition, we observed three seemingly stable behavioral patterns, and behavioral transition among those three patterns. This transition might have something to do with chaotic itinerancy (Ikegami (2007)). However, the dynamics of the neural network has not been studied and the cause of the VTEs has yet to be uncovered. Additional studies of this model, such as analyses based on chaos theory (Ogai and Ikegami (2008); Nakajima and Ikegami (2008)), or analyses from the field of differential topology (Thom (1972)), could shed some lights on the mechanisms of VTEs.

## Acknowledgements

We would like to thank three anonymous reviewers for their useful comments. We would also like to thank Simon Bovet for his help on reproducing the original experiments. Julien Hubert thanks the Monbukagakusho Scholarship from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

# Devil in the Details: Analysis of a Coevolutionary Model of Language Evolution via Relaxation of Selection

Luke McCrohon<sup>1</sup> and Olaf Witkowski<sup>2</sup>

University of Tokyo, Japan.

<sup>1</sup>luke.mccrohon@gmail.com

## Abstract

Computational modeling is an important tool in the study of language evolution. It is not only used to test hypotheses, but also as a source of data on difficult to observe evolutionary dynamics. This makes it particularly important to distinguish the emergent behaviors of evolutionary systems being studied, from the behaviors of specific models. In this paper we provide an in-depth analysis of one recent model of linguistic bio-cultural coevolution (Yamauchi and Hashimoto, 2010) and show that several of its reported behaviors are artifacts produced by the model's design and parameter settings. Specifically, we show that the model's population size setting and agent "geography" place strong limits on both cultural and biological diversity in the model. These limits interact with the model's learning mechanism and result in a number of semi-stable attractor states. We argue that it is the properties of these attractors that account for the long run behavior of the model, directly conflicting with the analysis given in the original paper. Our results are confirmed by experiments altering the model's population size parameter which result in a qualitative change in the observed model behavior.

## Introduction

The study of human evolution is complicated by the fact that in our species, phenotypes are shaped by the interaction of two separate evolutionary processes; biological evolution affecting our genes and cultural evolution affecting our learning environments. This *dual inheritance* (Richerson and Boyd, 2006) is perhaps most obvious in the study of human language, where despite the human ability to use language being biologically determined, the forms of the actual languages an individual acquires are determined by their cultural environment. The importance of this interaction diachronically, the so-called phenomenon of gene-culture coevolution, has in the last decade received growing recognition in the field of Evolutionary Linguistics (Deacon, 1997; Tomasello, 1999; Hurford and Kirby, 1999) and is also coming to be recognized in mainstream linguistics (Briscoe, 1998).

The most famous theoretical evolutionary gene-culture interaction is the Baldwin Effect (Baldwin, 1896; Simpson, 1953), a suggested process whereby initially learnt behav-

iors are gradually integrated into the genome. If the Baldwin Effect were in operation in language evolution it would work to increase the overall genetic contribution to the phenotype. Deacon (1997, 2003) however has suggested that language evolution is characterized by the opposite, a decrease in genetic contribution. He suggests that a relaxation of biological selection pressures, similar to that seen in domesticated animals, has given our lineage the evolutionary flexibility to evolve complex language. It has been argued that the cause of this relaxation of selection may have been through a cultural niche construction process (Odling-Smee et al., 2003; Yamauchi, 2004) in which cultural transmission was able to take over some of the burden of transmitting communicative behaviors between generations. This would have removed any selective pressure to keep these traits genetically hardwired, effectively allowing our ancestors to "self-domesticate" themselves via the culture they created.

Unfortunately, for anyone wishing to study the Baldwin effect, or other similar coevolutionary interactions, very little direct historical data exists. Biologically, the soft tissues on which our language ability depends seldom fossilize, and culturally, spoken words never do. This has led researchers to turn to a variety of indirect sources of data, such as comparative animal models, archaeological data, language acquisition studies and, recently, computational modeling. Not only are computational models being used to test hypotheses, but they are also being used directly as a source of data. This makes it particularly important that we understand the models that we are working with. Specifically, we need to be careful to determine whether any interesting dynamics we observe in our simulations are truly emergent properties of interactions of the target systems, or are just artifacts of our particular model designs.

In this paper we provide a detailed analysis of one recent exploratory computational model designed to investigate gene-cultural coevolution. The model was originally presented in Yamauchi and Hashimoto (2010) and we chose to investigate it due to its claimed cyclic repetition of stages in which biological selection was masked by cultural evolution, followed by stages in which biological selection was

vigorously reasserted. As such a cycle has not been at-tested in real world data, it was our intention to investigate its cause, and determine whether it was a product of an artificially high rate of simulated biological evolution when compared with the rate of cultural change. A possibility suggested by Chater et al. (2009), who argued that faster rates of culture change provide a moving target that biological evolution has a hard time adapting to.

However, on analysis, we show that the model's apparent cyclic behavior can be better described as a random walk between a linearly ordered set of attractor states. Furthermore, we show that the existence of these attractors is the result of arbitrarily chosen model parameter settings, and is not necessarily a consequence of properties of the target co-evolutionary system. We give a precise characterization of the set of attractor states and the transition probabilities between them and explain why the attractors exist and behave as they do. Finally, we show why the original set of parameters led to this behavior in the first place. We believe our analysis will prove useful to others interested in constructing gene-culture coevolutionary simulations and hopefully help prevent similar dynamics compromising future models.

This paper is structured as follows. The following section provides a description of the model we will analyze. This is followed by a summary of some key results from the original paper. We then describe our implementation of the model and where it can be obtained. This is followed by an in-depth analysis of the model's behavior based both on additional data from our implementation and a detailed study of the model's design. The final section then briefly discusses the implications of our analysis and highlights several points that need to be carefully considered during the construction of future coevolutionary models.

## Model of Language Evolution

In this section we describe the original model of Yamauchi and Hashimoto (2010).

In general terms, the model can be characterized as an agent-based language evolution simulation in which agent phenotypes are determined by a combination of their *biologically* inherited genomes and *culturally* transmitted knowledge. The model is designed to investigate the interactions between the biological and cultural aspects of agent evolution and is based on an earlier gene-culture coevolutionary model by Kirby and Hurford (1997). The main difference when compared with this earlier model is in the ways in which agents "learn", and specifically how their ability to learn is affected by their biological inheritance.

In Yamauchi and Hashimoto's model, each agent has a *chromosome* (a length 12 binary array), which represents its genetic predisposition towards learning each of 12 different linguistic alleles. For each allele the agent may be predisposed to learn either of its two possible forms; either zero or one. In addition to this chromosome, each agent also has a

*grammar* (a 12-value ternary array), representing its knowledge of its local language. For each allele the agent's grammar can either specify which form is used, zero or one, or may specify a lack of knowledge about the local language's instantiation of that allele, in which case its grammar will contain a *null* value. Additionally, agents also possess a certain supply of cognitive *learning resource*, initially set at 24 units.

The simulation proceeds via discrete generations, which each contain four phases. First, in the *Learning Phase* the current generation of agents are exposed to utterances from the previous generation and are given a chance to learn their grammars. Second, in the *Invention Phase* agents who still have null values in their grammar are given a chance to invent new values. Third, in the *Communication Phase* agents interact with their neighbors to determine their *fitness*. Finally, in the *Reproduction Phase* a new generation of agents is created via sexual recombination of agents from the current generation.

Prior to the beginning of the simulation, all agents in the current and previous generations have their chromosomes randomly initialized to zeros and ones. The grammars of both generations are also initialized to contain only nulls. This means that in the first generation of the simulation, agents will not receive any non-null inputs which they can learn from. Thus the initial chromosomes do not directly determine the initial culturally transmitted language of the agents.

Each generation contains 200 agents that are geographically arranged in a cycle. An agent's position in the cycle affects which agents it learns from in the Learning Phase and which agents it communicates with in the Communication Phase, but has no effect on the agent during the Reproduction Phase. That is, learning and fitness are determined locally on the cycle, but reproduction is determined globally. The motivation for this is discussed in Kirby and Hurford (1997).

In the Learning Phase agents are presented in turn with *utterances* taken randomly from members of the previous generation at a distance of at most two from the learner agent. Utterances are produced by looking at the source agents grammar and randomly selecting one of the 12 alleles. The utterance is then a pair of the allele index (1–12) and its value (zero, one or null). If the value of the utterance is null, it is instantly discarded and the learner agent moves on to the next utterance. Otherwise, the agent takes the utterance and compares its value with its own grammar at the specified index. If the value of the utterance is different from its own grammar, the agent attempts to update its grammar to match the utterance.

Updating the grammar requires the agent to have sufficient learning resource remaining to make the update. An update that sets the grammar to a value equal to the value of the agents chromosome at the same index costs the agent 1

unit of learning resource, an update to a value different from the agent's chromosome costs the agent 4 units of learning resource. If sufficient learning resource is available, the cost is subtracted from the agent's supply of learning resource and the update is made. If the agent has insufficient learning resource, the agent's learning resource is set to 0, and no update is made. For each agent, the learning phase continues until either it has been exposed to a total of 200 utterances or until its learning resource is depleted.

Once the Learning Phase has been completed for all agents, the Invention Phase begins. All agents that have learning resource left are given a chance to use that resource to fill in any null values left in their grammars. For each left over unit of learning resource an agent has a 0.01 chance of filling a single null with a randomly selected value of zero or one. Once either the learning resource is exhausted or no nulls remain in the grammar, invention stops, and the grammar of the agent is fixed for the remainder of the simulation.

Next the simulation enters the Communication Phase. This phase serves to establish the fitness of each agent, which will be used to determine their likelihood of contributing to the next generation of agents in the Reproduction Phase. Initially each agent has its fitness initialized to a base value of 1. Beyond this, fitness is determined by the ability of the agent to successfully communicate with its neighbors. Each agent has 6 chances to communicate with each of its immediate neighbors on the cycle in the same generation.

To determine if the agents are successful in communicating, one of the 12 grammatical alleles is randomly selected and the grammars of both agents are compared at that allele. If either agent has a null value for that allele, or if the two agents disagree on its value, then communication is declared a failure and the agents' fitness is left unchanged. However, if both agents' grammars agree, communication is declared a success and both agents receive plus 1 to their fitness score. When this process is complete all agents will have been assigned a fitness score of between 1 and 13.

Finally, the simulation enters the Reproduction Phase in which the next generation of agents is produced. To create each new agent, two parent agents are selected from the current generation via roulette wheel selection. The location of agents on the cycle is ignored for the purposes of their selection. The chromosomes of the two parent agents are then combined via obligatory single point crossover. Then with a probability of 0.00025 each allele is mutated. This chromosome is then used to create a new agent which is initialized with an empty grammar (all null).

Once reproduction is completed, the current generation is replaced by the new generation and the above four phases are repeated. For a more complete description of the model please refer to the original paper or examine the freely available source code of our implementation.

Before proceeding to the results that this model produces, we would like to note that, as is fairly common in this type of

modeling, the majority of parameter values are set to largely arbitrary values. That is to say there is no external linguistic factor motivating setting the population size to 200 or in setting an agent's initial learning resource at 24 units, they just happen to be values that seem to work and produce the intended dynamics.

## Simulation Results

Figure 1: Gene-Grammar Match in the Original Model<sup>1</sup>

Figure 2: Number of Genotypes in the Original Model<sup>1</sup>

Two key charts from Yamauchi and Hashimoto (2010) are reproduced as figures 1 and 2. The first shows the progression of the Gene-Grammar match (average hamming distance between mature agents' grammars and chromosomes) and the learning intensity (average amount of learning resource consumed by agents in the Learning Phase). The second shows the number of different genotypes present in the population over time. The original paper divides the discussion of these results into three stages as marked by the dashed vertical lines in the figures.

<sup>1</sup>Reproduced with permission of the original authors.

### Stage 1 - Baldwin Effect

The first stage spans the first few hundred generations and covers the period in which agents go from initially having no culturally transmitted language (and a very low fitness) to having a highly uniform language shared between all agents (and consequently maximal fitness). The language that results from this phase is shown to match the grammar to an above chance level, and by the end of the phase, the genetic diversity has decreased significantly. This is claimed to be the result of an assimilatory process akin to the Baldwin effect, operating to allow agents to save more learning resource for the invention of new tokens to replace any null elements in their grammars.

### Stage 2 - Functional Redundancy

The second stage takes place over several thousand generations throughout a period in which biological selection is masked by a culture. Following stage 1, the culturally transmitted language closely matches the agents' innate biases and provides them a stable uniform stimulus to learn from. This simplifies learning and allows all agents to successfully learn a single common language. As a result there are no problems in communication, and all agents are assigned the maximum fitness score. Biological selection has been effectively masked by culture. Throughout this stage the culturally determined language transmitted between generations remains largely unchanged. The masking of biological selection leads to a relaxation of selection on the agents' biases (the biases have been made functionally redundant), and they are free to degrade to values that no longer match the culturally transmitted language. The original paper claims that as a result of this "the degree of correlation between the gene-pool and the environment gradually, yet firmly declines" throughout this stage.

### Stage 3 - Unmasking of Natural Selection

This stage begins when the gene-grammar match has deteriorated to a point at which biological natural selection is no longer masked and biological selection again begins to take effect. It is claimed that this results in agents in a local area converging on different I-languages which decreases their fitness and cause problems for agents in the subsequent generation to learn the language. Due to this, a biological assimilatory process begins to take affect, similar to that seen in stage 1, which quickly returns the population to a point with high gene-grammar matches as was present at the beginning of stage 2. Having returned conditions to how they were at the onset of stage 2 it is claimed that stages 2 and 3 then repeat cyclically every few thousand generations.

### Our Implementation

Unfortunately the source code of the original model is not publicly available and so to investigate it further we reimplemented it ourselves following the details given in the orig-

Figure 3: Gene-Grammar Match in our implementation (c.f. fig.1) [Seed=1303050913721, Runs=1, Generations=5000]

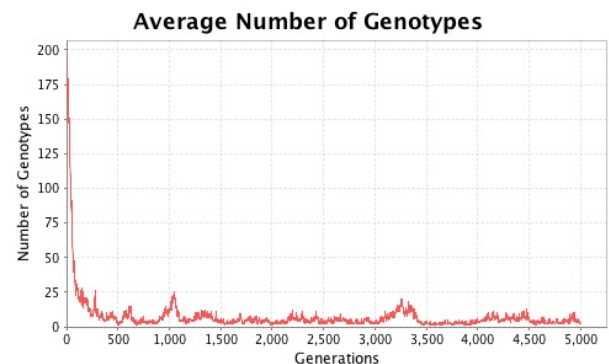

Figure 4: Number of Genotypes in our implementation (c.f. fig.2) [Seed=1303050913721, Runs=1, Generations=5000]

inal paper. The specifications were sufficiently precise that our implementation produces results which closely mirror those reported in the original paper. For comparison we present figures 3 and 4 which show the same range of behaviors as those of the original model depicted in figures 1 and 2.

In presenting our own results we generally concentrate on only the gene-grammar match, ignoring the learning intensity. This is because except for the initial generations, where there is a significant number of nulls, the learning intensity is essentially a scaled inverse of the gene-grammar match. We also tend to ignore the number of nulls, fitness, number of genotypes, et cetera, as for the most part they tend to produce relatively stable values throughout the simulations.

Our implementation of the model is available for download at:

<http://code.google.com/p/suzume/>

To run the model as described in this paper select "YamauchiHashimoto2010" as the Agent Type, "CyclicBag-Model" as the Population Model and "RouletteWheelSelection" as the Selection Model. The version of our code used

to conduct the experiments presented in this paper was Rev ac9d4c742fe2.

Unless otherwise specified, all simulation results presented in this paper were conducted with the default configuration parameters settings. Each result set is presented together with the random generator seed, run count and generation count used to produce it. This information should suffice to reproduce the data underlying all figures presented in this paper.

## Analysis

### Genetic Diversity

One of the features that led the authors of the original paper to conclude that stage 1 was the result of a Baldwin Effect style assimilatory process was the overall decrease in genetic diversity during this stage. But as figure 5 shows, even when selection has been set to ignore agent fitness values (resulting in neutral biological selection), the same reduction in genetic diversity is observed. This reduction is caused by genetic drift in the relatively small population fixing random alleles. This process brings the overall number of genotypes down to approximately 5-10. The number of genotypes never reaches 1 because new variations are constantly being introduced by mutation. 5–10 is the level at which new variants are being introduced by mutation at the same rate as which they are being removed by drift.

This process of drift removing variation and mutation adding it, continues throughout the simulation and results in a rather constant level of genetic variation despite the absence of biological selection in stages 2 and 3. The level at which the number of genotypes stabilizes can be altered by changing the mutation rate of the agents or by changing the population size (smaller populations are more easily affected by drift fixing values). Looking at just the number of genotypes actually makes the degree of variation in the population seem greater than it actually is. While there may be 5-10 variants at any given time, it should be noted that these are normally very closely related to each other and are usually only represented by a small number of individuals.

What the decrease in variation from random drift implies is that the initial reduction in genetic variation observed during the first stage should not be seen as evidence of an adaptive genetic process such as the Baldwin Effect.

### Masked Genetic Selection

As was reported by the authors in the original paper, genetic selection is effectively masked in stages 2 and 3 of the simulation (approximately 1000 generations onwards). And so we should expect genotypes to take a random walk through the space of possibilities for as long as selection remains masked. If we look at figure 6, which shows 10 separate runs over 10000 generations, we see this does in fact occur to a certain degree, but the gene-grammar matches never drop below 8 for any significant period of time. This would

Figure 5: Genotype Variation over initial 1000 generations under neutral biological selection (c.f. fig.2) [Seed=1302966692486, Runs=50, Generations=5000]

Figure 6: Gene-Grammar Match for 10 independent runs over 10000 generations [Seed=1303127096921, Runs=10, Generations=10000]

suggest that this is the limit to which cultural shielding can operate. That this is in fact the case, can be argued directly from the model design.

There are two ways in which an agent's learning resource can be depleted. First, an agent may be exposed to conflicting inputs which causes it to repeatedly switch the value of a grammatical allele, quickly depleting the resource. But as our experiments and the results of the original paper show, this is unlikely to occur once a common language has been established, as that language is very stable. Alternatively, this may occur if an agent is presented with consistent input, but when that input is so divergent from its innate biases that the learning cost is greater than the agents initial learning resource supply. The value at which this occurs can be calculated based on the simulation parameters.

Agents begin with 24 units of learning resource and need to fill the 12 alleles in their grammar. The cost of filling an allele that matches their chromosome is 1, and the cost of filling a non-matching allele is 4. Therefore the maximum

number of non-matching alleles the agent can learn while successfully filling its chromosome is four, any more and it won't have sufficient resources left to fill the remaining alleles ( $4 \text{ non-matching} \times 4 + 8 \text{ matching} \times 1 = 24$ ). Experiments changing learning costs and the agents supply of learning resource alter the shielding level as expected.

This means any agent dropping below a gene-grammar match of 8 will not be able to fill its grammar, and so would have its fitness penalized and would be selected against by biological selection. This is different to the reasoning presented in the original paper where it was suggested that at this point the agents would be selected against due to increasing variation in their learning input. This will occur in subsequent generations with agents being subjected to null inputs, but is not the original cause of the unmasking of biological selection.

### Coevolutionary Attractors

A close inspection of figure 6 shows that there are certain values at which the gene-grammar match occurs more frequently. Specifically those values centered around integer values between 8 and 12. This can be seen clearly in the probability density plot shown in figure 7.

Figure 7: Gene-Grammar Match Density [Seed=1303046232707, Runs=100, Generations=5000]

The reason the gene-grammar match occurs most frequently around these values is due to the previously mentioned facts that the language is uniform across agents, and that genetic variation is highly limited. If there is only one language, and if the vast majority of agents share the same genes, then the average gene-grammar match will fall close to an integer value. It is only when significant portions of the population possesses different genes that the population will move away from these points. In cases where this does happen, genetic drift will usually sweep the population back to its original integer value point. In rare cases however, if the population moves sufficiently far away from its previously stable genetic state, drift may cause the population to be swept to a new uniform genetic state (and hence a differ-

ent integer gene-grammar match value).

Of course there may be several different chromosome-grammar matches that result in agents exhibiting the same gene-grammar match value. However, as nothing in the agent's learning algorithm changes their probability of learning individual grammatical alleles due to a particular set of genetic biases (only the number of matches ultimately influences learning), these different model states will behave identically. Because of this it is safe to view the integer value gene-grammar matches as attractor states in the simulation, despite them potentially representing a number of different underlying gene-culture states.

	to 12	to 11	to 10	to 9	to 8
from 12	.55	.05	—	—	—
from 11	.01	.52	.07	.01	—
from 10	—	.02	.42	.08	—
from 9	—	—	.02	.61	.03
from 8	—	—	—	.04	.78

We calculated the likelihood of the simulation jumping between each of these attractor states ( $\pm 0.2$  units) over a period of 200 generations. The transition probability matrix is presented in the table above and in the transition diagram in figure 8. We tested these results against transitions between equally sized intervals positioned directly between the attractor states and obtained probabilities of the simulation staying in those intervals approximately 5 times lower than in the case of the attractors. This indicates that the attractors are significantly more stable.

Figure 8: State Transition Diagram [Seed=1303037425613, Runs=50, Generations=20000]

### Shape of the Attractors

As can be seen in figure 7 the attractors are not symmetrical. For all attractors except the lowest one (at a gene-grammar match of 8) there are significantly more values in the region directly below them, than in the region above. This is representative of the fact that deviations from the fixed point are more likely to be in a downward direction. This

happens because these deviations are the result of biological changes, and as the four attractors in question (at gene-grammar matches of 9, 10, 11 and 12) all represent genotypes in which more than half of the grammar alleles match the agent's biases. Thus the majority of random changes to agent's genotypes will result in a decrease in the gene-grammar match.

Figure 9: Average Gene-Grammar matches [Seed= 1303037425613, Runs=50, Generations=20000]

This results in a greater probability of downward transitions between attractors, and in the long run attractors results in the lower attractors having a greater chance of being occupied. This long run effect is visible in figure 9. For approximately the first 5000 generations the model has yet to settle down following the high gene-grammar matches attained in the first few hundred generations.

### Attractors and Population Size

Figure 10: Gene-Grammar matches for a large population of 400 agents [Seed= 1303033229645, Runs=50, Generations=12000]

As the culturally determined language is largely stable throughout the simulation, the primary requirement for falling into an attractor is that all agents show very little

genetic variation (if there is significant variation the average gene-grammar match is unlikely to approach an integer value). As was discussed earlier the main reason the simulation generally ends up in states with little genetic variation is due to genetic drift sweeping away what variation that does exist. Unsurprisingly this is more of an issue with a smaller population, and our experiments show that the lower the population size, the less genetic variation exists, and the more defined the fixed points become.

Conversely, increasing the population size makes the fixed points less distinct as can be seen in figure 10 which shows gene-grammar occurrence frequencies in a population of 400 agents. What is surprising is when we increase population size further still (as shown in figure 11 with a population of 1000 agents), the fixed points disappear entirely. With the fixed points removed, the simulation loses the downward ratchet effect caused by the shape of the fixed points and demonstrates a qualitatively different behavior than was seen with smaller population sizes. We think this is likely the behavior that was originally intended by Yamauchi and Hashimoto (2010). Unfortunately an analysis of the dynamics of the model with this larger population size is outside the scope of this paper.

Figure 11: Gene-Grammar matches for a very large population of 1000 agents [Seed= 1302981824159, Runs=50, Generations=12000]

### Conclusions and Discussion

While the model presented in Yamauchi and Hashimoto (2010) does reproduce many of the interactions it sets out to capture (Cultural Shielding, Niche Construction etc.), the behavior of the model within the limits set by these interactions has been shown to be the result of the model's design, and not of any underlying emergent properties of its target system (e.g. gene-culture coevolution). We have not provided evidence directly contradicting any of the conclusions reached based on the original model, but have shown that additional work is necessary to understand the dynamics of the system that was investigated. We think that the analysis

presented in this paper will be useful to others seeking to design coevolutionary simulations, particularly as inspection of charts related to the coevolutionary simulation of Kirby and Hurford (1997) also suggests evidence of a similar sort of fixed points to those identified here.

**Population Size is Significant** Population size usually only has a quantitative effect on simulation behavior, but as was demonstrated in our analysis, under certain circumstances, it can have a significant qualitative effect. Given that increasing population size can be computationally expensive, we think that it might be sensible to investigate alternative population structures that may be able to imitate the behaviors of larger populations. At a minimum we think our analysis demonstrates the necessity of testing coevolutionary simulations on a wide range of population sizes to see if there exist any qualitative effects.

**Cultural Diversity is Important in Coevolution** Many of the dynamics we identified in this model were the result of it only supporting limited cultural diversity. The fixed points we identified would not have been present if the model had been able to support multiple culturally determined languages concurrently. Additionally, when the model strayed away from the zone in which biological evolution was shielded by culture, and biological selection reasserted itself, had there been more than a single language present the dynamics would have likely proved more interesting. The lack of cultural diversity/change in the present model can be traced directly to its learning mechanism, when learning resources are sufficient as they are throughout the majority of the simulation, there is a near zero probability of cultural change occurring. Future simulations should be designed to allow at least a certain level of diversity, not just in their representation of biology, but also of their culture.

**Biological Selection Geography** Running roulette wheel selection on a relatively small population of 200 agents in which there is no concept of distance resulted in low levels of genetic diversity throughout the simulation. Genetic diversity was shown to be raised by increasing the population size which effectively removed the fixed points seen in the simulation, but at the cost of a heavily increased computational burden. We suggest that future simulations could take advantage of alternative selection methods such as trimming some fraction of poorer performing agents from the reproductive population as in Kirby and Hurford (1997). Or alternatively by adding some concept of geography into the replacement algorithm.

**Random Walks in a Binary Space** During Stage 2 of the original paper's analysis, the authors claim that the relaxation of selection leads to a gradual yet firm degradation in the gene-grammar match of the agents. But as we have

shown, this is in fact simply a random walk which also has the possibility of increasing the match. If instead of using a binary space of language possibilities the authors had of used a higher dimensional space, the random nature of the walk would have been far less likely to increase the gene-grammar match, and would have better demonstrated the degradation dynamic that was intended.

# Evolution of Self-Maintaining Cellular Information Processing Networks

Barry McMullin<sup>1</sup> and James Decraene<sup>2</sup>

<sup>1</sup>The Rince Institute, Dublin City University, Ireland

<sup>2</sup>School of Computer Engineering, Nanyang Technological University, Singapore  
barry.mcmullin@dcu.ie

## Background

This contribution is an extended abstract of (Decraene and McMullin, 2011). What we here term Cellular Information Processing Networks (CIPNs) are biochemical systems of interacting molecules occurring in living cells. CIPNs are responsible for coordinating cellular activities in response to internal and external stimuli (e.g., chemotaxis signalling pathways). CIPNs can be regarded as special purpose computers (Bray, 1995). A single enzyme molecule effectively carries out pattern matching to identify and bind target substrate(s), and then executes a discrete computational operation in transforming these into the product molecule(s). The concept of *collective autocatalysis*, formulated by Farmer et al. (1986), denotes a collection of molecular species where each of them is the product of at least one reaction catalysed by at least one other species of the set. Fontana and Buss (1994) developed this into a more general formal concept of (collective) *self-maintenance*, and it has more recently been elaborated and refined in the *Chemical Organization Theory* of Dittrich and Speroni (2007). Self-maintenance ensures that reaction networks can reconstitute themselves when subjected to perturbations and during cellular divisions. It may thus mediate between the conflicting objectives of robustness and evolvability in reaction networks.

In contrast to modern living cells, the cellular model considered here does *not* incorporate a distinct genetic translation system. It is motivated by the (presumed) evolution of information processing in (proto-)cells *prior* to the emergence of the genetic architecture.

## The Artificial Chemistry (MCS.bl)

We employ an agent/string-based Artificial Chemistry called the Molecular Classifier System (MCS.bl<sup>1</sup>) which is based on Holland's broadcast language (Holland, 1992, pp. 143-152). The basic elements (the abstract "molecules") are formally strings on a specified symbol alphabet ("atomic" species). Chemical reactions are stochastic (molecular "mutation" may alter the generated product strings), reflexive

(no distinction made between operands and operators) and catalytic. Any single molecule may contain several condition/action rules which define its binding and enzymatic properties. In general the broadcast language allows arbitrary string transformations (computations) to be expressed; however, for the specific experiments described here, individual autocatalysis (self-catalysed replication) is explicitly disabled. Populations of molecules are encapsulated in containers to form "cells"<sup>2</sup>. Each cell functions as a separate well-stirred reactor. The number of molecules in a cell may increase until the cell matches a specified division criterion; a cell then divides with stochastic assortment of molecules into two daughter cells. Where particular molecular species are present in small numbers in a parent cell they may be absent completely in one of the two daughter cells, giving rise to distinct, cell-level, mutation events. The total number of cells is fixed: each division triggers the removal of another cell selected at random. The system is implemented on a small parallel computer cluster, with one CPU per cell. The real-time required for individual molecular interactions may vary with the specific detailed structures of the molecules involved. Cell reproduction rate is dependent on the real-time rate of catalytic reactions occurring in the cell, and on the specific criteria in effect for cell division. Distinct, interacting, selectional dynamics arise at both molecular and cellular levels.

## Experiment: Molecular Amplification

In the first experiment cells are evolved to carry out amplification of a given molecular species. This is motivated by conceptually similar *in vivo* investigations reported in the literature (Fong et al., 2005). The cell division criterion is configured so that cells divide when a target molecular species ( $s_T$ ) reaches a threshold number of instances. The cellular reproduction rate (fitness) therefore depends on the ability of the cell to promote the growth of  $s_T$  while still preserving overall collective self-maintenance of all required molecular species. The system is initialised ("seeded") with

<sup>1</sup>MCS.bl source code and documentation is available at: <http://esignet.net/dokumente/upload/WP13>

<sup>2</sup>For brevity, we say simply "cell" here; but this should be read as "proto-cell" throughout.

a hand-designed, viable cellular species (self-maintaining at the molecular level, including the target molecular species, so that cellular division is possible).

Similar phenomena are encountered in multiple runs. One typical run is described and analysed in more detail. In the course of this run, 1235 different and unique cellular species were generated in total, but of these, just three successively came to dominate the cellular population, through three identifiable displacement events. Careful analysis of both the molecular dynamics within the dominant cellular species and the cell-level population dynamics allowed determination that the first observed displacement in this run was selectional, with a clear increase in fitness (molecular amplification function); but the subsequent two displacements represented drift among essentially equal-fitness cellular species. That said, more fine-grained examination of the displacement events also shows that they are correlated with significant transient increases in cellular species diversity. These displacements are thus significantly more intricate than straight selection or drift between two “pure” cell lines. In effect, a single molecular mutation event can give rise to a complex cascade of cell-level mutations.

### Experiment: Crosstalk

Crosstalk phenomena arise very naturally in real biochemical information processing networks due to the fact that molecules from different signalling pathways may share the same physical reaction space (the cell). Depending on the relative specificities of the reactions there is then an automatic potential for any given molecular species to contribute to signal levels in multiple pathways. Here we describe an experiment investigating the evolutionary dynamics arising when distinct cells, with potential crosstalking pathways, are forcibly merged, but subsequent cell division is constrained to maintain selected molecular components from *both* pre-existing reaction networks (so cellular species in which one network simply displaces the other cannot continue to reproduce). This work is naturally related to the symbiogenesis theory which was originally postulated by Mereschkowsky (1910), and already explored computationally by Barricelli, on the first stored program digital computers, in the 1950's (Barricelli, 1957).

Over a number of runs, various common features are observed under these experimental conditions. A very rich variety of cellular species emerges, and in general there is significantly more cellular species diversity than in the previously described experiment: it is rare in this case for a single cellular species to exceed more than half of the population. Nonetheless, distinct displacement events can still be observed; and it is possible to analyse the molecular behaviour of a selection of mutant cellular species in detail. It is typical to observe the emergence of cellular species containing a “meta-reaction network”, still including all the seed molecular species, but also additional molecular species, exploiting

crosstalk and bridging between the seed species, and participating in the collective self-maintenance. In this sense, this experiment demonstrates a some (limited) evolutionary growth in the complexity of the self-maintaining reaction networks — both in terms of number of species and number of reactions composing the network. It is also observed that the gestation time of the dominant cellular species successively decreases

### Conclusion

We have presented a preliminary investigation of the role of collective self-maintenance in the evolution of (proto-)cellular information processing reaction networks. To assist this research, we built a novel agent-based multi-level selectional Artificial Chemistry. This was applied to the evolution of a single and multiple/crosstalking self-maintaining reaction networks. In these experiments, cellular species were successfully evolved to achieve the pre-specified information processing functions more effectively and exhibited a relatively higher level of complexity (by at least some reasonable measures). This proof of concept should contribute, to some extent, to understanding of the much more general problem of *open-ended* evolutionary growth of complexity using Artificial Chemistries.

## Abstract

Many theories have sought to explain the evolution of sex, but the question remains unanswered owing to the scarcity of compelling empirical tests. Here we summarize the results of two of our published studies investigating the evolution of sex using digital organisms. We used these evolving programs to test the hypothesis that sexual reproduction is advantageous in changing environments. We found that sex evolved to be the dominant mode of reproduction only when the environment was changing rapidly and substantially. Additionally, we measured the effects of sexual reproduction on genetic architecture, specifically modularity and epistasis. We found that sex profoundly influences genome organization, increasing modularity and decreasing the effects of interactions between mutations. Our studies have contributed to understanding both the causes and consequences of sexual reproduction, while also demonstrating the efficacy and power of *in silico* approaches to these issues.

## Introduction

Why sex? The paradox of sexual reproduction – a process that is costly and complicated, yet widespread in nature – has fascinated biologists for well over a century, and has in turn generated a wide range of hypothesis and experimental tests [1-3]. One of the simplest and perhaps most intuitive explanations is that sex accelerates the rate of adaptation to novel or changing environments by increasing genotypic and phenotypic variation [4]. Here we summarize a previously published study testing this theory *in silico* [5] as well as another study examining the effects of recombination on genetic architecture [6].

## Methods

All experiments were conducted using Avida software (freely available at <http://avida.devosoft.org/>), previously used in many studies of evolutionary trajectories and outcomes [7-8]. Digital organisms in Avida are short self-replicating computer programs that mutate, evolve, and reproduce either asexually or sexually, depending on which divide instruction they execute. Genomes were built from the default instruction set with 27 instructions including 2 divide instructions, divide-sex and divide-asex, only one of which can be expressed by any individual. In these studies, point, insertion, and deletion

mutations occurred at rates of 0.002, 0.0005, and 0.0005 per instruction copied, respectively, with the same mutation rates applied to the divide instructions as all others. When a population was at its carrying capacity (here 3600 organisms), each new offspring replaced a randomly chosen organism. All experiments ran for 100,000 updates (the Avida time unit), and a generation typically required 5–10 updates, with the precise number depending on the organisms' genomic and phenotypic complexity.

**Digital metabolism.** An organism's genome may contain instructions that encode the ability to metabolize one or more substrates present in the environment. Metabolism of a substrate either accelerates or decelerates an organism's replication rate by a factor of  $2^m$ , where  $m$  is the substrate's metabolic value and is positive or negative, signifying a nutrient or a poison, respectively. Fitness is calculated as the organism's total energy (energy obtained via metabolism in addition to basal energy provided equally to all organisms) divided by the time used to produce an offspring.

**Environmental conditions.** For the study of the effects of sexual versus asexual reproduction on genetic architecture, we evolved populations in a constant environment with 9 substrates that were always available in unlimited amounts. When testing the possible benefit of sex in changing environments, we used the same constant environment for the first 1000 updates of each experimental run, after which additional and changing substrates were introduced.

**Recombination mechanism.** Recombination is initiated by pairing up the genomes of two progeny that were produced sexually (i.e., divide-sex was expressed) and consecutively. The pair then exchanges a single continuous genomic region. The recombining region is chosen at random, but is matched between the organisms based on its relative position in the genomes. After recombination, both offspring are placed at random locations in the population, in the same manner as asexually produced organisms. The Avida mechanism of recombination (see [9] for a more detailed explanation) differs from others presented elsewhere in the Artificial Life literature. For example, in Tierra, sex involved recombination between living and deceased organisms [10], while in another system recombination somewhat resembled plasmid transfer [11]. Moreover, those studies were not driven by hypothesis

testing, but rather were descriptive and phenomenological in scope, making any comparisons difficult.

## Results

### Effects of changing environment on reproductive mode.

The trajectories of the relative abundance of sexual and asexual organisms were highly variable during our experiments. Overall, asexual reproduction prevailed, except at the highest rates of environmental change, when sexual reproduction tended to be more common. This result was obtained both when comparing the final mode of reproduction and when measuring the time that populations spent as predominantly sexual or asexual over the course of their evolution.

**Origin versus maintenance of sex.** Given the costs of sexual reproduction, it may be easier to maintain sex than to evolve it *de novo* [12]. We found that over the entire duration of the experiment, the populations started with sexual ancestors were predominantly sexual 38% more often than those with asexual ancestors. However, when considering only the latter half of the experiment, this difference was reduced to 25%, indicating the time necessary to make the switch between the modes of reproduction also played an important role. Overall, sex overcame the barriers that hindered its establishment in previously asexual populations only about half the time even under the most favorable treatments.

**Mode of reproduction and modularity.** We conducted extensive mutational analysis of organisms randomly sampled from populations that evolved in a constant environment with either obligatory sexual or obligatory asexual reproduction. We found that sexual organisms evolved to have both higher physical modularity (shorter distance between the genomic sites encoding a computational trait) and higher functional modularity (less overlap between the sites that encode two or more traits) than asexual organisms.

**Mutational sensitivity and epistasis.** Sexual populations also evolved to be significantly more robust to individual mutations than the asexual populations. Under both modes of reproduction, the predominant mode of epistasis was alleviating (positive), with multiple mutations reducing fitness less than expected from their individual effects. This epistasis was weaker, however, in sexual than in asexual organisms.

## Discussion and Conclusions

Our experiments show that rapidly changing environments can promote the evolution of sex, but at the same time, they call attention to some limitations of this theory. In particular, the parameter space that favored sex was quite limited, and the origin of sexual reproduction was more difficult than its maintenance. We also failed to observe a preponderance of aggravating (negative) epistasis, which is a key component of the mutational deterministic hypothesis [13], another well-known theory for the evolution of sex, thus adding to evidence against this hypothesis obtained in other systems [14-16]. Instead, our results suggest that an indirect benefit for sexual reproduction might arise from increased genomic modularity, perhaps leading to greater evolvability that sustains long-term

increases in fitness [17-19].

More generally, the studies summarized here highlight the utility of digital organisms for testing complex evolutionary theories because they allow one to manipulate any relevant features of the environment, control for the confounding effects of ancestry, compare the origin and maintenance of organismal traits under the same conditions, and obtain data across many replicate populations and for many thousands of generations. Finally, the insights gained from our experiments with digital organisms may also lead to future research on biological systems to examine the generality of these results.

# Modeling Cell Division of *B. subtilis* Using Dynamic Division of Reaction Spaces in a Membrane Artificial Chemistry

Takuma Miyake<sup>1</sup> and Kazuto Tominaga<sup>1</sup>

<sup>1</sup>Tokyo University of Technology  
tomi@acm.org

## Abstract

Localization of molecules in a natural cell plays important roles in interesting behavior of organisms like cell division and morphogenesis. Such localization is mostly formalized in a continuous space or lattice. This paper takes another approach using an artificial chemistry with membranes; we propose a dynamic division of reaction spaces to deal with molecular localization. As an application of the method, we modeled the cell division of *B. subtilis*. We executed the model on a simulator and observed the intended results.

## Introduction

Living organisms show many kinds of interesting behavior whose mechanisms are not easily understood. They include reproduction, morphogenesis, evolution, etc. In some of them, the properties and dynamics of lipid membranes play important roles. As one of the main interests in the field of artificial life is to understand the essence of living system, numerous formalisms have been proposed and used to model the behavior of life in which membranes take their part; artificial chemistries (AChems) are among them (Dittrich et al., 2001). For example, Madina et al. studied the formation of proto-cell structures using their 3D Lattice Artificial Chemistry (Madina et al., 2003). They observed in the model that amphiphilic molecules are organized into membrane-like structures.

Besides the properties of membranes, another factor is also important to understand interesting behavior: localization of molecules. For example, in the early stage of *C. elegans* (a kind of worm) embryogenesis, the point where the sperm enters decides the localization of specific proteins, which induces asymmetric cell division (Kemphues, 2000). It is beneficial for a formalism to be capable of dealing with such localization.

There seem to be two established methods to handle it: one assumes a continuous space and the positions of molecules; the other employs a lattice (1D, 2D or 3D, of squares or other shapes) and places molecules in lattice cells (Arjunan and Tomita, 2010). But both methods would have drawbacks when they are to be applied to modeling and simulating a life-like system with many compartments separated

by membranes. The first method may require much computational resource to calculate the behavior of molecules. With the second method, it seems difficult to scale and adapt the lattice size and granularity when, for example, morphogenesis from zygote to adult is to be modeled and simulated.

In this study, we take a different approach. Instead of using the position of molecule in a continuous space or introducing a pre-defined spatial structure, we divide reaction spaces dynamically. To express it, we extend our AChem (Amari and Tominaga, 2009). Then we model the cell division of *B. subtilis* to evaluate the expressiveness of the extended AChem.

The organization of the following sections is as follows. First, we illustrate part of the cell-dividing mechanism of *B. subtilis* which we are going to model. Second we briefly explain the base AChem and its extension. Then we model *B. subtilis* cell division and show the result of its execution. Finally, we discuss the proposed approach.

## Mechanism of *B. subtilis* Cell Division

*B. subtilis* is a gram-negative rod-shaped bacterium (Adams and Errington, 2009). It is a model organism in molecular biology. Its cell division has been studied, by which *B. subtilis* reproduces itself, for it is a single-cell creature. The mechanism of division is not completely understood, yet some details have been elucidated up until today.

This section illustrates part of the mechanism that controls the division of *B. subtilis* cell which we model in our AChem.

### Forming of Z-ring and division septum

In the process of division, a Z-ring and a division septum are formed at the mid-cell of *B. subtilis* (Adams and Errington, 2009; NW and J, 2005) (Fig. 1). A Z-ring is a ring-shaped polymer of cytoplasmic protein named *FtsZ*; it is formed by the polymerization of the protein on the inside surface of cytoplasmic membrane. Then the Z-ring constricts towards the deep-cell, and the septum formation follows it; the septum becomes one pole of each daughter cell when the division is complete.

Figure 1: The Z-ring and septum.

In order for a cell to divide evenly, the position of Z-ring (and septum) must be regulated. Two mechanisms are regarded as contributing to the regulation, namely, *nucleoid occlusion* (Adams and Errington, 2009) and the *MinCDJ system* (Adams and Errington, 2009; van Baarle and Bramkamp, 2010; Bramkamp et al., 2008). Nucleoid occlusion prevents the Z-ring from forming near nucleoids (shown as gray ellipses in Fig. 1), while the MinCDJ system prevents one from forming near the cell-poles. In the present study, we model the latter mechanism.

Four kinds of proteins play their roles in the MinCDJ system, namely, *MinC*, *MinD*, *MinJ* and *DivIVA*. DivIVA localizes to the inner surface of cytoplasmic membrane at the cell-poles. It recruits MinJ, and MinJ recruits MinD, and MinD recruits MinC. MinC then prevents the polymerization of FtsZ near the cell-poles. Although the mechanism of the localization of DivIVA to the cell-poles is not yet fully understood, the protein is known to have a characteristic that tends to bind to a concave curve of lipid membrane surface (Ramamurthi and Losick, 2009; Lenarcic et al., 2009).

## Completion of cell division

These mechanisms restrict the Z-ring and the division septum to be formed at the mid-cell. The constriction of Z-ring makes the septum curve inward, so DivIVA binds to the cytoplasmic membrane near the Z-ring (Ramamurthi and Losick, 2009; Lenarcic et al., 2009). Then DivIVA recruits MinJ, MinD and MinC proteins, which will work again in the next cell division.

Following the completion of Z-ring constriction, the synthesis of division septum is complete, which is the end of cell division. The Z-ring at a new cell-pole is depolymerized by MinC and other proteins (Gregory et al., 2008); the FtsZ monomers will re-polymerize to form the next Z-ring.

## The Base Artificial Chemistry

The present study attempts to model the cell division of *B. subtilis* using an extended AChem, which we propose in this paper. Before we describe the extension, we give an outline of the base AChem (Amari and Tominaga, 2009).

A *v-atom* is an atom in this AChem, whose name starts with an upper-case letter followed by lower-case letters and/or digits, such as Abc and D2e. A *v-molecule* is a stack

of one or more lines of v-atoms. Shown in Fig. 2 is an example of v-molecule consisting of two lines, which is denoted by 0#AbCd/1#EfGh/, where 1 is the displacement of the second line relative to the first.

A *recombination rule* is a chemical equation in this AChem, which is phrased in terms of *patterns*. A pattern matches (or does not match) a v-molecule. A pattern consists of *atomic patterns* and/or *wildcards*.

An atomic pattern is denoted by a name of v-atom, and matches that v-atom; for example, the atomic pattern Ab matches a v-atom Ab.

There are two kinds of wildcards, namely, *atomic wildcard* and *sequence wildcard*. An atomic wildcard, denoted by a non-negative integer and surrounding angle brackets like <1>, matches any v-atom. The integer is the wildcard's ID, which is referred to by recombination. A sequence wildcard, denoted using an asterisk like <\*> or <3\*>, matches any sequence of zero or more v-atoms. The pattern shown in Fig. 3 (left) is denoted by 0#<\*>Ab<1><2\*>/0#Cd<3\*>/, and matches all of the three v-molecules shown in the right of the figure.

The left-hand side of recombination rule consists of one or two patterns, and the right-hand side may have any number of patterns. A recombination rule recombines a v-molecule (or v-molecules) matched by its left-hand side to v-molecule(s) represented by the pattern(s) on the right-hand side. Shown below is an example recombination rule.

$$0\#<*>Ab<1><2*>/ + 0\#Cd<3*>/ \\ \rightarrow 0\#<*>Ab<1><2*>/0\#Cd<3*>/ \quad (1)$$

If this rule is applied to the two v-molecules 0#ZyAbEf/ and 0#CdGhIj/, they are recombined to one v-molecule of the form 0#ZyAbEf/1#CdGhIj/.

In this AChem, a *membrane* surrounds a *cubicle*. Membranes can be nested to make a *system*. A system can model a natural cell including cell organelles. Each cubicle has a multiset of v-molecules, and so does each membrane; both are called *reaction spaces*. Each reaction space has its own set of recombination rules. Although reaction spaces are assigned to membranes and cubicles, each reaction space has no spatial structure; it is “well-stirred,” i.e., any v-molecule can react with any other v-molecule in the space. An example system is shown in Fig. 4(a). A system is represented by a tree structure, where a cubicle corresponds to a node and a membrane to an edge (Fig. 4(b)).

A v-molecule in the reaction space of a membrane (which can model a protein embedded in a lipid bilayer membrane),

Ab	Cd	
	Ef	Gh

Figure 2: An example v-molecule.

Figure 3: A pattern using sequence wildcards and its matching example v-molecules.

Figure 4: An example system of our AChem.

Figure 5: Directions of membrane v-molecules.

called *membrane v-molecule*, has its direction, as the membrane protein does. The direction of membrane v-molecule is *top* (represented by a preceding hat sign (^)) or *bottom* (by an underscore (\_)), and is relative to an adjacent cubicle from which the v-molecule is viewed. If a membrane v-molecule is top when it is viewed from a cubicle (as  $\sim 0\#AB/$  viewed from Cubicle 1 in Fig. 5(a) for example), it is bottom when viewed from the opposite cubicle ( $_0\#AB/$  from Cubicle 2).

A recombination rule specifies the types of v-molecules using directions. In a recombination rule of cubicle, if a pattern has no direction such as those in Rule (1), it represents a v-molecule in the reaction space of the cubicle. If a pattern has a preceding direction, as in the following examples, it represents a v-molecule having that direction in the reaction space of an adjacent membrane.

For example, if Rule (2) is applied to a bottom v-molecule  $_0\#AB/$  of a membrane (suppose the rule is defined in Cubicle 2 of Fig. 5 and we are viewing the v-molecule (a) from Cubicle 2) and a cubicle v-molecule  $0\#Z/$  (in Cubicle 2, not shown in the figure), they are recombined to a bottom mem-

Figure 6: Membrane dynamics in this AChem.

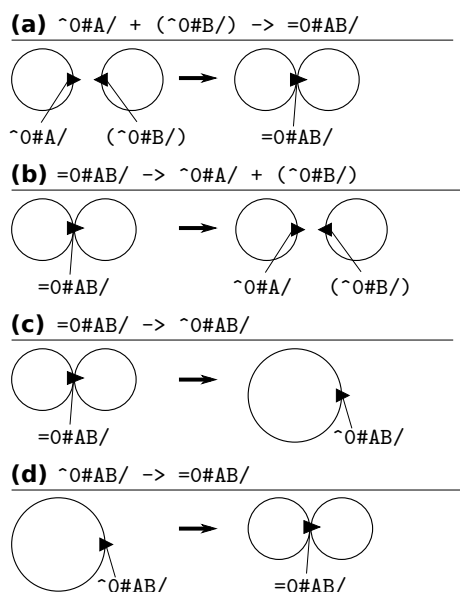

Figure 7: Recombination rules change membrane structure.

brane v-molecule (of Membrane 2) of the form  $0\#ABZ/$ , i.e.,  $_0\#ABZ/$ .

The AChem can express the division and merger of membranes (Fig. 6). The processes go through an intermediate state where two membranes are connected by a v-molecule. This v-molecule is called *connecting v-molecule*; it is represented by equal sign (=) in a pattern. The division and merger of membranes are not described by specifying membranes explicitly; instead, they are defined in terms of recombinations of v-molecules. Four kinds of recombination rules that change membrane structures are shown in Fig. 7 (the rules are supposed to be given to the parent cubicle of the membranes in this case). A pattern surrounded by parentheses like the second term of “ $\sim 0\#A/ + (\sim 0\#B/)$ ” expresses that the two patterns represent v-molecules of different membranes.

Figure 8: Membrane, cubicle and reaction spaces.

Figure 9: Reference to a boundary v-molecule.

A system is interpreted nondeterministically as follows.

1. Initialize the system: each reaction space is given initial v-molecules.
2. Choose a reaction space  $S$ .
3. Choose a recombination rule  $R$  from  $S$ .
4. Choose one or two v-molecules, if any, that  $R$  can apply to.
5. Recombine the v-molecule(s); change the membrane structure if specified.
6. Go to Step 2.

When a system is run on a simulator software, choices are made by a specific algorithm of the simulator (called its *reactor algorithm*). Some of our simulators make choices randomly; others employ physicochemical methods.

## Extensions to the Base Artificial Chemistry

This study extends the base AChem described in the previous section, and models the cell division of *B. subtilis* with the extended AChem. This section illustrates the extension.

In the process of the cell division, there occur the recruitment of division proteins (DivIVA, MinC, etc.) to the cell-poles and the localization of FtsZ at the mid-cell. Since the base AChem gives one reaction space to a cubicle and employs the well-stirred reactor algorithm, it cannot express such localization of proteins in a straightforward manner.

The present study extends the AChem so that a cubicle can have multiple reaction spaces, and so can a membrane, to express such localization. Reaction spaces of a cubicle (or a membrane) have adjacency relationships among them. Figure 8 depicts a cubicle that have three reaction spaces (Cubicle Reaction Spaces 1, 2 and 3), and its surrounding membrane that also have three reaction spaces (Membrane Reaction Spaces 1, 2 and 3); the arrows indicate their adjacency relationships.

## Boundary between reaction spaces

Two adjacent reaction spaces of a cubicle/membrane have a *boundary* between them. Unlike a membrane, a boundary has no reaction space. A boundary can be specified by a membrane v-molecule. This special kind of v-molecule is called *boundary v-molecule*. A boundary v-molecule has a direction. It can be viewed from the outside and the inside of the membrane (same as a normal membrane v-molecule), and also can be viewed from the reaction spaces it specifies. Figure 9 illustrates how a boundary v-molecule can be viewed from reaction spaces around it. The boundary separates the membrane into two reaction spaces (Membrane Reaction Spaces 1 and 2) and the cubicle into two (Cubicle Reaction Spaces 1 and 2). Each reaction space can refer to the boundary v-molecule in its recombination rules using the pattern shown near the arrow from the space; a boundary v-molecule is expressed by a tag “[bnd]” in a pattern.

## Migration of v-molecules between reaction spaces

In a natural cell, most of materials in cytoplasm can freely diffuse in the cytoplasm. To express such behavior, a recombination rule that makes v-molecules migrate between adjacent reaction spaces can be defined. This type of rule is called *migration rule*. An example rule is shown below:

The tag “[as]” means “another space.” When a rule of this type is applied to a v-molecule, the v-molecule migrates to any of the reaction spaces adjacent to the current space.

## Membrane division on a boundary

In the base AChem, a membrane is divided into two when a dividing rule is applied to a membrane v-molecule in the membrane. The division also divides the cubicle surrounded by the membrane; the contents of the cubicle (i.e., v-molecules and child membranes) are distributed to the new cubicles nondeterministically. This property, however, is not desirable when the AChem is to model cell division, because the contents of the cell should be divided evenly.

(a) [bnd]~O#AB/ -> =O#AB/

(b) [bnd]\_O#AB/ -> =\_O#AB/

(c) [bnd]\_O#AB/ -> =~O#AB/

Figure 10: Membrane division on a boundary.

Dividing membrane and its inside cubicle on a specified boundary enables the system to distribute the contents of membrane/cubicle as intended. One can distribute the contents of a membrane/cubicle to its reaction spaces (by recombination rules) before division, then can divide the membrane/cubicle to make two membranes/cubicles.

Such division is performed when a specific type of recombination rule is applied to a boundary v-molecule. Three types of rules and their effects are depicted in Fig. 10. Each pair of eyeballs indicates the reaction space where the recombination rule is defined. An application of any of the rules (a), (b) or (c) divides the membrane/cubicle on the left to the two distinct membranes/cubicles on the right; the black triangle represents a connecting v-molecule. At the same time, the boundary disappears.

### Dividing a reaction space

A reaction space is divided dynamically by the application of recombination rule to a membrane v-molecule. There are two types of rules. One is a rule that creates a boundary molecule (Fig. 11(a)). An application of such a rule makes the membrane v-molecule a boundary v-molecule, divides the membrane reaction space where the membrane v-molecule has been residing, and also divides the inside cubicle reaction space from which the v-molecule can be viewed. The contents of each of the original reaction spaces are distributed nondeterministically to its daughter spaces.

The other is a rule that creates “neighboring space” (Fig. 11(b)), which is indicated by the tag “[nsp]”. When this type of rule is applied to a membrane v-molecule, a new cubicle reaction space that is adjacent only to the current (i.e., one having the rule) cubicle reaction space is created, and also a new membrane reaction space adjacent only to the current membrane reaction space (where the membrane v-molecule belongs to) is created. The contents of the original reaction spaces are distributed nondeterministically to the daughter spaces in the same manner as that for the previous case. In this type of division, the created boundary has no boundary v-molecule.

## Modeling the Cell Division of *B. subtilis*

Using the extended AChem, we constructed a model for the cell division of *B. subtilis*.

### Overview of the model

The conceptual diagram of the model is shown in Fig. 12. A small triangle represents a complex of MinC, MinD and MinJ, a small square represents DivIVA, and a small circle represents FtsZ. The process of division progresses as follows. (The numbers correspond to those in the figure.)

1. DivIVA-MinCDJ complex localizes to the inner surface of the both ends of the rod-shaped cell. FtsZ molecules are scattered over the whole cytoplasm.
2. FtsZ binds to any part of the inner surface of cytoplasmic membrane and starts to polymerize.
3. DivIVA-MinCDJ complex at the rod ends depolymerizes FtsZ polymers around it.
4. Since DivIVA-MinCDJ does not exist at the mid-cell, FtsZ polymerizes there.
5. The polymer of FtsZ becomes a Z-ring.
6. A septum starts to be synthesized as the Z-ring constricts. As the septum grows, DivIVA in the cytoplasm binds near the Z-ring.
7. The cell divides into two when the Z-ring constricts completely and the septum is fully synthesized.
8. MinC, MinD and MinJ binds to DivIVA that is recruited by the Z-ring, to make DivIVA-MinCDJ complex.
9. MinC in the complex depolymerizes the remaining FtsZ polymer. Go to Step 1.

### Definition of the model

The model is defined by the following specifications: the structure of the AChem system (membranes, cubicles and reaction spaces), the initial multiset of v-molecules for each reaction space, and the set of recombination rules for each reaction space.

The structure of the system is shown in Fig. 13. It consists of a membrane and a cubicle surrounded by the membrane. The membrane has three reaction spaces, namely, m-left-pole, m-mid-cell and m-right-pole; the cubicle also has three reaction spaces, left-pole, mid-cell and right-pole. All the membrane reaction spaces share the same set of four recombination rules; the cubicle reaction spaces also share the same set with each other, which comprises 13 rules.

Initial v-molecules are given as follows. The membrane reaction spaces at both ends of the cell, m-left-pole and m-right-pole, are given v-molecules representing DivIVA (\_O#Div4a/). The space m-mid-cell is given no v-molecule. All the cubicle reaction spaces, left-pole, mid-cell

Figure 11: Examples of boundary creation.

Figure 12: A conceptual diagram of the model.

Figure 13: Initial structure of the system.

and right-pole, are given v-molecules for FtsZ,  $0\#Ftsz/$ , and v-molecules  $0\#Mincdj/$ , which represent MinC, MinD and MinJ at once. We deal with the three proteins as an abstract molecule to make the description short.

Recombination rules define how the system works as follows. First, MinCDJ binds to DivIVA (5).

And FtsZ binds to the plasmic membrane (6). To the protein, an FtsZ monomer binds to polymerize (7); FtsZ polymers in the membrane also join (8).

MinC in DivIVA-MinCDJ complex binds to FtsZ polymer (9) and depolymerizes it (10).

Because FtsZ polymerization is prevented at the ends of cell by DivIVA-MinCDJ complex, FtsZ polymerizes at the mid-cell. Eventually a Z-ring is formed (11) (we regard a polymer of twenty FtsZ as a Z-ring; the number is arbitrary). The Z-ring is represented by a boundary v-molecule. The rule divides each of m-mid-cell and mid-cell into two reaction spaces.

The Z-ring constricts to the deep-cell and divides the membrane (12); the constricted Z-ring becomes a connecting v-molecule.

DivIVA in cytoplasm binds to the plasmic membrane near the constricted Z-ring (13, 14). Note that the viewpoints of the two rules are in the opposite cubicle to each other. DivIVA near the Z-ring is expressed by a v-molecule with multiple lines.

The divided membranes separate when a particular number (ten) of DivIVA have bound to the both sides of Z-ring (15), meaning sufficient time has elapsed for the complete constriction of Z-ring. (The first term is folded to fit in the

column.)

```
=0#<0..9><10*>/0#<*11><12..31><32*>/
      0#<33..42><43*>/
→ _0#<0..9><10*>/0#<*11><12..21>/
+ (_0#<33..42><43*>/0#<22..31><32*>/) (15)
```

After the division, there are remaining FtsZ and DivIVA binding nearby at the new cell-pole. In other words, they indicate the new cell-pole. The following rule creates a new reaction space that represents the new cell-pole (16).

```
^0#<0..9><10*>/0#Ftsz<11*>/
→ [nsp]^0#<0>/ + [nsp]^0#<1>/ + [nsp]^0#<2>/
+ [nsp]^0#<3>/ + [nsp]^0#<4>/ + [nsp]^0#<5>/
+ [nsp]^0#<6>/ + [nsp]^0#<7>/ + [nsp]^0#<8>/
+ [nsp]^0#<9>/ + [nsp]^0#<10*>/
+ [nsp]^0#Ftsz<11*>/ (16)
```

Then MinCDJ binds to DivIVA at the new cell-pole to make DivIVA-MinCDJ complex (5), and MinC there depolymerizes the FtsZ polymer remaining at the pole (6).

In addition, the system has migration rules (like (17)) that let v-molecules migrate to adjacent cubicle reaction spaces, and a rule that expresses the decomposition of DivIVA (18).

```
0#Div4a/ → [as]0#Div4a/ (17)
0#Div4aDiv4a<0*>/ → 0#Div4a/ + 0#Div4a<0*>/ (18)
```

## Execution of the model

We built a prototype simulator for the extended AChem by modifying a simulator for the base AChem; the both simulators are written in Ruby. When we ran the description for the cell division illustrated in the previous section, the model worked as intended.

A snapshot taken from the execution is shown in Figure 14. The text above is the output of simulator, and it is depicted in the illustration below. In this state, the first cell division is complete, and each daughter cell has started the next cycle of cell division. In Membrane 11 and Membrane 13, remaining FtsZ polymers (`_0#FtszFtsz...`) are observed.

## Discussion

In the extended AChem, while each reaction space is well-stirred, a cubicle/membrane can consist of multiple reaction spaces, so localization of molecules within the cubicle/membrane can be expressed.

The division of reaction spaces is performed by the application of recombination rule to a molecule. This is in the same framework we used to formalize membrane division and merger (Tominaga et al., 2007). The main advantage of this approach is that the same set of rules can be applied

after the structure of system has changed because rules do not refer to membranes, cubicles or reaction spaces by their IDs, positions, coordinates or addresses; the behavior is determined only by v-molecules they have. Though we did not model nucleoid occlusion, we think it can also be modeled using the division of reaction spaces.

Possible topologies of reaction spaces are limited. For example, a membrane reaction space and the cubicle reaction space inside (and adjacent to) it always correspond in a one-to-one manner.

In the illustrated application, the execution of the system is somewhat like a reaction-diffusion system; the number of FtsZ in the mid-cell space (or “concentration”) seems to contribute to the formation of the Z-ring. This is because the implementation of the simulator uses random numbers to decide which reaction to occur. The current implementation does not take physicochemical dynamics of molecules into account. Doing it will be our future work.

In (Madina et al., 2003), the formation of membrane-like structures is studied. They define the lattice and interaction among particles in the space. A membrane-like structure is observed as a collection of particles in lattice cells that enclose an area. So the lattice should be suitable for the study. In our AChem, a membrane is a primary entity and cannot be decomposed into parts; this property will be beneficial in modeling the behavior of membrane at a high level of abstraction.

A work using E-Cell to simulate the E-ring formation of *E. coli* (Arjunan and Tomita, 2010) predefines a hexagonal lattice with voxels having 12 neighbors in order to simulate the behavior of proteins in cytoplasm. In contrast, our study first only gives three reaction spaces to express the areas of cytoplasm and they divide dynamically as the execution progresses. This flexibility will contribute to the scalability of model, especially the membrane structure of which changes considerably, like the process of complete ontogenesis.

In this aspect, our approach has similarities with L-systems (Lindenmayer, 1968): symbols in an L-system can increase as rules are applied, and rules specify no position or ID of each symbol occurrence. Since ours is an artificial chemistry, membranes and cubicles can have (v-)molecules, and reactions among them can be described as recombination rules. We think this is advantageous in modeling a system based on known biochemical reactions.

## Concluding Remarks

In this paper, we presented a membrane artificial chemistry that can dynamically divide reaction spaces, as an extension to our previous artificial chemistry. The extension is introduced to express the localization of molecules.

We showed an application of it: a model for the cell division of *B. subtilis*. The model is defined by the initial structure, the initial v-molecules and 17 recombination rules. We executed the model on our simulator, and observed that a

# A Cultural Evolutionary Model for Artifact Capabilities

Felicitas Mokom<sup>1</sup> and Ziad Kobti<sup>1</sup>

<sup>1</sup>University of Windsor, Windsor, ON Canada N9B-3P4  
mokom@uwindsor.ca and kobti@uwindsor.ca

## Abstract

The use of tools or artifacts is essential to the human race and has been the subject of recent research in Artificial Intelligence. How individual agents acquire these capabilities and how they evolve can be considered vital steps towards understanding complex group capabilities. In a previous study, we designed and implemented an extended version of a theoretical model for artifact capability that accommodated biological evolution and learning via exploratory methods. Historical knowledge and genetic algorithms were combined with learning techniques to build agents that could learn either individually from observations of their own behaviour or socially by observation from a distance. In this study, we incorporate a collaborative form of cultural learning into the model in an effort to enhance the artifact capability-learning agents. This is accomplished via the design of a cultural evolutionary model that utilizes genetic and cultural algorithms to complement the cognitive abilities of the agents. Learning agents belonging to a social network cooperate with and benefit from each other by sharing individual experiences. Results obtained from the multi-agent simulation implementation confirm the efficiency of social learning over individual learning and demonstrate the benefits of cultural over biological evolution. They also suggest that as artifacts get more complex, social agents learning via cultural influence outperform those learning by observation from a distance.

## Introduction

The ability of humans to learn tool or artifact use, evolve these capabilities and transfer the knowledge to others has been of much interest to various researchers particularly in the cognitive sciences. Archaeologists (Plummer, 2004) are fascinated by the earliest recordings of tool use, philosophers (Preston, 1998) theorize on the importance of tool use relative to human intelligence and behavioural geneticists (Bacher et al., 2010) present arguments on the role of genetics in tool use behaviour. Preston contends in her work that the study of tool use be considered as important as the study of language because it is indicative of the high level cognition that humans are capable of. According to (Petroski, 1992) artifact evolution is driven by functionality rather than failure. Artifacts do not necessarily evolve because they fail at what they were intended for, but rather because they can

always be improved. These improvements are often identified during use of the artifact. Humans use tools by themselves but often combine their tool capabilities. In order to successfully model these complex group capabilities it is essential to understand how humans acquire individual capabilities and how these capabilities change over time.

In this study the terms tools and artifacts are used interchangeably and include any physical object in the environment that a human agent can use towards achieving a goal. The human agent is a rational agent that acts in its best interests, has beliefs about the world, and chooses its actions accordingly (Wooldridge, 2000). Based on the Belief-Desire-Intention (BDI) theory of (Bratman, 1987) the rational agent has beliefs, desires and intentions. The agent's beliefs describe its informative state about the world. Its desires represent what the agent would like to accomplish and are used to devise goals. Its intentions are adopted goals that the agent uses to generate plans or actions that it performs. According to (Acay et al., 2008) tool capability resides within the intentions of an agent and represents plans that the agent can realize with the help of a tool. If an agent has capability for a tool then it has at least one plan that specifies one way to use the tool towards one or more of its adopted goals.

In a previous study (Mokom and Kobti, 2011) we implemented an extended version of Acay *et al.*'s theoretical model for tool capability incorporating biological evolution and learning through exploratory methods. A representation of artifacts and the cognition of an agent that can learn artifact capabilities were provided. Learning techniques from (Russell and Norvig, 1995) were combined with genetic algorithms (GA) to build a multi-agent simulation that evaluated individual and social learning in the form of observational learning from a distance. The social learning agent observed another agent successfully apply an artifact capability without the acting agents' knowledge, noted partial information and subsequently formed a learning goal to apply the same capability.

One limitation of the previously implemented social learning agent is the fact that there must exist another agent in its vicinity that already possesses the capability to use

the tool. This limitation coupled with the contention by (Reynolds, 1997) that cultural evolution evolves faster than biological evolution is the inspiration for the work in this paper. We design and implement a cultural evolutionary model that supports agents that can socially learn an artifact capability without any prior knowledge. This is accomplished via the integration of a GA and a cultural algorithm (CA) with the framework of an artifact-capability learning agent. A learning agent can benefit from being part of a social network where individual experiences are shared by using the experiences of others to enhance its own learning process. Our objectives are to demonstrate how agents can collaboratively learn an artifact capability over time and compare the results to those obtained for observational learning agents.

The next section provides some background on related work. It is followed by our architecture of artifact capability-learning agents. We then provide details on our implementation and experiments conducted, followed by conclusions deduced and future work.

## Background

### Artifact Use

The subject of tool use particularly in animals has been explored in various fields. (Wood et al., 2005) provide a good background on this. Much of the underlying work involves the effort to understand how animals explore objects. (Power, 2000) provides some insight into exploratory methods utilized by children and animals when they encounter a new tool. He contends that the exhibited behaviour, which can sometimes be genetically predetermined, is species dependent and very much influenced by culture.

Robotic researchers have also explored the subject of tool use. This has involved the development of object recognition mechanisms in robots (Wood et al., 2005) and the creation of industrial robots programmed for specific tool use (Bluethmann et al., 2003). In an effort to investigate robots learning tool use through exploratory methods, (Stoytchev, 2005) provides a representation of a robot that can attempt various actions with a tool, record and remember the effects. (Schäfer and Bergfeldt, 2007) investigate the emergence of complex tool use behaviours acknowledging that they need to combine their efforts with learning and reasoning by agents in order to obtain more useful results. (Noble and Franks, 2002) simulate various social learning methods for tool use concluding that emulation is sometimes a more effective method of learning than imitation because it promotes exploration. Omitted from their research is an evolutionary aspect to their work.

### Cultural Learning

Knowledge among humans is often transmitted through experience and cooperation. According to Tomasello et al. (1993) in cultural learning, integrated patterns of behavior accumulate changes across generations of a social group.

They identify three different manifestations of cultural learning namely imitation, instructed learning and learning by collaboration. Cultural evolution describes the change of culture over time and can be used to study the effects of cultural learning.

(Curran and O’Riordan, 2007) simulate the instructed learning form of cultural learning using a teacher/pupil environment. In their study a GA and a neural network are used to evolve a population where fitter individuals are selected as teachers for the pupils of the next generation. The goal was to demonstrate how cultural learning improves the fitness of a population. (Acerbi and Nolfi, 2007) utilize simulated annealing to incorporate cultural evolution in their comparisons between individual learning and the imitation form of cultural learning concluding that a sequence of both yields the best results. Geared more towards robotics, much of their work involves robotic sensors and body schema. (Reynolds and Peng, 2004) capitalize on the emergence of cultural learning in their CA framework to demonstrate the power of learning and adaptation within cultures.

## Architecture of an Artifact Capability-Learning Agent

An artifact capability-learning agent has the ability to employ learning techniques towards acquiring a tool capability, that is one way to use a tool towards the achievement of one or more of its goals. This can be accomplished via individual or social learning experiences. In the former case the agent learns solely through observations of its own behaviour and in the latter, the agent learns by observing or co-operating with other agents in its environment. We present the existing model of an artifact capability-learning agent from our previous study and demonstrate its expansion to cultural learning agents.

### Cognitive Elements of Learning Agent

The cognition of a rational agent endowed with the ability to learn artifact capabilities, was incorporated into a general model of learning agents developed by (Russell and Norvig, 1995). This can be appreciated in Figure 1 obtained from (Mokom and Kobti, 2011). The learning agent’s cognition is composed of a performance element, a critic and a learning element. The performance element bears the responsibility of selecting the agent’s external actions to perform. Once these actions are performed, the critic element measures resulting percepts against an external predefined standard of performance and generates feedback. This feedback is received by the learning element and used to improve the performance element so it can do better the next time. The rational agent’s beliefs, goals and capabilities reside within the performance element playing a role in the decision making process of action selection.

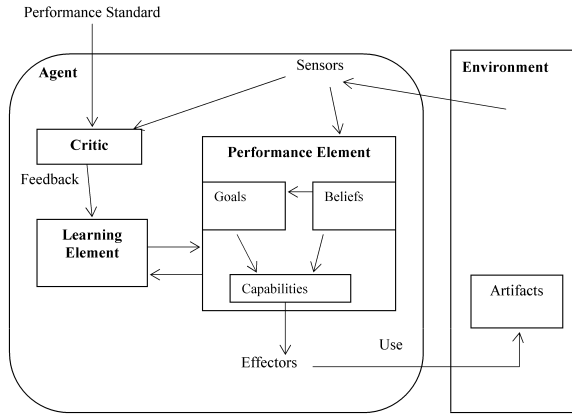

Figure 1: An artifact capability-learning agent

## Artifact and Agent Model

An artifact is represented as an object made up of one or more parts. Each artifact part is composed of a set of attributes. An artifact attribute has a set of possible values and a visibility property. The visibility property indicates whether an observing agent can copy the value of the attribute chosen by the agent it is observing. Let's consider a *pen* as an artifact. The part *shell* could represent the entire outer layer of the pen with an attribute *hold-position*. The set of values for the hold-position attribute indicate all possible points where the pen can be held. If the hold-position attribute is visible then an observing agent can copy the point at which the pen is held by the acting agent.

An artifact capability-learning agent has beliefs, goals and capabilities. A capability has an abstract functional ability and an ordered list of tasks. Abstract functional abilities represent all the things that an agent can do with an artifact regardless of whether the agent knows how. It is only when the agent acquires the knowledge to use the abstract ability that the agent can be described as having the capability. An agent can therefore select an abstract ability and use it to formulate a learning goal. For simplicity it is assumed in this study that an artifact has a single part and multiple attributes. The ordered lists of tasks represent attribute value sequences that the agent must determine in order to realize the capability.

External to the rational agent is a predefined standard of performance that is goal dependent for every artifact. This standard maintains information about the number of required tasks and the correct attribute value sequences for each task within an artifact capability. The performance standard is used by the critic element in evaluating the results of the agent's actions. The critic's feedback includes an average fitness score for the attempted sequence. The model supports a *range of values* performance standard that provides an inclusive range within which the selected attribute value is constrained to fall. For an attribute value sequence

$V = \langle v_1, \dots, v_n \rangle$  with  $n$  attributes, the critic calculates the mean fitness score  $MF$  as follows:

$$f(v_i) = \begin{cases} 1, & mn \leq v_i \leq mx \\ \frac{1}{mn-v_i}, & v_i < mn \\ \frac{1}{v_i-mx}, & v_i > mx \end{cases}$$

$$MF(V) = avg \left( \sum_{i=1}^n f(v_i) \right)$$

where  $mn$  represents the lower bound of the performance standard for the attribute with value  $v_i$  and  $mx$  represents its upper bound. The function gives the same score to all values that satisfy the standards' criteria. The rest of the values are scored based on their distance from the required range.

## Performance Element

One of the key decisions in the design of a learning agent is the design of the performance element. In accordance with (Russell and Norvig, 1995), the performance element of an artifact capability-learning agent should contain all the information needed by the agent to go about trying to use the tool. This is essentially how the agent deliberates and selects attribute values. We inherit two types of performance elements designed in the previous study and refer to them henceforth as PE1 and PE2. In this study we design a new type of performance element PE3.

All three performance elements' maintain a history of failed attempts in their respective beliefs. A *fitness-based attribute value selection* procedure is used in the selection of attribute values where one randomly chosen attribute of a selected sequence is modified at each attempt. For PE1 and PE2 the selection is based on the fitness of the agent's previous attempts. PE1 supports an agent learning on its own. The agent simply ensures that it does not repeat attribute value sequences that have previously failed. PE2 supports an agent learning socially via observation from a distance. Like PE1, it does not repeat attempted sequences. The variation lies in the fact that PE2 has partial knowledge of the capability at the start of the learning process. In determining new attribute values, the agent only selects and modifies the invisible attributes.

The new performance element PE3 is built to support an agent learning a tool capability through cultural experience. Its selections are based on both the fitness of its previous attempts and the fitness of all other agents that it cooperates with.

## Social Network and Cultural Algorithm

PE3 agents that collaborate with each other belong to a social network. In this study, it is not deemed necessary to define a social network with complex relationships. The social

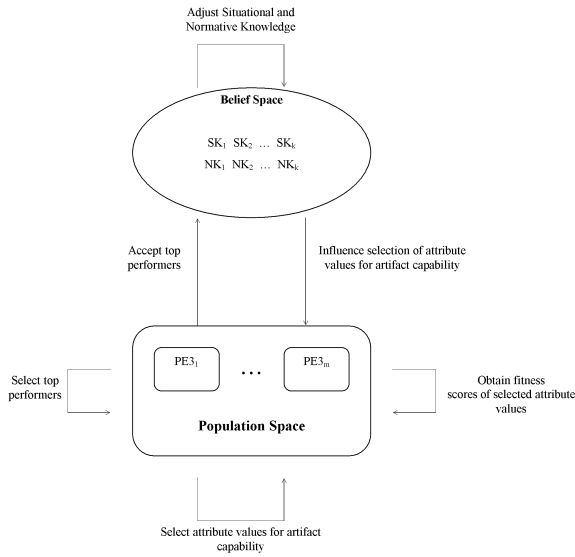

Figure 2: Cultural learning by  $m$  agents of a  $k$ -task artifact capability

network exists only to facilitate the exchange of information between agents towards enhancing the learning process.

PE3 agents are designed within the CA framework. CA's were introduced by (Reynolds, 1979) to facilitate the modeling of cultural evolution. A CA is made up of a belief space, a population space and a communication protocol between them. Selected individuals from the population space contribute to knowledge maintained in the belief space. The contribution is transmitted through an acceptance function and the knowledge in the belief space is adjusted accordingly. That knowledge influences the evolution of the individuals in the population space via an influence function. A CA supports the use of any kind of evolutionary algorithm in the implementation of the population space. The framework for PE3 agents learning an artifact capability is shown in Figure 2. It demonstrates PE3 agents belonging to a single social network sharing one global belief space within the CA. In the figure, there are  $m$  agents trying to learn the same artifact capability with  $k$  tasks.

**Knowledge Sources** Reynolds identifies five types of cultural knowledge that can be maintained in the belief space of a CA. They are situational, normative, topographic, historical or temporal and domain knowledge. Figure 2 shows the belief space in our design using situational and normative knowledge. Situational knowledge maintains the best performers so far. For artifact capability-learning agents cooperating with each other, these would be the highest scoring selections of attribute value sequences. Normative knowledge maintains encouraging ranges for each attribute value making it feasible for agents to “jump into the good range”

(Chung and Reynolds, 1998). The learning agents can adjust their attribute value selections using the guidance of these ranges that have been derived from selections of the top performers.

PE3 agents utilize knowledge from two types of belief spaces. The agent's personal belief space  $PB$  maintains a history of its failed attempts for the current task being learned and is local to the agent. Thus  $PB = \{\langle v_1, \dots, v_n \rangle\}$  where  $n$  represents the number of attributes for the artifact and each  $v_i$  is the selected attribute value for the sequence. The global belief space shared by agents in a social network henceforth referred to as  $GB$  is defined as:  $GB = \langle S, N \rangle$ , where  $S = \{SK_1, \dots, SK_k\}$  represents the situational knowledge and  $N = \{NK_1, \dots, NK_k\}$  represents the normative knowledge for  $k$  tasks of an artifact capability. The situational knowledge maintains the single best exemplar found so far for each task:

$$SK = (t, s_{SK}, \langle kv_1, \dots, kv_n \rangle) \quad (1)$$

where  $t$  is the task id,  $n$  represents the number of attributes for the artifact, each  $kv_i$  is the selected attribute value and  $s_{SK}$  represents the score of the sequence. The normative knowledge keeps favourable ranges for each attribute value. This is defined as:

$$NK = \{t, R_1, \dots, R_n\} \quad (2)$$

where  $t$  is the task id and  $n$  is the number of attributes for the artifact. Each  $R_i$  is a tuple:

$$R_i = \langle sl, su, [l, u] \rangle \quad (3)$$

where  $l$  and  $u$  represent the favourable lower and upper bound values of attribute  $i$ , with  $sl$  and  $su$  as their respective scores. A PE3 agent contributes to and uses both belief spaces in the learning process.

**Adjusting the Belief Spaces** The agent's local belief space is updated with the failed attempt every time the agent tries a new attribute value sequence for a particular task and fails. For  $GB$ 's adjustment when top performers are accepted, they are sorted according to their scores. If  $h$  contains parameters for the individual with the highest score:  $h = (t, s_h, \langle v_1, \dots, v_n \rangle)$ , then it is used to adjust the situational knowledge  $SK$  defined in Eq. (1) as follows:

$$SK' = \begin{cases} h, & s_h > s_{SK} \\ SK, & \text{otherwise} \end{cases} \quad (4)$$

Thus the situational knowledge is always the highest performer so far among all the attempted attribute values for the specific task by members of its social network.

In order to adjust the normative knowledge we need to deal with one attribute at a time. For each attribute  $i$  we

obtain and sort its values for all top performers. The lowest selected value  $x_i$  and the highest selected value  $y_i$ , with their corresponding scores  $sx_i$  and  $sy_i$  can now easily be extracted. Normative knowledge for the task being learned defined in Eqs. (2) and (3) is updated for each attribute  $i$  using the following formulae:

$$\begin{aligned} l'_i &= \begin{cases} x_i, & (x_i < l_i \text{ and } sx_i = sl_i) \text{ or } sx_i > sl_i \\ l_i, & \text{otherwise} \end{cases} \\ sl'_i &= \begin{cases} sx_i, & (x_i < l_i \text{ and } sx_i = sl_i) \text{ or } sx_i > sl_i \\ sl_i, & \text{otherwise} \end{cases} \\ u'_i &= \begin{cases} y_i, & (y_i > u_i \text{ and } sy_i = su_i) \text{ or } sy_i > su_i \\ u_i, & \text{otherwise} \end{cases} \\ su'_i &= \begin{cases} sy_i, & (y_i > u_i \text{ and } sy_i = su_i) \text{ or } sy_i > su_i \\ su_i, & \text{otherwise} \end{cases} \end{aligned} \quad (5)$$

Using these rules, the agents will progress towards learning the correct range required by the performance standard.

**Population Space and Influence from Global Belief Space** The population space in our cultural algorithm uses a genetic algorithm. As in the previous study the GA uses a bit representation for solutions in the population. It employs two-point crossover and mutation to modify a single attribute value for each attempt. Selection for reproduction is accomplished via roulette wheel selection. With PE3 agents however, mutation is carried out differently. In order to benefit from knowledge in *GB*, the situational and normative knowledge are used to determine direction and step size for the mutation respectively. This effectively permits attribute value sequences to follow the exemplar and at the same time strive to get into a desirable range. If the sequence being influenced is  $q = (s, \langle v_1, \dots, v_n \rangle)$ , then the chosen attribute's value  $v_i$ , is mutated using the following formula derived from Chung and Reynolds (Chung and Reynolds, 1998):

$$v'_i = \begin{cases} v_i + |(u_i - l_i) \cdot N(0, 1)|, & v_i < kv_i \\ v_i - |(u_i - l_i) \cdot N(0, 1)|, & v_i > kv_i \\ v_i + (u_i - l_i) \cdot N(0, 1), & \text{otherwise} \end{cases} \quad (6)$$

where  $kv_i$  represents the exemplar value in the situational knowledge as defined in Eq. (1),  $l_i$  and  $u_i$  correspond to the lower and upper bounds for that attribute in the normative knowledge defined in Eqs. (2) and (3), and  $N(0, 1)$  is a random value obtained using the standard normal distribution. All values correspond to the current task being learned.

## Cultural Learning Simulation

The simulation environment is a simple 20 x 15 toroidal grid world, in which each square contains an agent and an arti-

fact. There are three types of agents henceforth referred to as AG\_GA\_PE1, AG\_SOCIAL\_PE2 and AG\_SOCIAL\_PE3 varying based on the implementation of the performance element. All AG\_SOCIAL\_PE3 agents belong to a single social network. The agents can learn capability for artifacts with different complexity. All artifacts are made up of a single part but differ in the number of attributes. The grid is populated with 100 members of each type of agent and the same type of artifact is placed in each square. The agents simultaneously learn the same artifact capability by attempting different combinations of attribute values employing the respective technique of their performance elements.

For the genetic algorithm of AG\_GA\_PE1 and AG\_SOCIAL\_PE2 a mutation rate of 0.01 was chosen. For AG\_SOCIAL\_PE3 agents, mutation was determined by direction and step-size with a mutation rate of  $1/n$  where  $n$  represented the number of attributes for the artifact being learned. The crossover rate was set to 0.7 and the population size at 100 for the GAs of all agents. The range of possible attribute values for artifacts was set to  $[1..100]$  with the *range of values* performance standard covering 20% of the range. The number of tasks required by all agents to learn to use the artifact was 5. Finally, the top 5% performers for each agent's solutions were selected to be accepted into the global belief space.

The pseudo-code for cultural learning of an artifact capability is shown as Algorithm 1. At the start the social network is created and its global belief space is initialized to 5 tasks. For each task the exemplar is set to null and the normative range to the range of possible attribute values that is  $[1..100]$ . Agents are then added to the network. All agents perform the rest of the algorithm simultaneously. Each agent gets the artifact at its location and uses its cognitive elements to learn the capability. The learning element selects an appropriate ability and formulates a goal. The performance element initializes the agent's local belief and capability to null and the goal to false. Every simulation step the agent generates an attribute value sequence, attempts it and performs the necessary updates. If the feedback of the attempt indicates failure, the sequence is added to the agent's local belief. If there is some form of success, the agent has either reached its goal or has met the minimum requirement to proceed to the next task. If the goal is achieved, the learning element advises the performance element to perform the final capability update and the agent is done. If the goal is not yet reached, the performance element is asked to update the capability with the learned task's successful attribute values, clear the local belief as well as the agent's population space and continue on to the next task.

The knowledge maintained by *GB* is utilized when PE3 provides an attribute value sequence. The pseudo-code is shown as Algorithm 2. POP\_SIZE is a constant that specifies the number of attribute value sequences being evolved by the GA used to implement PE3's population space and

    PE3 provides attribute value sequence
    Critic tests attribute value sequence
    Critic generates feedback
    Learning element generates changes
    PE3 applies changes
end
```

---

is set to 100 in our experiments. The initial population is randomly generated without repeating sequences that have been attempted already. Once that is complete PE3 provides attribute value sequences by checking if there are still sequences to be attempted, selecting and returning one. If all attribute value sequences in the population have been attempted, fitness scores are used as the criteria to vote top performers for acceptance into *GB*, which is responsible for its own adjustment. A new population is then generated influenced by *GB*'s situational and normative knowledge. One attribute value sequence is selected from the new population and returned for the agent to attempt.

CA's require the evaluation of the entire population space prior to communication with *GB* via the acceptance function. For an artifact capability-learning agent this means that an agent's selections have no impact on *GB* until after all attribute value sequences in the population have been attempted. This is necessary because the agent has to test every generated sequence and obtain its fitness before the top performers can be identified. There is one more instance however, where it would be useful to update *GB*'s knowledge. That would be when the critic element declares success for an agent either at the task or the goal level. This can occur at any time during the evaluation process of the population space. In this specific case, when applying the learning elements suggested changes PE3 requests that the successful attribute value sequence be accepted into *GB*. It does not vote for top performers since it is likely that the entire population has not yet been evaluated. After the successful sequence is accepted *GB* adjusts its situational and normative knowledge using the same rules as when it receives top performers. This allows the agents to benefit from the success of others.

## Experiments and Results

AG\_GA\_PE1 agents are the individual experience-learning agents that strive to acquire an artifact capability on their

Figure 3: Average Convergence For All Agents Learning Capability for 4, 8, 12 and 16-attribute Artifacts (Visibility of attributes applies only to AG\_SOCIAL\_PE2 agents)

own. An AG\_SOCIAL\_PE2 agent learns socially by observing a capable agent from a distance, copying visible attributes and learning the remaining attribute values on its own. AG\_SOCIAL\_PE3 agents benefit culturally by cooperating with other agents in an effort to enhance their individual learning abilities. Figure 3 shows the results of 100 representatives of each type of agent learning capability for artifacts with 4, 8, 12 and 16 attributes. Figure 4 shows the results of 100 representatives of both types of social agents learning capability for artifacts with 8, 12, 16, 20 and 24 attributes. In all experiments 25% of the attributes were made visible for AG\_SOCIAL\_PE2. At the end of each test run, the mean convergence times for each type of agent were computed. These are the average number of iterations needed by the agents to learn the artifact capability.

Figure 4: Average Convergence For Social Agents Learning Capability for 8, 12, 16, 20 and 24-attribute Artifacts (Visibility of attributes applies only to AG\_SOCIAL\_PE2 agents)

It can be observed in Figure 3 that AG\_GA\_PE1 agents were outperformed by both AG\_SOCIAL\_PE2 and AG\_SOCIAL\_PE3 agents in all conducted experiments. The results show an increase in the difference in convergence rate between the individual and social learning agents as the number of attributes increased from 4 to 16 attributes with the individual learning agents needing more time to learn the capability. An interesting observation in Figure 4 is the difference in convergence rate between the two types of social learning agents. AG\_SOCIAL\_PE2 learn faster than AG\_SOCIAL\_PE3 agents for 8, 12 and 16 attributes. However at 20 attributes the cultural learning agents outperform those learning via observation from a distance. The trend continues at 24 attributes as AG\_SOCIAL\_PE3 agents learn even faster.

In our previous study it was demonstrated that learning socially outperforms individual learning therefore, it is no surprise AG\_SOCIAL\_PE2 agents do better than AG\_GA\_PE1 agents. The fact that AG\_SOCIAL\_PE3 agents outperform AG\_GA\_PE1 agents supports the contention that artifact capability-learning via cultural evolution should proceed at a faster rate than through biological evolution. To understand the results that show agents learning via observation from a distance outperforming their cultural learning counterparts with simpler artifacts or artifacts with fewer attributes it must be remembered that these agents have partial knowledge of the artifact capability upfront. We believe that this partial knowledge gives AG\_SOCIAL\_PE2 agents a head start in the learning process. AG\_SOCIAL\_PE3 agents on the other hand begin with no knowledge of the capability and simply use the best of their social group to improve the process over time. According to Reynolds (1997)

knowledge compiled over time and maintained in the global belief space should guide the learning process such that it improves at every trial. As the number of attributes increase, the artifacts get more complex and the search space larger AG\_SOCIAL\_PE3 agents get better and eventually outperform AG\_SOCIAL\_PE2 agents. Although the observed threshold may vary and be problem dependent CA's have been used to optimize complex applications Chung and Reynolds (1998). Therefore we suggest that as an artifact gets more complex the likelihood that its capabilities would be best acquired via cultural learning increases especially when the visibility of attributes for observational learning is low.

## Conclusions and Future Work

In this study, we have designed and implemented a cultural evolutionary model supporting an agent with the objective of learning artifact capabilities without prior knowledge. Cultural learning agents benefit from belonging to a social network where individual experiences are shared. The model was designed by integrating a genetic and cultural algorithm with the framework of an artifact capability-learning agent. One of the objectives was to enhance the learning capacities of a previously implemented learning agent through cultural learning. Another objective was to compare cultural learning of artifact capabilities to observational learning from a distance. On a larger scale, we maintain that understanding the acquisition and evolution of artifact capabilities for single rational agents is a vital step towards representing their capacity to combine them into group capabilities, towards the accomplishment of more complex goals.

Results obtained from our multi-agent simulation implementation confirm that social learning outperforms individual learning and suggest that complex artifact capabilities are best learned via cultural learning. Although observational learning from a distance surpassed cultural learning for simpler artifacts, the fact that it requires access to an agent already in possession of the capability is a drawback. Additionally the agent must know how to copy the visible attributes with some degree of certainty. A cultural learning agent needs no capable agent in its vicinity and can begin the learning process without possessing any aspect of the artifact capability.

We believe that further experiments are necessary to investigate varying degrees of attribute visibility for agents learning via observation compared to the cultural learning process. One of the knowledge sources identified for the global belief space by (Reynolds, 1979) that was not used in this study is domain knowledge. For future work it can be used to influence the choice of goals for agents to pursue with regard to learning an artifact capability. It would be useful to simulate how goals evolve. One fitness function would no longer be sufficient in the learning process. The choice of a fitness function would be driven by the arti-

fact capability being learned, even for the same artifact. As an example, a knife can be used both as a cooking utensil and as a weapon. An agent's choice of one versus the other would require a different fitness function.

# Surviving the Tragedy of Commons : Emergence of Altruism in a Population of Evolving Autonomous Agents

Jean-Marc Montanier<sup>1</sup> and Nicolas Bredeche<sup>1</sup>

<sup>1</sup>TAO - Univ. Paris-Sud, INRIA, CNRS, F-91405 Orsay, France

## Abstract

This paper explores the following question: how a fixed-size population of autonomous agents (such as a swarm of robotic agents) may evolve altruistic behaviors during open-ended evolution. In particular, we focus on a situation where the tragedy of commons can possibly occur: a situation where individuals must display altruistic behaviors in order for the whole population to avoid extinction. Our approach considers a sub-individual framework, defined at the level of genomes rather than agents, in order to provide an efficient algorithmic solution for the emergent of coordination among the population. Experiments show that the proposed evolutionary adaptation algorithm favors the emergence of altruistic behavior under some assumptions regarding genome relatedness. In-depth experimental studies explore the relation between genotypic diversity and degree of altruism as well as the exact nature of the evolutionary adaptation process.

## Introduction

Altruism is a remarkable behavior observed in Nature, where actions of an individual benefit other individuals even though these actions may negatively impact the individual's chances of survival. A well-known example is given by individuals that watch out for a predator and signal danger to the group whenever it is required, thus potentially drawing the predator's attention to them. The reason why some individuals may sacrifice themselves for the benefit of the group has long been studied and there are now some widely accepted theoretical basis regarding the relation between genotypic relatedness among individuals and degree of altruism, as first described by Hamilton (1964). Altruism has long been actively studied from Biology to Economics, from Sociology to Game Theory, to cite a few domains. It differs from cooperation as altruism requires no direct benefit nor reciprocity. Moreover, its benefit can only be measured at the level of the population, as summarized by Lehmann and Keller (2006).

This paper is concerned with the emergence of altruism in a fixed-size population of evolving autonomous agents where the environment is such that selfish behaviors lead to extinction. This situation is known as the tragedy of (unmanaged) commons, as introduced by Hardin (1968, 1994):

individuals must share a common limited resource, and possibly sacrifice their own benefit, so that the population survives through generations.

The main motivation behind this research is to propose a practical implementation of evolutionary adaptation in *a priori* unknown environments in the scope of a fixed-size population of autonomous agents. This assumption is central to our motivation as the long term goal is to provide practical algorithmic solutions that can be deployed in a swarm of virtual agents in complex environments as well as real world autonomous robots. The contribution in this paper is then both fundamental and practical as the emergence of altruism during the course of evolution is experimentally studied, with a particular focus on its causes and consequences, and is considered within an experimental setup that is closely related to the target application: a 2D virtual environment with realistic assumptions inspired from autonomous robotics.

The paper is organized as follow: the definitions of altruism and tragedy of commons are provided in the next section, along with a short description of relevant contributions from the fields of Artificial Life and Evolutionary Robotics. Then, the environment-driven evolutionary adaptation algorithm is described as well as the experimental settings used for the experiment. Results from the experiment are given and discussed, with a particular focus on the nature of altruism observed. Finally, the last section provides a discussion and conclusion and sketches future directions for this work.

## Context and Motivation

This section starts with a definition of the Tragedy of Commons, a well-known social dilemma where the population welfare strongly depends on individual behaviors. Then, a definition of altruism is given as well as a brief overview of its theoretical foundations in Biology. The section ends with a short review of related works in the field of Artificial Life and Evolutionary Robotics.

## The Tragedy of Commons

The tragedy of (unmanaged) commons ((Hardin, 1968, 1994)) is a particular kind of social dilemma where a pop-

ulation of individuals have access to a finite common resource pool: each individual may temporarily increase its fitness through selfish behavior, but this inevitably leads to exhaust the common resource pool, ultimately ending with population extinction. The classic example describes farmers optimizing their personal benefit by owning as many cows as possible without any regards for the common grazing the cows feed from, which will quickly suffer from over-exploitation, ending with cows dying from starvation.

The tragedy of commons has been widely studied in both Evolutionary Biology and Economics (Mankiw, 2009). Using a terminology from Economics, the conditions for the occurrence of the tragedy of commons requires that the resource must be accessible to anyone ("non-excludable") but in limited quantity, thus implying competition ("rivalry") among individuals. It shares some similarities with the well-known public goods dilemma<sup>1</sup> regarding the condition of unrestricted accessibility to the resource, but also differs as the subtractability of the resource may penalize the survival rate of the population (e.g. because of free-riders). From the Biology viewpoint, the tragedy of commons is known to be responsible of in-group competition among individuals.

A possible explanation for the tragedy of commons is the negative impact of reciprocity, where free-riders are favored as they focus on their own personal fitness gain with no regards to the cost at the level of the population (Sober, 1992). However, several strategies have been identified and discussed in the literature for "solving" the tragedy of commons: kin selection, policing (self-regulated punishment) or diminishing returns (population behavior depends on ecological feedback) are all good candidates observed in Nature (Rankin et al. (2007)).

## Definition of Altruism

The emergence of cooperation and altruism has been the focus of a particular attention from many research fields, including of course Biology.

The distinction between cooperation with mutual benefit<sup>2</sup> (West et al., 2007) and "strong" altruism (termed altruism from now on) depends on the nature of the fitness benefit at the level of *either* the individual *or* the population (Lehmann and Keller, 2006). Cooperation implies that a given individual benefits from its behavior during its lifetime, either through direct or delayed (i.e. through repeated interactions) reciprocity. Altruism, on the other hand, characterizes the sacrifice of (part of) one own's fitness for the benefit of others. Therefore, an altruistic behavior bene-

fits other individuals and possibly has a positive impact on longer time-scale (e.g. more than a single lifetime).

Several theories have been identified, covering different kinds of behavior observed in Nature, from mutualism to conditional cooperation. On the one hand, mutualism is the case where cooperation leads to direct benefit even though a single individual displays a cooperative behavior (Maynard Smith J., 1983; Lima, 1989; Packer C., 1988; Dugatkin and Wilson, 1992). On the other hand, the more classic conditional cooperation scheme implies that all individuals share the same cooperative strategy so that the whole population welfare is increased: kin selection (Hamilton, 1964; Maynard Smith, 1964), reciprocity (Trivers, 1971; Axelrod and Hamilton, 1981) or the more controversial group selection (Wynne-Edwards, 1986; Dugatkin, 1994; West et al., 2007) can be accounted for such conditional cooperation.

While the emergence of cooperation can be explained by the fact that every individuals benefit from such a behavior (i.e. no cost to cooperate), the justification for altruism is not as straight-forward. The idea of inclusive fitness proposed by Hamilton (1964) is now widely accepted to account for the emergence of altruism: inclusive fitness considers the fitness of a particular individual to depend both on its own behavior and the behavior of its close relatives. The basic idea is to consider individuals as vehicles for genes, therefore kinship must be taken into account rather than the sole interest of one individual/vehicle. Of course, sacrificing oneself depends on several parameters such as the expected fitness loss (from sacrifice) and benefit (for others) as well as the genotypic relatedness of the individuals concerned (closer relatives may imply increased altruistic behaviors).

Hamilton formalized the relationship between cost, benefit and relatedness in the following equation:  $C/B < r$ . The Cost  $C$  is the amount of fitness lost by an altruistic individual. The benefit  $B$  is the amount of fitness gained by the recipient that benefits from the altruistic behavior. And  $r$  is the genotypic relatedness between the two individuals. The term *kin selection* has been introduced by Maynard Smith (1964) to illustrate the mechanism and consequences with inclusive fitness: if one's individual is willing to sacrifice itself for closely related individuals, the gene responsible for such an altruistic behavior may spread through natural selection as it is likely to be present also in the genotypic material of its parents.

## Models of Altruism in Artificial Life

Altruistic behavior, as well as the emergence of altruism, has also been investigated in the field of Artificial Life. All the major theories have been studied: kin selection (Sober, 1992; Leticia et al., 2004), group selection (Fletcher and Zwick, 2004, 2007) and other mechanisms such as effect of increased environment's viscosity (Mitteldorf and Wilson, 2000), communication (Ackley and Littman, 1994) and tag mechanism (Spector et al., 2004; Spector and Klein,

<sup>1</sup>In the public goods dilemma, individuals may choose to invest a part of their benefit for the group welfare.

<sup>2</sup>Cooperation is also sometimes used as a synonym for altruism (e.g. cooperation in the prisoner's dilemma corresponds to altruism (Sober, 1992)). In this paper, we assume the restricted and well-accepted definition of cooperation as a behavior leading to mutual benefit.

2006). Previous works have provided studies with various approaches, from game theoretic models to discrete and continuous virtual world simulations. Moreover, kin selection, reciprocity and group selection have been described as variations of a similar mechanism favoring the correlation of interaction between agents (Woodcock and Heath, 2002).

The emergence of altruism under specific condition have also been studied in virtual or real environments, in particular with respect to the public good dilemma (Connelly et al., 2010; Waibel et al., 2009) and to the tragedy of commons (Spector et al., 2004; Scogings and Hawick, 2008), with similar concerns for different selection schemes.

Waibel et al. (2009) discusses the ability to evolve altruism in team of homogeneous robots with group selection in a setup similar to the public good dilemma. Facing the same environmental conditions, Connelly et al. (2010) experimentally show that altruism naturally emerges as long as resources is widely available.

The tragedy of commons has been addressed by Spector et al. (2004), where tag recognition favors the interaction between altruistic agents facing a tragedy of commons, and by Scogings and Hawick (2008) in a prey-predator setup. Even though their work considered population with fixed strategy (rather than evolutionary adaptation), they illustrated the ability of altruistic population to survive in aggressive environment even when confronted to selfish individuals.

## Method

In this paper, we are interested in identifying the emergence of altruism in the scope of environment-driven self-adaptation in a population of autonomous agents. The motivation behind this work is two-fold. Firstly, our long-term motivation targets the design of an evolutionary adaptation algorithm for a limited group of autonomous agents that is capable of facing *a priori* unknown situations. An important requirement is that the algorithm should be implementable in a virtual or real-world environment (e.g. multi-agent simulation, agents in virtual worlds, robot swarms).

Secondly, we ask the following question: what can be expected when a population of evolving agents faces the tragedy of commons. This implies to identify if a strategy emerges, but also the nature of this strategy, if any.

In this section, we describe the algorithm and the experimental setting used for this work. In particular, the experimental setting has been designed so that the population faces a setup where the tragedy of commons is expected to occur. Lastly, methodological tools for monitoring altruistic behaviors are introduced at the end of the section.

## Algorithm

The mEDEA<sup>3</sup> algorithm takes inspiration from the selfish gene metaphor popularized by Dawkins (1976) and performs as an evolutionary adaptation algorithm that can be

<sup>3</sup>*minimal Environment-driven Distributed Evol. Adaptation.*

distributed over a population of robotic agents (i.e. each agent in the population runs the same algorithm, but carries different genomes). It was first introduced by Bredeche and Montanier (2010) to address robustness issue with dynamic unknown environments and has been successfully validated on real e-puck autonomous robots (Bredeche et al. (2011)).

In this framework, each agent contains an *active* genome, which (indirectly) controls the agent's behavior, and a *reservoir of stored genomes*, which is empty at first. At each time step, each agent *broadcasts* in a limited range (approx.  $1/32^{th}$  of the arena's width) a *slightly* mutated copy of its active genome (e.g. with gaussian mutation) and stores genomes received from neighbors, if close enough. At the end of a "lifetime" (i.e. a pre-defined number of time steps), each agent "forgets" its active genome and *randomly* picks one genome from its reservoir of stored genomes (if not empty). Then the reservoir is emptied, and a new lifetime starts. This algorithm is duplicated within each agent in the population, even though agents' behaviors differ depending on each agent's current active genome.

There are three major claims why this algorithm works. Firstly, selection pressure occurs at the population level (the more a genome spreads itself, the higher its fitness) rather than at the individual level (random sampling). Secondly, genomes survive only through spreading (as an active genome is automatically deleted locally at the end of a generation). Thirdly, individual fitness improves over time as conservative variations generate new candidates that explore alternative (but closely related) behavioral strategies.

In practical, this algorithm provides an evolutionary adaptation mechanism, but does not provide a control function. The actual control of the agent behavior shall be performed by a dedicated controller whose parameters are determined from the genome. In other words, the mEDEA algorithm provides evolutionary adaptation by tuning the control architecture. In the rest of this paper, the controller used is a Multilayer Perceptron whose weights are decoded from the genome (more details in the next Section).

The mEDEA algorithm shares some similarity with the basic concepts demonstrated in Tierra (Ray, 1991), AVIDA (Adami et al., 1994) and followers, but also differs as it was originally designed for real world environments with a limited number of moving autonomous agents such as mobile robots. It can also be related to Embodied Evolutionary Robotics (Watson et al., 2002) regarding the possible implementation on physical agents, but with the major difference that it is not meant to optimize a pre-defined objective function.

## Experimental Setup

In order to account for the existence of altruism, we have defined a foraging task where a population of autonomous agents must eat food items to maintain a positive energy level. The experimental setup used in the next section is il-

illustrated in figure 1, with food items (circles), agents (small dots) and obstacles. The environment and task depends on the following elements: (1) *Self-sustainability*: foraging is necessary to survive, as each food items give a small amount of battery energy. However, an agent's battery is limited to a maximum amount of energy, and foraging may end up in wasting resource. (2) *Foraging behavior*: an agent may choose to harvest *all* or *part* of a food item. (3) *Re-grow rate*: whenever a food item is harvested, it is removed from the environment until it grows back after some delay. The time to grow back depends on the quantity of energy harvested from the food item.

As a consequence, the environment features a common resource pool for which agents compete: a perfect setup for the Tragedy of Commons to occur. Indeed, it is then enough to set the appropriate delay before a given food item would grow back. This is achieved by setting the maximum re-grow delay for a food item ( $EP_{LagMax}$ , with  $EP$  as in "Energy Point"), which in turn will be used to compute on-the-fly the re-grow delay of a food item that was just harvested ( $EP_{Lag}$ ). This is described in equation 1, which also takes into account the amount of energy harvested by an agent from the food item ( $E_{harvested}$ ) and the amount of energy available in each food item ( $EP_{eMax}$ ).

$$EP_{Lag} = E_{harvested} / EP_{eMax} * EP_{LagMax} \quad (1)$$

Within this setup, it is expected that altruistic agents in aggressive environments shall harvest the minimum amount of energy from each food items, therefore increasing the availability of the resource (short re-grow delay, no wasted energy). On the other hand, selfish behaviors are likely to be fitted for small values of  $EP_{LagMax}$ , but are expected to become more and more critical as the value of  $EP_{LagMax}$  increases.

Figure 1: Snapshot from the simulator: food items (circles), agents (dots) and obstacles

## Methodology

In order to account for altruism, we define a measure for monitoring the *cost of altruism* for one foraging agent. In the setup described earlier, this corresponds to measuring the

amount of energy that *could be* consumed when harvesting a food item, but which is actually *not consumed* by the agent. This is formally defined in equation 2.

$$Cost = \max(0, \min(EP_{eMax}, r_{E_{max}} - r_{E_{now}}) - E_{harvested}) \quad (2)$$

Where  $EP_{eMax}$  is defined as before (i.e. maximal energy in a food item),  $r_{E_{max}}$  is the maximal energy level of an agent,  $r_{E_{now}}$  is the current energy level of the agent and  $E_{harvested}$  is the energy harvested by the agent from the food item.

While a selfish agent shall have a cost of zero, an altruistic agent should be able to perform a trade-off between its altruistic nature and its survival needs. Therefore, the cost of altruism can be seen as the agent's level of sacrifice which is continuous (a quantity of energy) rather than discrete (eat or don't eat).

## Results and Analysis

This section presents results obtained running the mEDEA algorithm in the environment described in the previous section. The organization of the section is as follow: the algorithm is evaluated for its ability to evolve agents with altruistic behavior. Then, the nature of altruistic behavior is investigated, considering the balance between environmental pressure and the algorithm's mechanisms. Finally, the relation between genotypic relatedness and the degree of altruism is explored along with its impact on the survival rate of the population.

All experiments were conducted with 100 robotic agents in the environment described and illustrated in the previous section. The environment contains 800 food items and an agent may harvest a maximum of 50 units from a food item. Each agent consumes 1 unit of energy per step, and can store up to 800 energy units (harvesting surplus is lost). If the agent's battery level drops to zero, the agent stops and its genome is lost. It is then refilled with a small portion of energy, but remains still until it receives a new genome.

The control architecture is a Multilayer Perceptron (MLP) with 5 hidden neurons, 11 inputs (8 proximity sensors, battery level and orientation/distance to the closest food item) and 3 outputs (left/right motor and proportion of energy to be harvested from a food item, if any). The weights of the MLP are decoded from the active genome of the agent. Each agent broadcasts a mutated copy of its own genome and receives genomes from neighbors within a limited range (roughly 1/10th of the length of the larger side of the environment). The mutation operator used in the Medea algorithm is defined as a gaussian mutation with a  $\sigma$  parameter.  $\sigma$  is included into the genome (i.e. similar to a self-adaptive Evolution Strategy) and ranges from 0.01 (low mutation rate) to 0.5 (large mutation rate).

All results shown here have been achieved in ROBORO,

a fast 2D simulation for robotic agents, originally introduced by Bredeche and Montanier (2010). The source code for reproducing the experiments is freely available for download (<http://www.lri.fr/~montanier/roborobo-ecal>). For each experimental settings, a set of 600 independent runs have been performed during 320000 iterations (= 800 generations) to provide statistically significant data.

## Emergence of Altruism in Medea

A large set of experiments was performed under various environmental pressures by setting a specific value of  $EP_{LagMax}$  for each run, ranging from 25 steps (easy environment) to 400 steps (aggressive environment), for a total of 16 setups. For each setup (i.e. a fixed value of  $EP_{LagMax}$ ), 600 independent runs were performed and results were aggregated to extract various indicators: number of active agents, average cost measure and energy balance (i.e. a positive value means agents harvest more than the minimal requirement). In all experiments, the course of evolution is similar: the number of active agents quickly increases to a stable value while costs start from random values and stabilize to (possibly) positive values. While the increasing number of active agents is expected from evolutionary adaptation, the second observation is of primary importance regarding the possibility of altruistic behavior: a positive cost value would imply that agents do not systematically harvest all possible energy from the food items.

Results are summarized in figures 3(a), 3(b) and 2 (resp. number of active agents, cost measure and energy balance), by taking into consideration the last 10 generations of all runs for each setup (i.e. after convergence to stable behaviors). Altruistic behavior in the context of increasing environmental pressure can be observed by looking at the cost, which converges to a stable value, while the energy balance converges to zero (i.e. the limit for survival). Indeed, altruistic behaviors are observed starting with environments with  $EP_{LagMax} = 100$ , and remains afterwards. With stronger environmental pressures (larger values of  $EP_{LagMax}$ ), the number of active agents decreases, which confirms that the environment is becoming more and more challenging.

Several observations can be drawn from these results. Firstly, altruistic behaviors are difficult to observe when environmental pressure is low and tragedy of commons not bound to occur (median values are close to zero for values of  $EP_{LagMax}$  under 100 steps). This tends to reveal the greedy nature of the algorithm: without environmental pressure, altruism does not emerge spontaneously. In fact, it is possible to classify the individuals' behavioral patterns with respect to (a) their fellow agents (*selfish* vs. *altruistic* behavior) and (b) the environment (*frugal* vs. *greedy* behavior). the mEDEA algorithm tends to generate *greedy* but *altruistic* agents depending on the environment at hand. Secondly, altruistic behaviors remain stable in the population even though the environmental pressure increases and

the number of active agents starts to drop, implying limited correlation between the level of altruism and environmental pressure. This is explored in the following.

Figure 2: Results with  $EP_{LagMax}$  between 25 and 400 : Energy Balance (data: boxplots are drawn from the median values from each run, i.e. for each run, some agents (not shown) are likely to have larger positive energy balances)

## Investigating the Nature of Altruism

In order to explore the dynamics of the algorithm, a first experiment is designed to evaluate its ability to converge towards the same results from different initial conditions. Starting with a population of agents already evolved in a challenging setup ( $EP_{LagMax} = 400$ , strong pressure, used during 1000 generations), the population is abruptly changed to a smoother environment ( $EP_{LagMax} = 200$ , moderate pressure) and re-adaptation (if any) is studied. The expected outcome is that the number of active agents and the cost measure should converge back to the expected values (shown before). This is indeed what is observed, as shown in figure 4, advocating for the robustness with regards to initial conditions, at least in this case (i.e. starting from already evolved genomes rather than pure random genomes). This is also confirmed by a Mann-Whitney's statistical test.

However, a careful analysis of the results reveals a surprising feature occurring when the environmental pressure is changed: the number of active agents rises significantly before going back down to its final stable value. The same holds for the cost measure, as a sudden drop is observed, preceding a slow convergence to the expected, higher, value. This is indeed a surprise as, for a brief moment, individuals actually have a better survival rate even though more egoistic behaviors are monitored. A closer look at the results in the close vicinity of the change in the environment (not visible at this resolution) actually confirms this: after the environmental change, the number of active agents (resp. cost measure) quickly rises (resp. drops), before slowly converging back

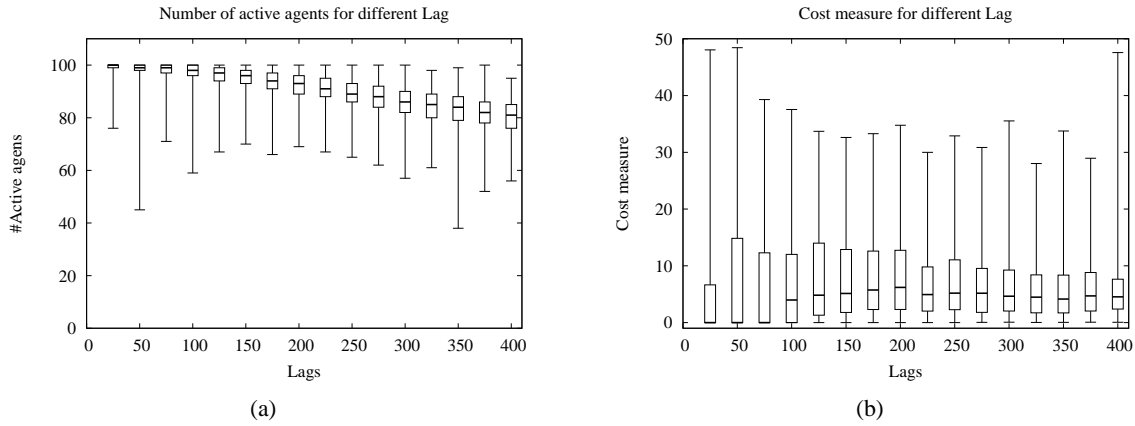

Figure 3: Results with  $EP_{LagMax}$  between 25 and 400: *a*) Number of active robots (data: value from each run) ; *b*) Cost measure (data: median values from each run)

to its final expected value.

A candidate hypothesis for explaining the algorithm's behavior is to reconsider the very nature of *what* can be stated as its intrinsic motivation: mEDEA may be performing a trade-off between survival *and* stability of evolutionary dynamics, rather than survival only. In order to investigate this hypothesis, we define a measure of evolutionary stability that takes into account the number of ancestors from a previous generation for individuals of the current generation (i.e. the larger the number, the more the ancestor with one offspring only). Larger numbers imply a more stable population as it means that more genomes actually survived through their offsprings. In other words, a population with many ancestors imply lack of selective pressure. In practical, this is defined as follow:  $nbStrains_{gen=N-b}/nbActiveAgents_{gen=N}$ , with  $nbStrains$  the number of ancestors from  $b$  generations ago with at least one descendant in the current generation. The value is normalized in  $[0, 1]$ . Lower values imply increased selective pressure.

Figure 5 tracks this value for a few generations: for each generation (i.e. each boxplot), the (normalized) number of ancestors from  $b = 10$  generations ago with at least one offspring in the current generation is drawn. During the short increase in performance after the environmental change, the number of ancestors decreases for at least 10 generations, which indicates that fewer genomes actually benefited from a stronger selective advantage. However, selective pressure then goes back to a more conservative level, even though behaviors end up being sub-optimal with respect to survival (as shown before). Why the best genomes for survival do not remain in the population is yet to be fully understood. In this context, it is likely that egoistic agents may only temporarily benefit from the change, as they may not be enough in numbers to take over the population before altruistic agents adapt to the new environment. Indeed, very specific initial con-

ditions (forcing egoistic behavior at start-up) or dedicated mechanisms in the algorithm (see next section for a discussion) may be required to obtain the best population wrt. surviving rate.

Figure 5: Ancestors from generation  $N - 10$  with at least one offspring in the current generation (34 generations before and after the change are shown).

## Discussion on Diversity and Altruism

As stated previously, it is likely that selective pressure acts in favor of a trade-off between optimizing survival and algorithmic internal stability. But what happens if one were to deliberately enforce genotypic homogeneity? In the following, we address this question and discuss its possible implications. The motivation is two-fold: firstly, the goal is to explore the relation between genotypic homogeneity, level of altruism and survival rate. Secondly, part of the answer

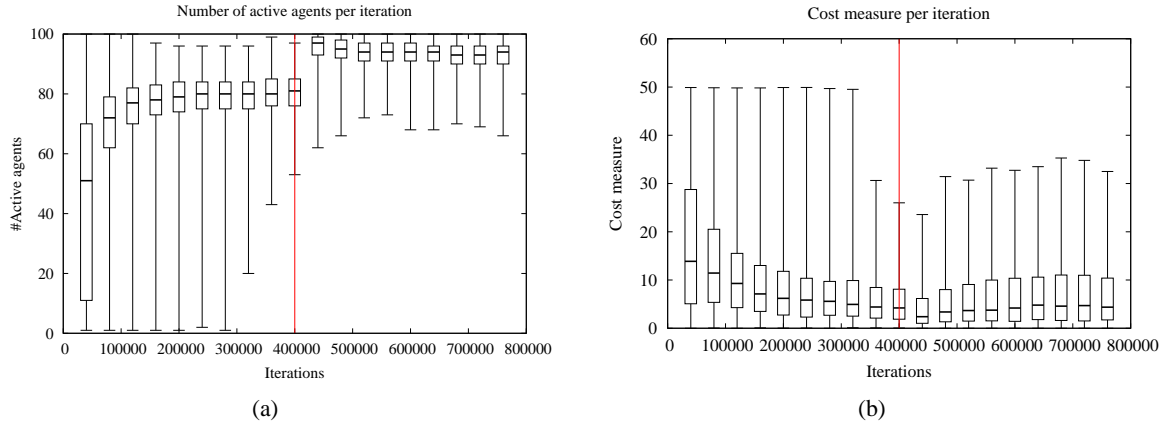

Figure 4: Environment change from strong to moderate pressure (see text). *a)* Number of active robots ; *b)* Cost measure

to this question is a first step towards controlling the evolutionary dynamics at work in the algorithm.

A set of additional experiments have been performed where genotypic relatedness is favored during the selection process, in order to decrease genotypic distance among individuals in the population. In practical, the algorithm's random selection that is embedded in each agent is replaced by a tournament selection (Miller and Goldberg, 1995) (also embedded in each agent), where ranking is based on the genotypic (euclidian) distance between the previously active genome and the locally available genomes (the closer, the better). Tournament selection combined with genotypic distance (termed kin-tournament from now on) makes it possible to introduce an explicit pressure towards kin selection, which can easily be tuned by the size of the tournament.

Experiments with a tournament size of 3 (roughly corresponding to medium pressure towards kin selection) have been achieved with two setups, one with moderate environmental pressure ( $EP_{LagMax} = 200$ ) and the other with a strong pressure ( $EP_{LagMax} = 400$ ). For each setup, 200 runs were performed, and statistical test are computed with Mann-Whitney's Test to clearly establish the difference in performance. Performing kin selection increases the level of altruism in both cases (roughly doubling it,  $p - value < 10^{-15}$ ). While the number of runs with extinctions is roughly similar ( $p - value = 0.07$  for  $EP_{LagMax} = 200$ , and  $p - value = 0.71$  for  $EP_{LagMax} = 400$ ), enforced kin selection suffers from a smaller number of active agents ( $p - value < 10^{-15}$ ).

These results can be put in perspective with Hamilton's idea of inclusive fitness (Hamilton, 1964). The intrinsic mechanisms in the algorithm, in particular conservative mutation, already imply a strong genotypic relation between one genome and its offsprings. Kin selection is shown to artificially increase the already existing level of altruism, at the cost of a decreased overall performance wrt. to individual survival. This is not a surprise as altruistic behaviors

were already shown previously to lead to sub-optimal survival rate, which is even more critical when environmental pressure is aggressive. Nevertheless, the kin-tournament selection as proposed here actually does provide an interesting tunable mechanism to act on the level of altruism, and could possibly lead to a more competitive, heterogeneous population if kin selection is penalized rather than favored.

## Conclusions and Perspectives

In this paper, we investigated evolutionary adaptation in a population of robotic agents whenever altruistic behaviors are mandatory to survive. The algorithm under scrutiny was shown to naturally evolve greedy-altruistic agents within aggressive environments (ie. greedy behavior whenever it does not impact the survival rate of the population). An important message from this paper is that evolutionary adaptation in this context does not automatically lead to the best survival strategy but rather converge towards a trade-off between algorithmic stability and survival. Also, the relation between genotypic relatedness and the level of altruism was confirmed and a possible mechanism to control the level of altruism has been identified.

Perspectives from this work include deeper investigation regarding the exact causes of the sub-optimal survival strategies obtained. Moreover, tuning the level of altruism offers interesting perspectives with regards to modeling environmental-feedback induced altruistic behaviors, such as *diminishing returns*, where altruism may be regulated by the environment (Rankin et al., 2007).

## Acknowledgements

This work was made possible by the European Union FET Proactive Initiative: Pervasive Adaptation funding the Symbion project under grant agreement 216342. Some of the experiments presented in this paper were carried out using the Grid'5000 experimental testbed (cf. <https://www.grid5000.fr>). We'd like to thank Simon Carrignon for his last minute (much appreciated) help with generating figure 5.

## Abstract

Physiological studies suggest that humans have internal dynamics models for both themselves as well as their environment, which are integral components in motion planning and control. Although robotic systems rely on similar models, a primary constraint for robotic applications is how such models are acquired and developed. Traditionally human engineers derive the dynamics models for robots; this approach is not scalable for increasingly complex designs. As a result, there is growing interest in model inference methods, which automate the modeling process and extends the design range of robots. This paper proposes a novel method that infers dynamics models as mathematical expressions via Symbolic Regression and applies them for robotic motion planning and control tasks. The advantage of this expression is not only the accuracy but also the computational efficiency. Experimental results on underpowered pendulum domains validate that our inferred models enable fast motion planning and real-time control based on rapid re-planning, with significantly superior results over Support Vector Regression and Gaussian Process Regression.

## Introduction

Recent advancement in robotics has resulted in multitude of morphologically diverse robots, ranging from joint-based, legged robots to soft, continuous robots. The traditional approach to designing robot controllers requires that human engineers derive a dynamics model using first principles and prior knowledge about robots. However, as these robots increase in complexity, obtaining the dynamics model using analytical methods becomes significantly more difficult. Instead, inferring a dynamics model via machine learning approaches is a promising alternative.

Physiological evidences suggest that humans also acquire dynamics models that are vital for motion planning and control (Wolpert et al., 1995). Such dynamics models are classified into two types: *forward* and *inverse models* (Kawato, 1999). Forward models predict the consequence of motor commands, while inverse models determine the necessary motor commands to achieve a desired state transition.

The goal of this work is to infer a robot's forward model and to effectively apply it in motion planning and control

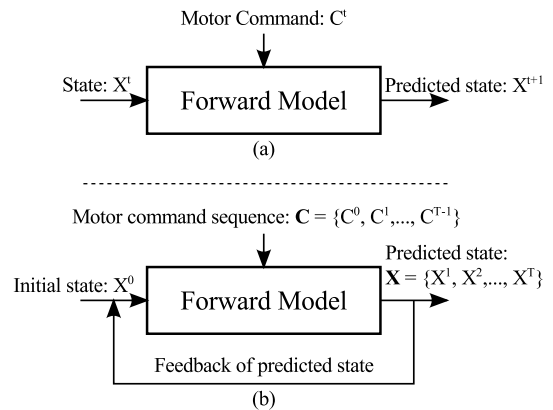

Figure 1: Diagrams of forward modeling. (a) One-step state prediction with forward model, and (b) iterative state prediction with internal feedback for simulating command sequences.

tasks. In robotics, forward models take current state and motor command as input, and predict the next state without actually executing the command (Fig. 1(a)). Furthermore, they can also simulate command sequences of arbitrary length by iterating one-step predictions with internal feedback loop (Fig. 1(b)). The latter provides an infrastructure for subsequent command optimization, which generally takes the form of motion or trajectory planning.

For applications in robotic motion planning, forward models should be accurate as well as computationally efficient. Model accuracy is essential as faulty prediction may lead to misleading optimization. Since simulating command sequences requires iterative use of forward models, even minor errors in individual predictions can accumulate, resulting in significant discrepancies over the course of the simulation. Real-time re-planning is an effective remedy to this problem; however this requires that the model is computationally lightweight for rapid evaluations under a strict time constraint.

This paper introduces a novel method to infer the forward model of an arbitrary robot and apply them for mo-

tion planning and control problems. Our method uses Symbolic Regression (SR) (Koza, 1992) for model inference. Models inferred via SR are mathematical expressions that accurately explain robot’s dynamics and are computationally lightweight. Experiments on underpowered pendulums show that the accuracy of our models are comparable to those learned with Gaussian Process Regression (GPR), while being superior to those with Support Vector Regression (SVR). Another advantage of SR models is that they can be evaluated for prediction at least three orders of magnitude faster than GPR and SVR models. This allows for fast motion planning and real-time control based on rapid re-planning. For motion planning, our method can find a more desirable plan with smaller computational effort compared to GPR and SVR-based methods. Furthermore, our method can achieve large performance gain via real-time re-planning, while methods based on GPR or SVR models cannot meet strict time constraints.

## Background and Related Work

There are a wide range of approaches and applications for autonomous modeling of robots’ dynamics. This section provides a brief survey of previous studies, summarized in Table 1.

Sturm et al. (2008) investigated an autonomous modeling approach that used Gaussian processes to infer the dynamics model of robot arms. Their models inferred the relationship between the motor targets of all joints and resulting pose of the arm. In contrast, our formulation relates the actuated torque or force with resulting state transition. Our approach allows for better generalization and applications in underpowered control domains such as legged locomotion.

Nguyen-Tuong and Peters (2008) proposed similar approach for autonomously modeling the dynamics of robot arms. Their models inferred the inverse kinematics of robot arms and are used in real-time feedback control. They inferred the model using Local GPR (LGPR) that can be inferred and evaluated efficiently. While we also focus on computational efficiency, we extend the use of such efficient models from feedback control to rapid motion planning and real-time re-planning.

Dearden and Demiris (2005) proposed a forward modeling approach based on Gaussian processes to model two motored arms. Their model relates motor commands to the re-

sulting arm motions. However the motor command in their work is binary, while our experiments investigate continuous motor command.

Bongard et al. (2006) inferred the morphology of robots autonomously via an Evolutionary Algorithm (EA) and modeled them in a 3D simulator. The simulated model was used as a surrogate for the real robot and was sufficiently accurate to develop gait. An advantage of their approach was resilience against unexpected damage. However, this work relied on the accuracy of the 3D simulator to develop the model. The design of such 3D physics simulations raises the same fundamental issue of requiring laborious derivations from human engineers. Moreover, since their 3D models require heavy computation, they are not suitable for real-time control.

For goal-oriented control tasks, behavior-based control approaches, such as Reinforcement Learning (Sutton and Barto, 1998) and Neuroevolution (Yao, 1999), are widely studied as alternatives to model-based approaches. These approaches do not rely on models, but instead try to optimize sensorimotor mappings to achieve predefined goals. Although they are successful for achieving given goals, such as inverted cart-pole tasks, they lack the ability to generalize the learned knowledge to other tasks.

## Learning Forward Models

### Forward Modeling

In this work, we seek to find a *forward model* that explains the dynamic relationship between given commands and robot’s state transition. We assume discrete time dynamics in which a robot’s state at time  $t$  is represented as a set of  $m$  sensed values  $X^t = \{x_1^t, \dots, x_m^t\}$ . A forward model for such a dynamics is a function that predicts the state  $X^{t+1}$  at time  $t + 1$  as

$$X^{t+1} \approx f(X^t, C^t), \quad (1)$$

where  $C^t = \{\tau_1^t, \dots, \tau_n^t\}$  is a set of  $n$  command signals at time  $t$ .

An advantage of this formulation is that it can extrapolate the resulting motion of an arbitrary length of motor commands. That is, given initial state  $X^0$  and a command sequence  $C = \{C^0, \dots, C^{T-1}\}$ , resulting state at time

Figure 2: A sample SR model. The DAG representation of a function:

$$f(\tau, \theta, \dot{\theta}) = 1.23 * (4.56 - \tau) + (4.56 - \tau) * 7.5 * \dot{\theta} - \cos(\theta)$$

$t \in [1 : T]$  can be predicted as

$$\begin{aligned} X^t &\approx f(X^{t-1}, C^{t-1}) \\ &\approx f(f(X^{t-2}, C^{t-2}), C^{t-1}) \\ &\approx f(f(\dots f(X^0, C^0) \dots), C^{t-1}). \end{aligned} \quad (2)$$

In this study, all state variables are continuous. The modeling problem is simplified by explicitly predicting second-order differentials of these state variables. We assume that state variables  $X$  can be decomposed as  $X = \langle q, \dot{q} \rangle$ , where  $q$  is a set of linear and angular position variables, and  $\dot{q}$  is a set of their first-order differentials (i.e. velocity variables). We formulate the modeling problem as predicting the function:

$$\ddot{q}^{t+1} \approx g(q^t, \dot{q}^t, C^t),$$

instead of directly inferring function  $f$  in Eq. 1. We calculate state values  $\dot{q}^{t+1}$  and  $q^{t+1}$  via following integration:

$$\begin{aligned} \dot{q}^{t+1} &\approx \dot{q}^t + \ddot{q}^{t+1} \Delta t \\ q^{t+1} &\approx q^t + \dot{q}^{t+1} \Delta t. \end{aligned}$$

The robot's state is represented as a set of angular and linear parameters in most robotic systems. By using generalized state variables, this approach of inferring second-order differential systems can be readily adapted to arbitrary robotic systems. To generate training data set for model inference, random commands are sent to robot's actuators, and  $\langle \ddot{q}^{t+1}, \dot{q}^t, q^t, C^t \rangle$  at each time step is collected as a training data point.

### Learning Models with Symbolic Regression

An SR uses evolutionary algorithm that searches mathematical expressions to explain a given data set. SR has been successfully applied to infer non-linear dynamics, such as conserved laws of nature, accurately (Schmidt and Lipson, 2009). Our work uses SR to search for mathematical expressions that explain the relationship that exists in the training

data. The fundamental idea of SR is to use Genetic Programming (GP) to evolve populations of expressions and selectively generate populations of lower error. Mathematical expressions are represented as Directed Acyclic Graphs (DAGs). GP searches the space of possible graphs and minimizes error by applying genetic operators, such as mutation and crossover. A sample mathematical expression and its DAG representation are shown in Fig. 2. We used Eureka (Schmidt and Lipson, 2009) as SR implementation in our experiments.

## Motion Planning and Control

### Offline Motion Planning

For motion planning, we propose an approach that directly searches the command space via a hill-climbing heuristic, which searches for an optimal command sequence to maximizes a target function. Inferred forward models are used for simulating candidate command sequences in such a function. Optimization algorithm is sketched in Algorithm 1.

**Algorithm 1** Motion planning with forward models using a hill-climbing heuristic

---

```

if Offline planning then
     $C_{\text{best}} \leftarrow$  random commands
     $X^0 \leftarrow$  initial state
else if Real-time planning then
     $C_{\text{best}} \leftarrow$  current motion plan
     $X^0 \leftarrow$  observed state
end if
 $E_{\text{tmp}} = \text{target}(C_{\text{best}}, X^0)$ 
repeat
    for all  $C$  in neighbor( $C_{\text{best}}$ ) do
        if target( $C, X^0$ ) >  $E_{\text{tmp}}$  then
             $C_{\text{best}} = C$ 
             $E_{\text{tmp}} = \text{target}(C, X^0)$

---

Note the evaluation of command sequences is completely dependent on the predicted state transition. Thus, the optimality of the plan depends highly on the accuracy of the predictive model. On the other hand, since the command space is high-dimensional and continuous, the search for the optimal command requires numerous iterations. Therefore, rapid evaluation of target function is vital. Since mathematical expressions are evaluated extremely efficiently on modern computers, SR models can evaluate the function quickly.

### Real-time Motion Control by Re-planning

In practice, the fundamental issue of predicting state transition with forward models is the accumulation of errors

Table 2: Specification of the experiments.

Arm size (H W D)	2 0.4 0.2m
Arm mass	1kg
Gravity	10m s <sup>-2</sup>
Maximum torque for $P_1$	$\tau_{\max}$ : 1.25kg m
Maximum torque for $P_2$	$\tau_{\max}$ : 4kg m
Time step resolution	60Hz
State variables	$X = \{\theta_1, \dot{\theta}_1\} (P_1)$ $X = \{\theta_1, \dot{\theta}_1, \theta_2, \dot{\theta}_2\} (P_2)$ $\theta_1, \theta_2 \in [-\pi : \pi]$
# of neighbors in Algorithm 1	10

over iterative use of prediction as seen in Eq. 2. We resolve this problem using real-time re-planning to adapt accordingly to the errors. As the robot obtains real-time sensor values, it is able to ground the predicted state with the recorded observations. This is implemented by modifying offline planning in accordance to the new observations. In case of re-planning, the hill-climbing algorithm takes the observed state as the initial state and current motion plan as initial command sequence. Since typical robotic systems require high frequency control and feedback, real-time planning must be equally constrained by such critical restrictions. SR models are sufficiently computationally efficient to allow for re-planning, while GRP and SVR models are not. Although re-planning was introduced primarily to adapt to cumulative error, it can start with random motion and plan the motion in purely online fashion.

## Experiments

In this section, we present experimental results. We evaluate our method in the motored single and double pendulum problems, called  $P_1$  and  $P_2$  (Fig. 3). While robots in these problems are mechanically simple, motion planning in this domain remains a challenge for autonomous robotic controllers. Pendulums used in our experiments are under-powered, and thus, achieving most angular positions is a non-trivial task which often requires unexpected motions.

### Experimental Settings

$P_1$  is composed of an arm that is hinged to a stationary point via a motored joint.  $P_2$  has two arms: motor joints connect the first arm to stationary point, while connecting the second arm to the first arm. These pendulums are simulated with Bullet Physics Library (Coumans, 2010), a popular, open-source 3D physics simulator. Detailed specification of the experiment is provided in Table 2.

The goal of the control task in this domain is to move the only arm (of  $P_1$ ) or the upper arm (of  $P_2$ ) to the upright position within allotted time steps (i.e., 600 steps in  $P_1$ , and 1200 steps in  $P_2$ ). Task start with the initial state

Figure 3: Single ( $P_1$ ) and double ( $P_2$ ) motored pendulum.

of  $X^0 = O$ , where the arms are in the stable equilibrium position. The torque output of each joint motor is limited so that controllers cannot reach to the upright position by simply applying maximum torque in a single direction. Instead, a successful motion requires that the pendulum be swung to accumulate sufficient momentum to eventually achieve the upright position. This additional complexity makes it difficult for existing automated motion controllers to achieve the goal, since evaluating long motor commands via forward models is vital to planning successful motion.

To generate training data set, we actuate a robot using random motor commands. For the pendulum domain, each motor is actuated with a randomly generated torque curve whose torque,  $\tau(t)$ , at time  $t$  is calculated as

$$\tau(t) = \frac{\tau_{\max}}{\sum_{i=1}^N a_i} \sum_{i=1}^N a_i \sin(b_i t + c_i), \quad (3)$$

where  $\tau_{\max}$  denotes maximum torque, and  $a_i$ ,  $b_i$ , and  $c_i$  are random values drawn from uniform distribution under following constraints;

$$\begin{aligned} a_i &\in [0 : 1], \\ b_i &\in [\frac{1}{4} \frac{\pi}{60} : \frac{\pi}{60}], \\ c_i &\in [0 : 2\pi]. \end{aligned}$$

This formulation results in a composite wave of  $N$  individual sine waves. We set  $N = 3$  throughout the experiments. Random actuation lasts for 1 minute, resulting in 3600 time steps. In the double pendulum domain, two distinct torque curves are generated with different random seeds.

### Model Inference and Cross-validation Evaluation

Given the training data, we can learn forward models using off-the-shelf regression algorithms. We compare Symbolic Regression (SR) with Support Vector Regression (SVR) and Gaussian Process Regression (GPR). We used Eureqa (Schmidt and Lipson, 2009), libSVM (Chang and Lin, 2001), and Weka (Hall et al., 2009) libraries for SR, SVR, and GPR, respectively.

Table 3: Comparison of regression algorithms. Listed numbers denote correlation coefficients of inferred models. Computation time for inferring each model is shown in parenthesis.

Target	GPR	SVR	SR (short)	SR
$\ddot{\theta}_1$ in $P_1$	0.9996 ( $\approx 4\text{min}$ )	0.9733 ( $< 1\text{sec}$ )	<b>1</b> ( $= 4\text{min}$ )	<b>1</b> ( $= 2\text{hours}$ )
$\dot{\theta}_1$ in $P_2$	0.7063 ( $\approx 4\text{min}$ )	0.9588 ( $\approx 18\text{sec}$ )	0.9639 ( $= 4\text{min}$ )	<b>0.9700</b> ( $= 8\text{hours}$ )
$\ddot{\theta}_2$ in $P_2$	0.7455 ( $\approx 4\text{min}$ )	0.9286 ( $\approx 27\text{sec}$ )	0.9080 ( $= 4\text{min}$ )	<b>0.9751</b> ( $= 8\text{hours}$ )

Figure 4: Average error on varying prediction periods.

The model inference results of all approaches were compared on cross-validation data sets and performance is measured with correlation coefficient. The results are summarized in Table 3. Computation time for inferring models on Intel Core2 Duo 3.06GHz are also listed in the table. Since SR is a stochastic process, longer training periods may yield better results, while GPR and SVM are deterministic algorithms that do not improve with additional time. We tested on short, being matched with the time GPR inference took, and long training period for SR. Since model inference is an offline process, time constraints are typically not strict.

The results indicate that SR is superior to both GPR and SVR, given long training time. SR inferred a virtually perfect model for  $\theta_1$  in  $P_1$ . Even with shorter training period, SR models are comparable to those inferred with GPR or SVR. In the following experiments, we use SR models inferred with longer training period.

### Model Accuracy on Novel Command Sequences

Since cross-validation results on training data sets do not necessarily reflect generalization performance of inferred models on novel data sets, we used additional tests to inspect and analyze differences in these models. To evaluate models on novel data sets, we generated 20 random torque curves using Eq. 3 with different random seeds and predicted resulting motion using the inferred models. Their prediction error was evaluated as the difference from actual motion. Since one of our concerns is the effect of cumulative errors, we vary the prediction period from 1 to 1800 steps to see how each model behaves during iterative predictions. Average predictive error on each joint angle over the prediction period is shown in Fig. 4.

We can readily see that average prediction error tends to

increase, as the prediction period gets longer. This implies that the cumulative error harms predictive performance over iterations. For predicting  $\theta_1$  in  $P_1$ , it is clear that the error is less pronounced in the SR models, suggesting that the symbolic representation has a more consistent model representation. SVR did poor job on novel data sets, in spite of good performance on cross-validation. The differences of performance among three models are statistically significant ( $p < 0.05$ ) for prediction periods of 60, 120, 600, and 1200 steps.

In  $P_2$ , SVR again marked poor performance, for predicting both  $\theta_1$  and  $\theta_2$ . GPR and SR performed comparably. While GPR models outperformed SR models for short periods (i.e., lower than 233 and 997 steps for  $\theta_1$  and  $\theta_2$ , respectively), SR was superior for long periods. This implies that SR models would be more robust to cumulative error over iterative predictions. Another implication is that cross-validation results, in which GPR models are evaluated badly, do not reflect the models' generalization performance appropriately.

### Evaluation of Offline Motion Planning

Given inferred dynamics models, the motion planning is formulated as an optimization problem. The target function is defined as follows:

$$\text{target}(\theta_1) = \max_{\theta_1^t \in \theta_1} |\theta_1^t|$$

where  $\theta_1 = \{\theta_1^0, \dots, \theta_1^T\}$ , and  $\theta_1^t$  is the angle of the target joint at time  $t$ . Only the initial state is provided to the models. Given candidate command sequence  $C$  and initial state variables  $X^0$ , the algorithm simulate entire state transition over  $T$  steps. Our method plans the motion by searching for

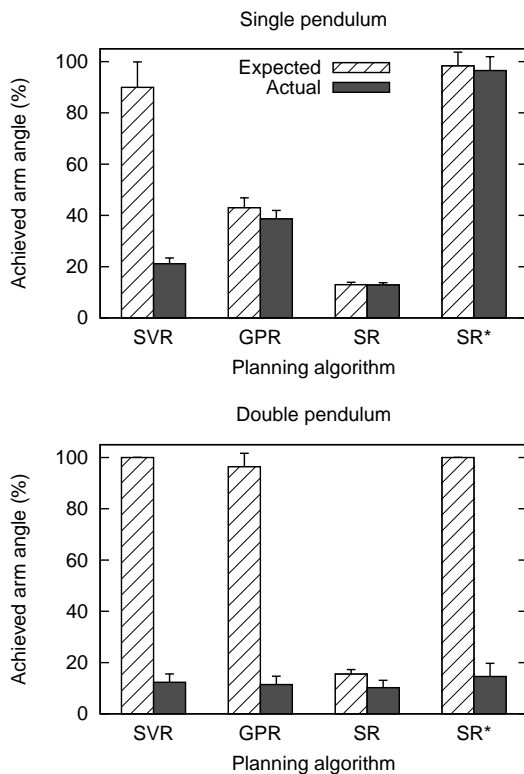

Figure 5: The performance on motion planning tasks.

a command sequence whose simulated motion maximizes this function.

To evaluate motion planning performance of each model, the hill-climbing approach, described in Algorithm 1, was applied for 20 runs per each. The planned commands were executed on actual robot, and their actual performance were evaluated based on Eq. 4. We compared the actual performance with the expected performance to analyze the discrepancy between predicted and actual performance.

In initial tests, the hill-climbing approach for all models was executed for 500 iterations. However, there is a significant difference in the computational efficiency of SR, GPR and SVR, with SR executing at least three orders of magnitude faster than GPR and SVR in both  $P_1$  and  $P_2$  experiments. To provide comparable results with respect to computational effort, an additional SR, called SR\*, experiment was implemented with 500000 iterations.

The performance of the SVR, GPR, SR and SR\* motion planning is shown in Fig. 5. It is clear that SVR and GPR tends to overestimate its capability, often allowing for highly optimized plans that do not translate to real world results. In comparison, SR provides a truer prediction of the real world even if the hill-climbing problem becomes subsequently harder. When normalized for computational effort, SR\* does a significantly better job, compared to SVR and GPR.

Figure 6: The performance of real-time planning. The performances of offline methods are given as baselines.

In the double pendulum problem, SVR and GPR predicted a nearly optimal solution with certainty, but in fact, the actual performance was poor. SR achieved similar performance, but had a more realistic prediction. Although SR\* had the best actual performance, its performance was far poorer than expected.

## Evaluation of Real-time Motion Control

This section provides the comparison for the real-time re-planning motion control. We experimented two re-planning approaches: first approach started with an initially optimized plan (i.e., re-planning of the plan generated by SR that is described in the last section); while second one started with a random plan, resulting in purely online planning and control. These two are compared with the offline GPR planning and SR\* planning. For the re-planning approaches, the number of iterations per step (IPS) was doubled until the real time constraint could not be achieved. This limit was resulted 160 IPS and 40 IPS for the single and double pendulum, respectively. Since SVR and GPR models could not achieve even 1 IPS for both problems, they are not applied to re-planning. The results are shown in Figure 6.

The performance of online and “re-planning of SR” approaches improve with increased IPS, significantly outperforming offline GPR and SR\* ( $p < 0.05$ ) with maximum

IPS (i.e., 160 for single and 40 for double pendulum). “Re-planning of SR” typically showed remarkable improvement over the purely online approach, resulting in the best performance among all tested approaches with maximum IPS. When the IPS is set to maximum, the total number of iterations required for “re-planning of SR” approach was 96500 iterations and 48500 iterations for single and double pendulum problems, respectively. While offline SR\* consumed 500000 iterations, its performance is poorer than that of “re-planning of SR”.

In summary, the benefits of SR modeling over GPR and SVR modeling are two-fold: first, it provides more accurate prediction that is vital to planning; and second, the reduced computational effort makes efficient real-time applications possible.

## Conclusion and Future Work

In this paper, an SR-based method was proposed to model a robot’s dynamics autonomously and the inferred model was used for motion planning and control tasks. The model is represented as a mathematical expression that accurately explains the robot’s dynamics and allows for fast computation. These features enable fast motion planning and real-time control based on re-planning, resulting in significantly superior control performance over GPR and SVR-based methods.

Possible applications of our method include forward modeling and motion planning for the locomotion of legged robots or soft robots. Soft robots are an area of particular interest since deriving a dynamic model is a difficult and daunting task. However, forward models of these robots are considered significantly more complex than of pendulums. Since the difficulty of model inference via SR is known to increase dramatically as the complexity of the true model increases (Schmidt and Lipson, 2008), we will need to develop novel techniques to infer models of more complex dynamics.

This paper is an initial investigation of applying SR for robotic modeling and there is room for further optimization. Although this work used a simplistic hill-climbing heuristic approach for motion planning, more complex and superior algorithms can be applied instead. It will also be possible to use SR to infer inverse models and utilize them in feedback control. We believe that the coexistence of accuracy and efficiency in SR models will help a novel class of algorithms in robotics to emerge.

## Abstract

Complex artificial life simulations can yield substantially distinct populations of agents corresponding to different adaptations to a common environment or specialized adaptations to different environments. Here we show how a standard clustering algorithm applied to the artificial genomes of such agents can be used to discover and characterize these subpopulations. As gene changes propagate throughout the population, new subpopulations are produced, which show up as new clusters. Cluster centroids allow us to characterize these different subpopulations and identify their distinct adaptation mechanisms. We suggest these subpopulations may reasonably be thought of as *species*, even if the simulation software allows interbreeding between members of the different subpopulations, and provide evidence of both sympatric and allopatric speciation in the Polyworld artificial life system. Analyzing intra- and inter-cluster fecundity differences and offspring production rates suggests that speciation is being promoted by a combination of post-zygotic selection (lower fitness of hybrid offspring) and pre-zygotic selection (assortative mating), which may be fostered by reinforcement (the Wallace effect).

## Introduction

Artificial life simulations exhibit complex agent-based behaviors, which persist and evolve through genetic recombination and mutation. Unless explicit speciation is built into the simulation, identifying emergent species in these simulations is difficult, both theoretically and practically. Here we demonstrate a technique for identifying subpopulations of agents using a clustering algorithm to identify groups of agents with shared genetic attributes. The resulting clusters might reasonably be considered distinct species, and allow us to identify some of the different adaptation mechanisms adopted in the simulation. Examining the temporal distribution of these clusters allows us to better understand the evolutionary course of speciation and adaptation in our simulations, and may offer some insights into speciation in biological ecosystems.

Understanding speciation is one of the key problems in biology. Much debate centers around the role of *allopatric* (geographically isolated) vs *sympatric* (shared environment) species divergence. The significance and driving forces

of sympatric speciation have been controversial since the ideas were introduced by Wallace (1899) and championed by Dobzhansky (1937). *Disruptive selection* (adaptation to distinct fitness peaks) in combination with *reinforcement* (the selection pressure that results from reduced fitness of hybrids; aka the *Wallace effect*) leads to *assortative mating* (a preference for related partners) thus providing a basis for sympatric speciation. Despite the simplicity and attractiveness of these ideas, the so-called Modern Synthesis largely discarded the idea of selective speciation, instead attributing divergence to more readily observable geographic isolation (Mayr and Provine, 1998), and a variety of models (reviewed in (Kirkpatrick and Ravigné, 2001)) have led many to conclude that sympatric speciation, while possible, will only be found under very limited circumstances (Felsenstein, 1981). However, though the jury is still out, empirical evidence for reinforcement driving sympatric speciation does exist ((Sætre et al., 1997; Ortiz-Barrientos et al., 2004; Silvertown et al., 2005) and others) and recent theoretical and modeling work have suggested potential mechanisms (such as competition overwhelming selection towards a single method of resource utilization) for overcoming the perceived limitations on sympatry (Dieckmann and Doebeli, 1999; Kondrashov and Kondrashov, 1999; Van Doorn and Weissing, 2001). For high-level reviews see (Butlin and Tregenza, 1997; Tregenza and Butlin, 1999; Weissing et al., 2011). In this work, both *pre-zygotic* (pre-mating) and *post-zygotic* (post-mating) selection are observed, suggesting reinforcement may be playing a role in our speciation events—both sympatric and allopatric followed by population mixing.

In the life sciences clustering algorithms are applied in many areas, including the analysis of clinical information, phylogeny, genomics, and proteomics (Zhao and Karypis, 2005). Mallet (1995) proposed gene clustering as a preferred method for the rigorous identification of biological species (as opposed to taxonomic features). We seek to import these concepts and tools from the realm of biology into our artificial life work to help us better understand the evolutionary dynamics of our model ecosystem, though we believe there may be some general principles that apply to both artificial

and natural ecosystems.

The use of gene clustering for speciation has been explored in genetic algorithms by Hocaoglu and Sanderson (1995) and in computational ecosystems by Aspinall and Gras (2010). The Aspinall and Gras predator-prey simulator has some traits in common with ours, but defines two distinct agent classes which do not interbreed, and the clustering analysis is performed during the simulation and allowed to control reproductive success, thus allowing it to drive the speciation process. By contrast, there is no impact of cluster membership or genetic distance on reproductive success in the work reported here, and all gene clustering analysis is performed *post hoc*, after a simulation has run its course.

Clustering algorithms (reviewed in Hartigan (1975); Kaufman and Rousseeuw (2005)) rely upon two key elements: the distance function used to measure object similarity and the algorithm used to partition the data. The distance function must account for the “curse of dimensionality” (Bellman, 1957) intrinsic to high dimensional spaces in general and evolutionary algorithms employing large, high-dimensional genomes in particular. Clustering algorithms with a pre-specified number of clusters—such as k-means clustering (MacQueen, 1967)—though widely used, suffer from the simple fact that the number of clusters may not be known *a priori*.

Information theory (Shannon, 1948) allows us to partially alleviate the curse of dimensionality. Through the process of variation and selection those genetic dimensions which most affect an agent’s fitness will be selected for and conserved, thus exhibiting low entropy across the population of agents, while those which are inconsequential will descend into a random distribution. By weighting genetic dimensions with *certainty* (i.e.,  $1 - \text{entropy}$ ) those genetic features most significant to the agents’ survival and reproduction will be emphasized during the partitioning into clusters, while spurious proximity in the inconsequential dimensions is ignored.

Algorithmically, we have chosen to use the QT (Quality Threshold) Clustering algorithm (Heyer et al., 1999; Scharl and Leisch, 2006), which clusters based on a maximum intra-cluster distance (diameter), rather than a set number of clusters.

## The Artificial Life Software

This research was carried out using Polyworld (Yaeger, 1994), a computational ecology with a long history, in which populations of haploid agents evolve, each possessing a suite of primitive behaviors (move, turn, eat, mate, attack, light, focus) under continuous control of an Artificial Neural Network (ANN) employing (in this case) discrete-time, firing-rate neurons with synapses that adapt via Hebbian learning. The wiring diagram of the ANN is encoded in the organism’s genome, via a statistical description of the number of neural groups of excitatory and inhibitory neurons, synaptic connection densities, regularity of connections, and learning

rates. The only epistatic interaction between genes derives from the role played by the genes expressing the number of neural groups and the number of neurons in each group in controlling whether the corresponding inter-group and inter-neuron connections are expressed. For a detailed discussion of Polyworld’s genetic encoding scheme, see (Yaeger, 1994).

Input to the ANN consists of pixels from a rendering of the scene from each agent’s point of view. Output from the ANN consists of the aforementioned primitive behaviors. For the simulation discussed here, there are 2,486 genes devoted to specifying the neural topologies (but not synaptic weights) of ANNs with up to 217 neurons and 45,854 synaptic connections. The actual neuron count ranged from 14 to 163, with a mean of 48, and the synapse count ranged from 46 to 9,034, with a mean of 656. A small number of genes (8) characterize the agents’ simple morphologies, metabolisms, and meta-genetics, in terms of size, strength, maximum speed, fraction of energy contributed to offspring, ID (green color component), mutation rate, number of crossover points, and lifespan. Thus there are 2,494 genes in all used in the clustering process.

All actions of the agents consume energy, so they must replenish their energy levels by seeking out and consuming food or by killing and eating other agents. Normally there are also per-neuron and per-synapse energy costs, but for consistency with some evolution-of-complexity experiments these were disabled for the results reported here. Reproduction occurs when two collocated agents simultaneously express their mating behaviors.

The simulation is initially seeded with a uniform population of agents that have the minimum number of neural groups and a nearly minimal number of neurons and synapses. While predisposed to some potentially beneficial behaviors, such as running towards food (green) and away from aggression (red; see (Yaeger, 1994) for details on color use in Polyworld), these seed organisms are not a viable species. I.e., without evolution they cannot sustain their numbers through their reproductive behaviors and will inevitably die out.

For these analyses the world was configured as in (Yaeger et al., 2008), with two barriers running 90% of the depth of the world, but left open for the remaining 10% of the world, so populations are able to mix relatively easily, but not with complete freedom. 80% of the food is grown in a patch occupying 40% of world depth at the open end of the barriers, 20% in a patch occupying 10% of world depth at the closed end of the barriers. This layout may be seen in Figure 1.

As simulations progress both the structural architecture of the ANNs and the activation of every neuron at every time step for every agent may be recorded, thus permitting investigation into evolutionary trends in network structure and function (Yaeger et al., 2010). Agent genomes may also be recorded, and these recorded genomes serve as the basis for

Figure 1: Polyworld simulation environment

the clustering analysis described here. Some genes exhibit smooth, general trends over the course of the simulation, but others demonstrate short, sharp changes that correspond to temporal cluster boundaries, as will be discussed later.

### The Clustering Algorithm

The clustering task can be divided into two subproblems: the distance function used to measure object similarity and the clustering algorithm used to partition objects. For the distance function, we used entropy-weighted Euclidean distance over each agent's genome. For the clustering algorithm, we used a variation of the QT-Clust algorithm (Heyer et al., 1999; Scharl and Leisch, 2006), with the addition of a new algorithmic improvement to allow for multiple cluster selection on each pass and a precalculation of point-wise distances for greater efficiency.

### The Distance Function

Genomic data in artificial life simulations are afflicted by the curse of dimensionality (Bellman, 1957), and the current Polyworld genome consists of nearly 2,500 genes! Fortunately, the process of selection in evolutionary algorithms gives a way to identify genes which are likely to differentiate subpopulations. Genes with a high impact on agent fitness will be selected for and conserved, while those which are inconsequential will trend towards a random distribution. By taking the information certainty (1 - Shannon Entropy) of each gene, the relative importance of each dimension may be used to weight the many dimensions:

$$H(g) = - \sum_{i=0}^{N_s} p(g_i) \log_2(p(g_i))$$

$$certainty(g) = 1 - H(g)$$

where  $g$  is a specific gene, the  $g_i$  are the gene values (states), and  $N_s$  is the number of possible gene states. Probabilities were calculated for 16 bins of 16 gene values, capturing the

full range of these 8-bit genes (0-255), over the entire population of 29,564 agents extent during the full evolutionary simulation.

While each gene of the Polyworld genome is specified by an 8-bit value, the full range of genetic values may not be expressed over the course of a simulation. In comparing genomic data, the difference along this distribution is more important than the raw score. To address this issue when calculating genetic distances between agents, we have normalized the measure of each gene dimension, by calculating the genes' z-scores:

$$z(x) = \frac{x - \mu}{\sigma}$$

where  $x$  is the raw gene value,  $\mu$  is the mean value of that gene, and  $\sigma$  is the standard deviation of that gene's values).

After normalizing gene values to produce gene z-scores, distances are calculated between z-scores, weighting the relative importance of each gene by its certainty. Our distance metric is therefore the certainty-weighted squared-Euclidean distance of z-scores:

$$dist(x, y) = \sum_{i=0}^{N_g} (w_i(z(x_i) - z(y_i)))^2$$

where  $x$  and  $y$  correspond to two agents and their genomes,  $N_g$  is the total number of genes in the genome,  $w_i$  is the certainty calculated for each specific gene  $i$ , and  $z(x_i)$  and  $z(y_i)$  are the z-scores of gene  $i$  in the genomes of agents  $x$  and  $y$ .

### The QT-Clust Algorithm

Clustering algorithms rely upon the fixation of one or more variables: number of clusters, similarity of elements in the cluster, or number of elements in each cluster. Effective clusters should maximize inter-cluster distances, while minimizing intra-cluster distances (cluster diameter). Traditional k-nearest-neighbor approaches (MacQueen, 1967) require the number of clusters to be specified *a priori*. Additionally, these algorithms encounter the hubness phenomenon in which a centroid may be a common nearest-neighbor in Euclidean space, building large diameter clusters. This phenomenon is exacerbated by high-dimensionality (Beyer et al., 1999; Radovanović et al., 2010).

To avoid these issues, we have opted to use the QT-Clust algorithm (Heyer et al., 1999; Scharl and Leisch, 2006), which is a nearest-neighbor clustering approach fixing cluster diameter ( $\epsilon$ ), rather than the number of clusters. This algorithm is particularly well suited for data discovery problems, such as gene analysis (the original use case). Adjustment of the cluster diameter parameter provides a means of controlling cluster fit that is both more intuitive and practical than algorithms requiring explicit specification of the number of clusters. (E.g., we are unlikely to have chosen

  QT-Clust( $G, \epsilon$ )
```

---

values of 8, 29, and 108 for the number of clusters we ended up focusing our attention on, but specifying cluster diameter in terms of standard deviations that produced these clusterings seemed reasonably natural.) The iterative approach used by QT-Clust also avoids issues of hubness common to nearest-neighbor clustering algorithms by creating an  $\epsilon$ -neighborhood graph around each agent. The largest of these groupings is then selected and removed from the population to be re-clustered, thus eliminating the effect of outliers and hubs (Radovanović et al., 2010).

The algorithm has two stages. First, a cluster is built starting with each agent within the population ( $G$ ). The cluster is built by adding the next closest agent to the cluster, until a threshold ( $\epsilon$ ) of maximum distance is reached. Cluster construction may be done in parallel for a significant speed increase. Then, each of these clusters is passed through a filtering step, which selects the largest candidate that does not overlap with a previously selected cluster, until no viable candidates remain. This multiple selection amortizes the time complexity of the original QT-Clust algorithm, while maintaining its quality control advantages. After filtering, unclustered elements are then reclustered within the remaining population until all elements are classified.

## Results

We ran this algorithm on Polyworld simulation data containing 29,564 agents (distributed over 30,000 time steps), contained in 1.9GB of genomic data. Simulation paramet-

$\epsilon$	1.5	1.75	2	2.125	2.25	2.5	2.75
# clust	2063	750	108	29	8	3	3

Table 1: Resulting cluster counts for different  $\epsilon$  thresholds

ters are identical to those presented in previous work on the evolution of neural complexity (Yaeger et al., 2008). While previous work has focused on general trends, combining the results of multiple runs and applying standard tests of statistical significance, here we wish to tease apart the dynamics of a particular simulation, and we are interested in the degree to which cluster analysis and a species/sub-population perspective can inform the understanding of those dynamics. We would expect the details of cluster/species formation to vary from run to run, even when nothing changes but the pseudo-random number generator’s seed, and have seen hints of such variation in previous work on complexity trends.

For the discussion below, we define  $\epsilon$  as a factor of the sum of all certainty weightings:

$$\epsilon(x) = x \sum_{i=0}^{N_g} w_i$$

This sum is equivalent to the weighted distance between two genomes which differ by 1 standard deviation on each dimension, due to z-score normalization. Thresholds were set between 1.5 and 3 times the sum of the certainty values, at increments of .25.

## Behavior Across Different Thresholds

Table 1 shows the number of clusters identified for varying levels of  $\epsilon$ . Figure 2a-c show the population of each cluster over time for  $\epsilon = 2.0, 2.125, 2.25$ . The progression from a large diameter to a smaller diameter shows each cluster splintering. Whether these show hierarchical clustering is a question for further empirical study.

## Temporal Trends in Clusters

Figure 2b shows that while the larger clusters tend to be replaced serially over time, other, smaller clusters emerge, coexist with one or more of the larger clusters for extended periods of time, and are ultimately extinguished, suggesting the emergence, persistence, and decline of subordinate species. This also suggests we may be seeing reproductive isolation of sub-populations, despite the fact that Polyworld does not in any way inhibit cross-cluster reproduction. This could be due to pre-zygotic, assortative mating preferences (unpublished work suggests agents attend to both genetically and behaviorally determined color expressions) or to post-zygotic disruptive selection effects in a Dobzhansky-Muller manner—hybrid offspring expressing neural architectures that are sub-optimal in themselves, or in combination with “physiological” characteristics that affect energy requirements. We look at both possibilities below.

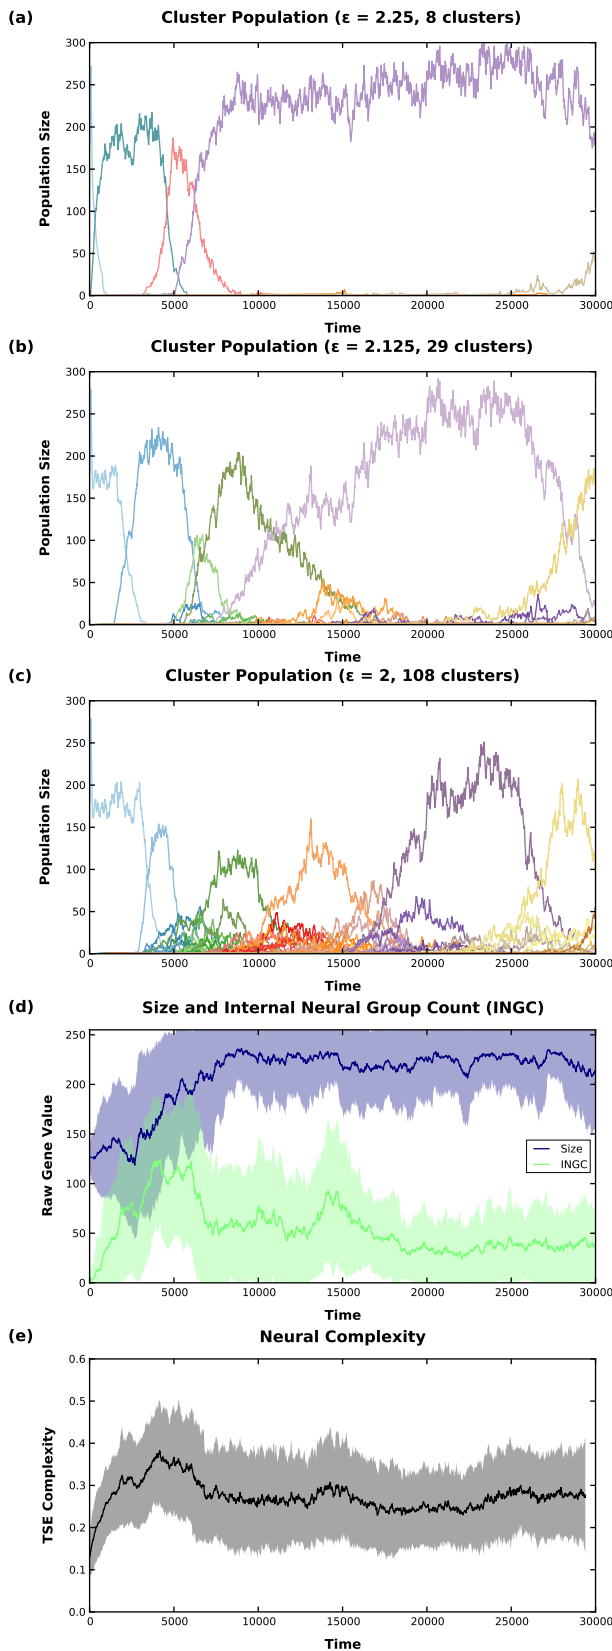

Figure 2: Temporal trends in cluster populations for  $\epsilon = \{2.0, 2.125, 2.25\}$ , two high-certainty genes (size and internal-neural-group count) exhibiting different selection behaviors, and TSE complexity. Genes and complexity shown as population means with standard deviation bands.

	Size	Start	Temporal Peak	End	Neural Complexity	Genetic Size	Genetic INGC
0	1062	0	78	3749	0.2445	133.6	35.1
1	2278	1311	4087	8441	0.3626	172.4	101.0
5	769	4408	6694	11585	0.3657	202.5	98.3
9	3983	5119	8772	17509	0.3058	224.7	62.3

24	273	13207	26594	30000	0.2619	185.3	29.1
27	2202	15126	29565	30000	0.3114	222.0	45.7

Table 2: Raw data from QT-Clust with  $\epsilon = 2.125$ . Shown are the origin, peak, and extinction of each major cluster, the TSE complexity, and mean values of the size and internal-neural-group-count (INGC) genes. Gene values are in the raw 0–255 range. Clusters with  $< 700$  members appear in light gray. Clusters with  $< 200$  members are not shown.

For the larger clusters, from cluster populations alone we cannot distinguish between roughly monotonic, anagenetic (within lineage) changes and true cladogenetic (divergent) speciation. However, long periods of temporal overlap during transitions suggest we may be seeing true speciation in large clusters as well, as distinct, new clusters emerge and are simply more successful than either the short-lived small clusters or the previous large cluster.

### Temporal Trends in Genes

The use of clusters allows us to identify genetic differences between different subpopulations, including temporal trends in specific genes known to distinguish different subpopulations. Figure 2d shows different selection patterns for two high-certainty genes positioned below the cluster population graphs to allow comparison of their temporal trends. Table 2 shows the corresponding raw data for all clusters with a population size greater than 200.

The size gene (*certainty* = 0.3515) shows a nearly monotonic selection pattern. Only the initial seed population has a relatively small size. By the time of the transition from the second to the third major cluster, size has reached the level at which it will plateau—around 220. By contrast, the internal-neural-group-count gene (*certainty* = 0.2058) shows a more variable selection pattern, which corresponds to trends in neural complexity as discussed below. These changes also correspond to cluster emergence and decline, as discussed in Cluster Characterization.

### Neural Complexity

Tononi-Sporns-Edelman neural complexity (TSE complexity) (Tononi et al., 1994) gives an indication of the neural structure and function for each agent. Figure 2e shows the mean TSE complexity over time for the simulation being analyzed. In a past study, complexity was shown to be highly selected for only during periods of behavioral adaptation of the agents to their environment (Yaeger, 2009), in keeping with the tautology of evolutionary selection applying only when the subject of selection confers an evolutionary ad-

Clusters	children	grandchildren	child-rate	grandchild-rate
Same	2.04 (0.02)	4.04 (0.05)	6.54 (0.06)	10.6 (0.2)
Diff	1.89 (0.00)	3.57 (0.03)	5.11 (0.12)	7.76 (0.3)

Table 3: Reproductive success—numbers of offspring from parents of the same or different clusters and child-production rates per 1,000 contacts with agents from same or different clusters (stderr in parens), using  $\epsilon = 2.125$ .

vantage. The current results are in general agreement with previous simulations, showing strong selection for complexity in early populations during the period in which they are evolving to adopt an Ideal Free Distribution (Fretwell and Lucas, 1970; Fretwell, 1972) of agents to the heterogeneous resources of the simulated environment, plateauing around step 7500, and followed by a long stretch of relative stability lasting for the rest of the simulation. However, we see here a bump in complexity around  $t=15,000$ , unique to this particular simulation, that our clustering analysis reveals to be the result of a corresponding bump in internal-neural-group count deriving from the emergence and decline of a pair of specific sub-populations (clusters 16 and 17).

## Discussion and Conclusions

Whether discussing the larger clusters, that replaced each other somewhat serially, or smaller clusters that represented sub-populations coexistent with the larger populations, we think it may be reasonable to conceive of these clusters as *species* within our artificial simulation. Since the simulation does not explicitly prevent interbreeding between clusters or base reproductive success on genetic distance, perhaps they should be considered *proto-species*, but the fall and rise of sub-populations, with significantly different genetic makeup from the dominant population, suggests a degree of specificity and persistence of species identity. Even the dominant populations may demonstrate speciation and competition between species, given the degree to which they overlap in time; e.g., note in Figure 2b that the cluster rising to dominance at the end of the run (light orange – cluster 27) first appeared barely over half way through the simulation ( $t=15,126$ ) well before the previous dominating population (light purple – cluster 21) had reached its peak population ( $t=20,672$ ). This occurs despite a relatively simple environment in which agents are free to mix and in which there is only one kind of energy resource (two if you distinguish between food that is grown and food derived from the carcasses of agents that are killed).

As Mallet (1995) notes, “Clusters can remain distinct under relatively high levels of gene flow provided there is strong selection against intermediates; species will be maintained when selection balances gene flow.” Lacking geographic isolation, sympatric speciation is typically thought to require disruptive selection to elicit distinct phenotypes and genotypes, coupled with selection for assortative mating to elicit reproductive isolation.

If disruptive selection and poor hybrid fitness are playing a role in balancing gene flow, we should see differences in the fitness, as measured by fecundity, of offspring from parents belonging to the same or to different clusters. To investigate this hypothesis we examined the number of children and the number of grandchildren produced by agents born to parents from the same or from different clusters. The left-hand columns of Table 3 summarize the results. Though the differences are modest, the offspring of parents from the same cluster produce more offspring than do the offspring of parents from different clusters, and those offspring are themselves more fecund. The magnitude of the differences are about 10x the standard error rates observed in the population (shown in parentheses), thus there is at least a modest post-zygotic selection pressure at work. Amplified across multiple generations it is easy to see how intra-cluster breeders will outperform inter-cluster breeders and produce ever more distinct sub-populations—species—even sympatrically. This is basically the first half of Wallace and Dobzhansky’s proposed route to sympatric speciation.

If reinforcement is producing pre-zygotic selection and assortative mating, we should see differences in the rate at which agents produce offspring when they come in contact with agents from the same or different clusters. To investigate this possibility we examined the number of children and grandchildren produced *per contact* with other agents from the same or different clusters. For this analysis it is important to normalize birth rates by contact counts, since any kind of temporal, behavioral, or geographical isolation can and does significantly skew the number of potential reproductive encounters between same and different clusters for a given agent. The right-hand columns of Table 3 summarize these results. Both the child- and grandchild-production rates (per 1,000 contacts) are greater for encounters with agents from the same cluster than for agents from a different cluster. Here again, though the magnitude of the differences is small, they are roughly 10x the standard error rates observed in the population. Thus there is at least a weak pre-zygotic selection pressure at work.

Certain characteristics of the current simulated environment—especially the partial barriers, that are a holdover from previous experiments looking at the evolution of complexity—make it difficult to entirely tease apart sympatric vs allopatric speciation. In movies showing cluster membership over time we see clusters emerge and persist alongside existing clusters in a fully sympatric fashion. But we also see evidence of allopatric speciation, with new clusters emerging in and coming to dominate one food patch before spreading to the other—in fact, having difficulty invading the second food patch. So we currently believe both forms of speciation are to be found in these simulations. A sample movie can be found at: [http://informatics.indiana.edu/larryy/cluster\\_movie.zip](http://informatics.indiana.edu/larryy/cluster_movie.zip)

Figure 3: Means and standard error bars for the strength, size, mate-energy-fraction (MEF) and internal-neural-group-count (INGC) genes, along with neural complexity, for clusters with more than 700 agents, using  $\epsilon = 2.125$ .

### Cluster Characterization

Clustered sub-populations can be characterized by their respective cluster centroid. Figure 3 provides a set of cluster fingerprints, summarizing the raw data in Table 2 for clusters of  $\epsilon = 2.125$  (showing only the major clusters, with populations  $> 700$ ). Specific evolutionary trends can be correlated to the rise and fall of particular species. The increase in size is readily apparent, along with a general decline in mate energy fraction and strength, and a variation in the internal-neural-group count. The earlier clusters 1 and 5 explore larger neural structures, achieving higher complexity. All dominant clusters exhibit a trend towards reduced energy consumption (low mate energy fraction and strength) and increased energy capacity (large size). Cluster 17 shows an exploratory population with slightly higher internal-neural-group count and neural complexity, coupled with a reduced emphasis on energy conservation, as evidenced by an increased strength and mate energy fraction, and slightly smaller size. This exploratory population is present in the middle third of the simulation, emerging out of the dominant cluster 21, but having only limited success, and, together with cluster 16, is responsible for the bump in internal-neural-group count and complexity as previously discussed.

### Future Directions

One direction is to apply these analysis methods to simulations with simpler environments, in order to eliminate the possibility of allopatric speciation. We are also investigating methods from the evolutionary biology literature, such as “heat maps” of genetic diversity versus geological origins of parents, that might help us quantify degrees of sympatric vs allopatric speciation. An analysis of the temporal history of the fecundity and child-production rates discussed

here might help distinguish pre-zygotic and post-zygotic selection and clarify the role of reinforcement in producing assortative mating.

Alternative clustering algorithms are also of interest. Information theory-based algorithms, such as that of Gokcay and Principe (2002), which maximizes cross-entropy between clusters, look particularly attractive. Alternatively, adopting a rival-penalization method, such as the  $k^*$ -means algorithm (Cheung, 2002), may provide a better metric for cluster selection than cluster diameter. It might also be interesting to adapt the hierarchical clustering scheme of Aspinall and Gras (2010), regardless of whether we adopt their practice of allowing clusters to modulate reproductive success. Such a comparison would provide insight into whether or not varying the thresholds of QT-Clust is suggesting hierarchies of sub-populations, as hinted by Figure 2.

Any of these clustering methods, including the current one, would allow us to evaluate the effectiveness of a “miscegenation function”, which establishes a probability of reproductive success that is inversely proportional to genetic distance between potential mates, that was long ago built into Polyworld, but which has never been explored to any substantial degree.

With the existing data, a study of the geographic locality of the origin and spread of each species may yield information about environmental effects on selection and degrees of sympatric vs allopatric speciation. This may provide theoretical insights into a common real-world speciation scenario in which initial allopatric (regional) divergence is followed by sympatric divergence, as seen in Darwin’s Finches and other taxa (Huber et al., 2007). We would also like to apply these methods to simulations with clearly differentiated niches that are geographically either overlapping or isolated, to distinguish and quantify the relative effects of niche specialization vs geographic isolation.

## Abstract

This work uses an ALife simulation to explore the implementation of embodied reaction logic in a chemical computer. Chemical systems have potential for computation. There are properties of a logical system that are desirable in any computational system, such as the ability of the system to change state in response to some input. An issue in chemistry is that the molecules must have some physical embodiment, which must somehow represent state; state is then interpreted as the presence or absence of certain molecular configurations in the system. The design of a chemical logic gate is a means of showing that a chemical system can change state appropriately and that the information encoded in the molecules is available to be processed *as* information. This paper compares two simulated chemical computing systems: Bindworld (a simple illustrative example) and Stringmol, (a fully implemented complex DNA-inspired evolutionary computing framework). The problems and design decisions involved in creating a NOT gate in each system are compared, showing that designed computational systems require a certain complexity and flexibility to be useful to human operators. Finally we discuss general extensions to the Stringmol reaction chemistry that would simplify the process of information processing in embodied systems.

Computation is a fairly new concept to science. Although the word itself has been in use since 1447 or before, until the early 20th century it referred only to manual calculation performed by humans (this is why early machines were called “automatic computers” to distinguish them from their human counterparts). It is only since the development of the mechanical and electronic computer that the term has been applied to a process external to human thought.

Artificial Life (ALife) is a simulation of biological life on a computer. These simulations are often considered to be “embodied thought experiments” (Di Paolo et al., 2000), which test whether the essential properties of biology have been captured. Simulations of biological processes are also seen as a step towards harnessing biological processes for our own ends (Brooks, 2001). (The successful simulation will process information in a similar, but more robust, manner to our electronic computers.) It is therefore legitimate to consider how a biological simulation is capable of information processing. The simplest form of this is logic.

Models of conventional computing deliver programming languages, based on logic, that abstract the functionality away from the implementation of the logic on electrical circuitry. Programmers take this for granted when designing software using these programming languages. Similar abstractions may be needed to program computers based on other media. Generally, computation proceeds in the following context:

1. **INPUT:** An observer encodes a problem and passes it to some external system (be it electronic, neural, biological, molecular, or otherwise) via a *setup function*.
2. **COMPUTE:** The system evolves, ending in some changed state. Where the change in state has involved some notion of information processing, *computation* has occurred.
3. **OUTPUT:** The observer uses an *output function* to extract some useful information from the system and decode it into a useful response.

The problem, or series of instructions, is encoded in a different way depending on the architecture of the computer. In electronic computers it is a program in a language such as C (or, equivalently, the machine code representation of that program). The usefulness of a computer is in the **COMPUTE** stage, when the computer performs a task so that we do not need to execute it ourselves.

Systems requiring two-way data exchange (such as a search engine, which alternates between taking queries and returning results) can be seen as a series of input-compute-output operations. We do not discuss parallelism and concurrency, but restrict our discussion to an input-compute-output problem analogous to a batch processing command.

The idea of a chemical computer is appealing: somehow encode the task in a solution of *input molecules*, place them in solution with the *computational molecules*, and find the result in the set of extractable *output molecules*. Molecular computing is massively parallel - there is potential for billions of reactions to take place at the same time in a single container. For example, in DNA computing (Păun et al., 1998; Lee et al., 2004; Adleman, 1994), the setup function consists of encoding a problem in fragments of DNA. The

computation occurs *in vitro*, in parallel, and without external interference. The output function often consists of using gel electrophoresis to extract and sequence DNA of a particular weight, which we know to encode a useful response. Importantly, the information is *embodied* – it is represented as a sequence of DNA that is processed via the laws of physical chemistry.

This paper compares two embodied computers. The first is a small theoretical novel computer, Bindworld, in which simple “atoms” bind with each other to form complexes. The second is a larger, implemented novel computer, Stringmol, in which long RNA-like sequences interact according to their embedded programs. We use the comparison to highlight the challenges and tradeoffs involved in designing a novel embodied computer.

It is important to emphasise the role of the molecules-as-programs in terms of their computing power. To demonstrate the importance of reactions within a chemical computation, we briefly describe some theoretical work based on the concept of complementary binding of molecules alone. We show the shortcomings of this approach, and extend it to incorporate the concept of reaction between molecules once they have bound together before presenting our experimental implementation of a NOT gate in an artificial chemistry.

Stringmol is an *artificial chemistry* (AC) that is being developed to explore a method of evolutionary computation based on the “RNA-world” model of biology (Gilbert, 1986). This is a computational simulation in which the genome-carrier molecule is composed of the same molecular building blocks as the enzymes that are encoded therein. The system, called Stringmol (Hickinbotham et al., 2010a,b, 2009) abstracts the concept of stochastic mixing and molecular binding and reaction into a tractable model for ALife experiments. The link between computation and open-ended evolution is that both paradigms require that it is possible to generate an unbounded set of possible states. In related work (Clark et al., 2011), we have demonstrated that the sophisticated binding protocols in Stringmol are key to the diversity that the system is capable of producing. Here, we show that binding *alone* is not a convenient form for computation.

In addition to being able to carry out computation, it must also be feasible for a human programmer to initialise the system “by hand”. The idea of logic gates is an appropriate area in which to start thinking about a novel computational system, since logic is familiar and universally used in traditional computational systems. A non-standard computer which can be used with a standard computing paradigm (logic) is more approachable than one which requires an entirely new way of thinking about computation; it requires less training to use and program, and existing results and algorithms are easier to re-use. Conceptualising such a familiar idea in a new system highlights the similarities and differences between the novel system and von Neumann computing. The two sys-

tems we compare here are both formally specified (Bindworld by its reaction rules, Stringmol by its program code); these mathematical and programmatical specifications are not included here, however, as conceptual analysis of the two systems informs our main conclusions.

Logic gates have already been implemented in a real chemical system based on DNA enzymes with catalytic action (Stojanovic and Stefanovic, 2003). Simulation is an important complement to experiments with real chemistry, since the simulation can be interrogated easily and completely, and complete understanding of the molecular model is available. The issue with simulation is whether the correct properties of real chemistry have been captured in the model. The systems we compare here differ from real chemistry: Bindworld is much more simple (containing only atoms and bonds); and Stringmol uses a programming metaphor in the place of the physical properties of atoms by containing a set of operators and pointers.

Teuscher provides a good review of realisations of logic elements in chemical computers (Teuscher, 2007), focusing on how to build in reliability through redundancy in membrane-based systems. The systems we explore here, however, are different from membrane computing systems; they lack a container-based physical hierarchy.

Two important properties of a useful computational system are *preservation of state* and *change of state*. Firstly, information must be preserved in some way; the system must have some kind of memory. Secondly, information must be modified in some sensible way; a system that does not change cannot perform computation. Logic encapsulates both the idea of preservation of state (truth values are held steady) and that of change of state (output values are modified).

## What are we looking for in a non-standard computational system?

We already possess a remarkably powerful and ubiquitous computational system: the von Neumann architecture (Aspray, 1990) implemented on electronic computers. This architecture is used by virtually all electronic computing devices, from the mobile phone to the supercomputer. There is therefore little point in developing and researching a novel computational system unless it is (or has the potential to be) in some way superior to the von Neumann electronic computer. Simulations are useful for research, but often difficult to implement on traditional computers. A platform amenable to evolution is also desirable. Thus, we require a different form of embodiment to that seen in electronic computers. We seek a general computational platform that is more amenable to biological systems in general, and biological evolution in particular.

The role of a computer is to carry out algorithms for humans, or even adjust these algorithms to cope with particular problems; informally, *computers solve problems* for us.

The Church-Turing thesis (which is widely regarded and accepted as correct, but is unproved, and indeed formally unprovable (Copeland, 1996)) states that every expressible or comprehensible algorithm is computable using a Turing machine. As electronic computers are equivalent to Turing machines, no novel computer will ever allow *more* problems to be solved than an electronic computer.

One advantage of a novel computer could be that there were some problems it could solve better (either faster or more accurately). Another could be that the **INPUT** stage were easier; that the problem encoding were more understandable or easier to generate. This is very important, as much of the effort involved in computer-aided problem solving goes into formalising the problem in a way that the computer can understand. Finally, a novel computer might not allow problems to be solved faster or more easily, but might offer practical advantages like being smaller, lighter, cheaper, or more energy-efficient. A novel computer might even be able to solve fewer problems than an electronic computer, but convey significant practical advantages.

### ***In vitro* experimentation versus *in silico* simulation**

We can explore non-standard computational systems in two ways: by implementing them in the real world, or in simulation. Real-world implementation has had interesting results, such as Adleman's solution of an instance of the directed Hamiltonian path problem using DNA molecules (Adleman, 1994) and Adamatzky's reaction-diffusion logic gates in a chemical medium (Adamatzky and Costello, 2002).

Simulating non-standard computational systems has also been successful; consider Winfree's simulations of computation by interactions between self-assembling tiles (Winfree, 1998) or Adamatzky's simulations of reaction-diffusion systems (Adamatzky, 1997). Winfree simulated sets of DNA molecules with 4 "sticky ends" (ends amenable to binding with other DNA molecules) and showed that they are capable of unsupervised self-assembly, in particular patterns, into nets of DNA. This system was used to simulate a self-assembling Sierpinski triangle. Adamatzky simulated (and also constructed) logic gates whose information carriers were interacting waves of chemical reaction proceeding across a medium.

When simulating chemical computation, we need to set up an environment which approximates real chemistry. As the mechanisms of real chemistry are currently intractable (too much computation is required) and indeed not fully known, we need to set up a simplified simulation-world. It should be qualitatively similar to real chemistry, but vastly simplified to make it computationally tractable.<sup>1</sup> There are several choices we have to make:

<sup>1</sup>Unconventional computation can be a rather recursive field; we are considering the computational power of a simulation whose complexity is limited by the computational power required to simulate it!

Figure 1: Two "atoms", complementary in shape, bonding together to form a complex.

- *Atoms*. What types of atoms (unsplittable entities) to include in the system.
- *Interactions*. How these atoms interact.
- *Determinism*. How large is the role of chance in the system.
- *Container*. The environment the simulation operates in; its dimensionality and boundary conditions.

### **Bindworld: a simple simulation and its drawbacks**

This section presents Bindworld, a trivial simulated chemical-analogue computational system designed around the concept of binding alone (with no explicit formalisation of reaction). This is a "thought experiment" that shows the necessity of reaction in computational chemistries.

A "program" in Bindworld consists of a population of *atoms*, so called because they are indivisible. Each atom has one or more *bindsites* of type  $k$  or  $k'$ ,  $k \in \mathbb{N}^*$ . For example, a shape could have the three bindsites of types 1, 2', 3. A bindsite of type  $k$  can only bind to one of type  $k'$ . For example, a bindsite of type 7 can *only* bind to one of type 7'. This rule reflects shape complementarity. Only bindsites on different atoms can bond; two complementary bindsites on the same atom cannot bond to each other. If a bond occurs, the two atoms in question are bonded to form a complex.

To implement a program in Bindworld, we must:

1. **INPUT**: Set up a population  $P_i$  of atoms, encoded in which are the truth values for our gate inputs. When setting up the population  $P_i$  (encoding our question) we have control of the presence or absence of atoms, and of the bindsites they possess. We can choose whether to include a certain atom in the initial population, and which bindsites to equip it with.
2. **COMPUTE**: Let the system evolve by forming all possible bonds between atoms.
3. **OUTPUT**: Interrogate the final population  $P_f$ , and infer the state of the system from the pattern of bonds found between atoms.

Bindworld can either be deterministic (if two atoms can bind at a particular moment, they certainly will) or non-deterministic (if two atoms can bind, they may either bind or remain unbound).

Figure 2: A molecular NOT gate; atom  $A_X$  (top) has bound to atom  $A_Z$  (bottom) via complementary bindsites of types 1 and 1'. Here the case where  $X = \text{true}$  is illustrated; the atom  $A_X$  is present. The case  $X = \text{false}$ , this atom would be absent and  $A_X$  would be bound to nothing.

One of the implications of having bonding with no reaction is that when reading the final population  $P_f$ , it is useless to read either the presence/absence of atoms or which bindsites they possess, as this information will be the same as in the initial population. The only way in which the system can change is by bonding atoms to other atoms and forming complexes. We must therefore extract the output value of our logic gate from information about which atoms are bound to which.

### Making logic gates in Bindworld

Suppose we have access to two binary variables  $X$  and  $Z$  and two atoms  $A_X$  and  $A_Z$  with complementary bindsites 1 and 1'. These atoms are notated  $A_{X,1}$  and  $A_{Z,1'}$  and will bond to each other as their bindsites are complementary. We then define the input rule and the output rule formally as:

$$\begin{aligned} \text{Input: } P_i &= \begin{cases} \{A_X, A_Z\} & \text{if } X = T \\ \{A_Z\} & \text{if } X = F \end{cases} \\ \text{Output: } Z &= \begin{cases} F & \text{if } \text{bound}(A_Z)^{P_f} \\ T & \text{if } \neg \text{bound}(A_Z)^{P_f} \end{cases} \end{aligned} \quad (1)$$

We set the output variable  $Z$  to true if atom  $A_Z$  is bound to anything in  $P_f$ , shown by the helper function  $\text{bound}(A_Z)^{P_f}$ . This implements the relation  $Z = \neg X$  in Bindworld; the chemistry of the system behaves differently depending on how we set up the initial population.

As shown, it is simple to engineer one gate on its own. It is also simple to run a set of gates in parallel by simply using sets of bindsites which do not interact with each other. It is when we come to link gates together by connecting the output of one to the input of the next (as we must to run any meaningful computation) that problems occur.

One way of doing this is with the NOT gate is by simply inserting another atom  $A_I$  with a bindsite of type 1. If we do this *after* the initial gate has run, the results will be sensible and  $\neg \text{bound}(A_Z)^{P_f}$  will reflect  $\neg \neg X$ . However, this means the computer's execution would have to be paused after the

operation of every gate, which would make the computer's operation intolerably slow, as such chemical manipulations are very slow. Furthermore, they would need to be controlled either by hand or by an electronic computer; using a traditional computer to facilitate the operation of a novel one (when it could just evaluate the gates electronically) is a waste of resources. We want to be able to program the computer and leave it to run unsupervised.

The process is even more complex when dealing with 2-input gates such as AND or NOR, which raises another disadvantage of Bindworld: the activity of programming it (setting up the atoms and the initial population) is very hard. It is conceptually very nonintuitive and difficult to reason about. This violates another goal in the design of novel computers, that they should be easy to control and program. There may be an arcane, complex way of setting up unsupervised chained gates in Bindworld, involving helper bindsites and ancillary atoms, but it escapes us.

To sum up, Bindworld has several down sides. Firstly, programming it is extremely nonintuitive. Secondly, it seems even simple one-input-gate chaining is very hard unless the population can be adjusted after the evaluation of every gate, a restriction which would cripple the system's power. Thirdly, although we can define the joining of two atoms as a "reaction," Bindworld has no *explicit* concept of reaction, which means it does not integrate very well with our mental schemas of computation and chemistry. The next section describes an artificial chemistry built around this concept.

### Computation with the Stringmol artificial chemistry

We give here a brief overview of our molecular system, which is described fully in Hickinbotham et al. (2010a, 2009). A summary of the chemistry is presented below, followed by a description and discussion of molecular structure.

In order to express our observations in a computational system, we identify three major domains. The first defines the underlying *physico-chemical properties* of the atomic components. The second is the coding of the proteins in genes - the *sequence of codes*. The third is the *embodiment* of both the physico-chemical properties and the sequence of codes in the physical world. The physico-chemical properties of the system are immutable, but they specify a space of possible realisations that is immeasurably vast. Genetic systems are specified by the sequence of codes, but importantly, the sequence is *embodied* within the system, thus allowing the enzymes that the sequence encodes to act on the embodiment of the sequence itself and thus modify it. This has places the sequence management apparatus under control of the sequence itself, eventually exploiting the available possibilities that the physico-chemical properties endow upon the embodied system. This phenomenon is the basis of bi-

ological evolutionary systems, where the embodiment of a genetic code in a carrier molecule allows the encoded proteins to “curate” the genome. Initial experiments by Hickinbotham et al. (2010b, 2009) into implementing such a system have resulted in the Stringmol chemistry.

## Molecular representation

In Stringmol, the molecular analogues are composed of sequences of token symbols (single letters or symbols such as ‘\$’ or ‘>’) which represent both the structure of the molecule and a series of programmatic instructions. Molecules bind at loci along sequences if there is a match between the sequences at that point. Importantly, the match is inexact, and is modelled as a probability of a bind occurring. The basis of the soft alignment scoring function is based on the scoring method of Smith and Waterman (1981).

Once bound, the two molecules have the potential (by following the programs specified by their strings of instructions) both to create new molecules and to change their composition, thus forming new molecules. This is the reaction component of the system. The sequence is treated like a program, commencing at the beginning of whichever aligned subsequence is furthest from the beginning of its string. There are 7 functional symbols, shown as non-alphabetical characters ‘\$’, ‘>’, ‘^’, ‘?’, ‘=’, ‘%’, and ‘}’. Stringmol uses functional symbols to specify the manipulation of a set of pointers which indicate positions on the molecular strings, and the symbols that the pointers index. During a reaction, alignments are used to specify program flow, commonly acting as place markers and analogues of “goto” statements.

Note that in Stringmol, binding and reaction are completely chronologically and conceptually separate. Once a bind is effected, it remains in place for the duration of the reaction. Another bind cannot interrupt a reaction; a third Stringmol cannot bind to a reaction in progress.

## System Architecture

A Stringmol simulation can be considered as a set of reacting molecules whose movements inside a container are governed by a stochastic mixing function. All molecules are subject to *decay* (spontaneous destruction), which places a requirement upon the system to act in order to maintain itself in the face of entropy. Should molecules come sufficiently close to one another, then they can *bind* and subsequent to binding occurring, *react*. The system has a discrete-time clock. At each time step, all the molecules in the system are processed. Actions only occur if energy is available. Energy is consumed via binding and executing each instruction in a reaction; these two events each have an energy cost. The likelihood of binding and the nature of the reaction is encoded in the string of each molecule in the encounter. At one particular time step, we specify that 25 energy units are available. The selection of which events consume the energy

is stochastic. The balance between energy availability and the decay rate of the molecule maintains a steady population of molecules. We currently specify that only two molecules can ever participate in a single reaction, and that raw materials for the assembly of new molecules are available in saturation.

## Strategy for implementing molecular logic

Our implementation of logic within this artificial chemical system allows us to demonstrate the ability of the system to change state. There are two points arising from this. Firstly, the implementation of the processing is not straightforward, since the reaction-language was not tailored to logic. Secondly, following from the first point, there naturally arises within the system the possibility of evolving the system to deliver fuzzier logical analysis from the initial bootstrap, via a built-in ability of the system to evolve.

We require that the chemical system acts to maintain a population of molecules in an environment where no molecule can persist indefinitely. We thus base our system on a molecular species that we call a *replicase*, R. This molecule R has embodied properties coded into its sequence that allows it to bind to copies of itself and create further copies.

Before an input data molecule D enters the system, the R molecules simply maintain a stable population. The input does not persist in the system, so in order for the system to generate a response that does persist, the input signal must induce two changes in R. In our implementation, R is ‘primed’ to implement changes to its own sequence when D binds to a specific region, to introduce a signal generating molecule S that not only acts as a replicase, but also generates an output molecule O.

Experiments showed (Hickinbotham et al., 2010b) that changes in the binding site of the replicase allowed new species of replicase to be preferentially copied, and thus drive other replicase molecules to extinction. We exploit this phenomena in the design of our state-change when an input data molecule appears – it changes the sequence of the replicase molecule R it interacts with to always *be copied* rather than *act as the copier*. This means that the original replicase R is swept out of the system, and a new replicase species S takes its place. S not only self-maintains, but also produces *output molecules*.

## Designing the molecular species

The sequences of logical Stringmol data input molecules D must perform two tasks. Firstly, they must bind to the replicase molecule, and secondly, they must encode the logical state of the input. For a “true” signal, we specify the sequences INPUTTTTTT and INPUTFFFFF for false. There are two regions to this molecule. The sequence INPUT forms the bind site (shown in yellow in figure 3II, where

Figure 3: The replicase NOT gate molecules. Yellow regions are bind sites, blue regions are program sequences, red regions are read/write areas external to the program regions. Dotted lines show binds. Black regions are parts of the sequence that are not used in the reaction. Particular regions of molecules are referenced by numbers and letters in triangles. There are three reactions **I**, **II** and **III**: **I**: The replicase **R** will copy anything that binds at position 1, using the program encoded at region 2. **R** can bind to other **R** molecules. **II**: The data molecule **D** binds to **R** at region 3. The program at 4 is executed, which changes sites **a** and **b** and uses the logic encoding at **c** to write a specification of the output molecule. This changes the sequence of molecule **R** to create a new molecule species **S**. **III**: The signal-producing molecule **S**. This molecule has the dual functionality of copying the molecule it binds to, and moving program flow from region 5 to region 6, where the output molecule is expressed.

as the sequences **TTTTT** or **FFFFF** encode the logical state (shown in red).

The central challenge in this experiment was designing the replicase molecule **R** to bind and process the input molecule. The string encoding the functionality for this molecule was 243 symbols long. The reactions that the sequence encodes are shown in figure 3. There are three reactions to consider. Reaction **I** is the replication function, encoded on region 2 the top row of the figure. We refer the reader to Hickinbotham et al. (2009) for a discussion of the replicase functionality encoded in this region. Reaction **II** occurs when **D** binds to **R** at region 3. The processing of the input molecule is encoded in region 4, and proceeds as follows:

1. **check-input**: Inexact alignments can form a bind with low but significant probability. It is therefore important to check the validity of molecules which bind at region 3. The sequence `?VACH` carries out this check, and terminates the reaction if the condition is not met.
2. **Mod-replicase**: This sequence carries out the modification of the replicase bind site at region **a**, and deletes the terminate symbol `}` at region **b**. This change means

- that region 5 will be executed in reaction **III** to initiate production of the output molecule when **S-S** binds occur.
3. **Check-boolean**: Switches program flow to create a template for an output molecule that embodies “true” or “false” in the system.
4. **Set-output-false** and **Set-output-true**: These sequences position the read pointer over the sequence encoding “true” or “false” respectively depending on the output of a NOT operation on the logical state of **D**.
5. **Make-output-message** writes the output of the NOT operation into the template sequence for the output molecule.
6. **Express-output-message** creates a new output molecule. Note this sequence is also shown in reaction **III** as region 6. The program executed by the **S** jumps to this region from region 5.

The output molecules are **ODTWKZFFFFF** for false and **ODTWKZTTTTT** for true. Note that we had originally coded this molecule using the sequence **OUTPUT**, but the last three letters of this sequence formed a partial match with the bind site for **INPUT**.

It is clear the mechanism for latching the system is more complex than in an electronic logic gate. This is a consequence of the fact that *everything* in the system is subject to decay, so in order to preserve the output, it must be repeatedly created by **S**. However, this does provide the facility for new configurations to arise by allowing mutation to occur in the system as in (Hickinbotham et al., 2009).

## Experimental trial

To demonstrate the effectiveness of the molecular specification, we ran 1,000 trials each of input conditions with true, false and **NULL** configurations. A previously implemented C++ incarnation of Stringmol was used to run the trials, all of which successfully produced the output signal molecule, maintaining the population indefinitely. Examples of processing a true and false input signal are shown in figure 4 (the null configuration is simply a constant population of the seed replicase). In both of these examples, the molecular population dynamics are similar. The Input signal binds to the Start Replicase, which executes the self-modifying code. This produces the “signal replicase”. We see the population of Start Replicase drop off more quickly than the input molecule, since it is subject to modification into the Signal replicase *and* decay, whereas the input molecule is only subject to decay. The bump in the population of the Signal replicase is due to an energy glut, since the input population is too small to consume available energy. Finally, we see the emergence of a steady state population of two molecular species: the Signal replicase, and the output molecule encoded with the appropriate boolean NOT response.

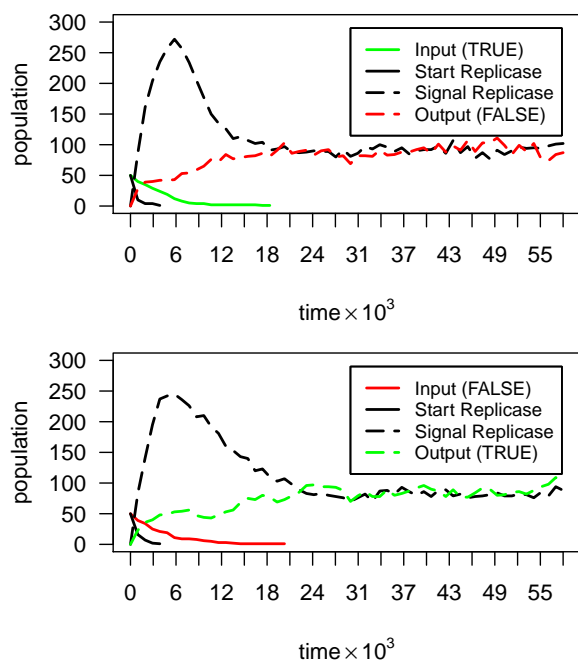

Figure 4: Reaction logic processing of an input molecule through a NOT replicase. **Top:** “true”, encoded as INPUTTTTTT (green line), when combined with the “start replicase” (black line), creates a population of output “false” molecules encoded as ODTWKZFFFFF (red dashed line), along with a Replicase-plus-signal enzyme (black dotted line). **Bottom:** Same as the above, but with “false”, encoded as INPUTFFFFF (red line), and a population of output “true” molecules encoded as ODTWKZTTTTT (green dashed line).

## Comparison and conclusion

We have shown theoretically and experimentally how an embodied reaction process enhances the computational power of chemical systems. The main demonstrator for this has been the design of a simple NOT gate. The differences between Bindworld and Stringmol mirror several important considerations in the design and engineering of novel computational systems.

A major difference is that Stringmol is more complex than Bindworld; it has more atoms, more complex combination rules, and a clear, hardwired border between binding and reaction. Informally, Bindworld is a simpler *world* than Stringmol. This means that, to express complex ideas like logic gates in the terms of Bindworld, we have to do more work to reduce them to its simple terms. Stringmol (like a high-level programming language) has more useful abstractions that we can incorporate when designing “code” that runs in Stringmol. Its programmatic instructions encode the reaction potential of each entity. Stringmol is in closer cor-

respondence with our mental schemas of the problems we wish to solve. As ease of programming is a very important computing property, this consideration is important. Stringmol vs. Bindworld is an example of how making a system more complex can make it easier to use.

Stringmol is also nondeterministic; this can be an advantage because it allows the same starting state to cause different behaviours, which may occur at different rates and can aggregate over time into more complex behaviours. Von Neumann computation relies on the permanent assumption of determinism, but this is not necessary (many biological computers, like the brain, do not require it) and means we have to work harder to implement nondeterminism (as in random number generators). It also leads us into a procedural, deterministic, local mental schema of computing, which is not something we want to be crippled by when designing distributed, concurrent or nondeterministic systems.

With artificial chemistries like Stringmol, there naturally arises the possibility of evolving the system to deliver fuzzier logical analysis from the initial bootstrap, via a built-in ability of the system to evolve. We plan to explore this avenue in future work, with a view to delivering a system capable of evolving solutions within the embodied chemistry.

In our experimental work, we have taken pains to develop a solution that required no changes to the artificial chemistry that was used in (Hickinbotham et al., 2010b) for applications in evolution. This is important, since biological evolution exploits the embodiment of the genome in much the same way as the embodied reactions we explore here. We had to overcome some difficulties with the functional codes in Stringmol, and also some difficulties with similarities in binding sequences that led to mis-alignments. These indicate that the Stringmol system would have more expressive power in both evolutionary and computational experiments were these issues addressed.

Rather like Newspeak in Orwell’s 1984, the expression of certain things in Stringmol is difficult if not well-nigh impossible. Intuitively, the process of simulating the physical copying of a sequence of letters seems to require more information processing than a single logic gate. However the process of copying information is not the same as actually processing the information itself. Thus in Stringmol it is easy to copy strings, but it is very difficult to express a straightforward logic gate because there are not the straightforward expressions available to do so.

We note that simple changes to the Stringmol language that would emphasise the concept of molecular embodiment of information would make the logic gate easier to implement. These are: • **Cut and paste** of strings, rather than copy and paste. Currently, we have to laboriously copy each symbol in a string to do some information processing. But some of these operations do not really require copies to be made. We could just as easily use what is being copied.

Thought of as an embodied system, the advantages of this are clear. Cut and paste in Stringmol would mean that subsequences could be excised and spliced into other sequences by manipulation of pointers. • **Regulation** of some behaviour could occur if repressors could be made possible. In our NOT gate, the input signal re-programmed the seed replicase so that it made an output signal. This programming would not have been necessary in a system where regulation of expression was feasible. • **Energy-dependent behaviour:** Our processing system is subject to energy constraints. If we could switch when energy was low, we could change behaviour to correct it. This would allow regulation of energy to occur and give rise to selection at the molecular level that is not currently possible • **More steps to copy:** If we could dismantle the '=' operator, we'd be able to do more sophisticated construction of signals. As it is, we have to string ===== together to copy short sequences, that is not obviously evolvable without six corresponding mutations. If we could use the Nellis-Stepney system, we could increment the write pointer without incrementing the read pointer, and thus have a copy of a symbol many times. • **Increment direction:** If we could switch this, it would be possible to write/evolve more compact programs. • **Pointer referencing:** If we could move *any* pointer to any other pointer, rather than the limited set currently implemented, we could more easily implement certain information processing behaviours. probable alignments.

It is interesting to note that many of these extensions could be applied to other string-based ALife systems, such as Tierra (Ray, 1991), Avida (Johnson and Wilke, 2004) and Typogenetics (Gwak and Wee, 2007). These systems were also designed to carry out the task of replication, and they are known to have limitations in terms of evolutionary openness. Our studies here indicate that there is potential to extend the instruction sets in these models to allow richer information processing, which may lead to richer behaviours.

Stringmol and Bindworld are doubtless far from any useful chemical computer, being after all only simulations. However, they allow us to explore the properties of chemical and bio-inspired long molecule computing, a strategy which we hope will eventually allow us to design a useful biological computer.

## Abstract

An environment plays an important role in behaviors acquisition for artificial creatures. Thus, the environment must obey the physical laws. In this paper, it is examined how the behavior differences appear when the artificial creature autonomously behaves in some fluid environments. We construct the approximate virtual fluid environment with low computing costs to simulate the behavior acquisition for artificial creatures. Also we propose a simulation method for artificial creatures in consideration of effects from the virtual fluid environment based on physics modeling. As a result of simulation, we verify that it is possible for the creature to acquire adaptive behaviors in different environments. After evolution, the creature behaves autonomously by leveraging effectively fluid forces in each virtual environment.

## Introduction

Many computer simulations have been performed for studying acquiring behaviors, evolution, and learning methodologies on virtual artificial life creatures in the field of Artificial Life (ALife) and evolving robotics. Artificial fish swims automatically by learning its behavior controller (Tu and Terzopoulos, 1994). This study makes it easy to create fish animation. A flock simulation approach is developed based on a distributed behavioral model without setting the orbit of each bird (Reynolds, 1987). This approach makes it easy to create flock animation. The virtual creature is able to acquire its morphology and behavior by an evolutionary methodology based on the creature's competition (Sims, 1994a)(Sims, 1994b). Many studies for behavior acquisition are based on Sims' studies. Sims' model is applied to the virtual catapult creatures to evolve (Chaumont et al., 2007). This creature could throw its parts of body as far as possible. The relation for co-evolution of virtual creatures is observed by fighting each other in Sims' virtual environment (Miconi, 2008). In these days, there are many simulations for artificial creature using the physical calculating engine. It enables these creatures to obey physics law easily. "Snake-Like Robot" acquires adaptive locomotion on the ground using it (Tanev et al., 2005). This model is robust for obstacles. In these studies, the experimental environment is set

as an ideal environment in a computer simulation space because they considered that the methodology of evolving and learning behavior in an ideal environment is more important than acquisition of the similar behavior in realistic environment. Therefore, the influenced force from the fluid environments to the artificial creature is not precisely analyzed. Instead, the implemented force adopts the simple calculation methods for reducing the computing time. On the other hand, in a field of numerical fluid dynamics, many fluid simulations are based on a finite element method and a particle method. The moving particle semi-implicit method makes it easy to create animation on the water surface (Koshizuka et al., 1998). A virtual anomalocaris model swims in the virtual two-dimensional water environment using the particle method (Usami, 2007). And an artificial creature behaves based on a rule method considering the fluid effect (Lentine et al., 2010). The finite element method and the particle method give accurate results. However, they consume much computational time. Therefore, it is unsuitable for a real-time simulation to acquire appropriate behaviors in the virtual fluid environment. However, we consider that the virtual environment needs to acquire a more natural policy of adaptive behaviors.

In this paper, it is examined how the behavior differences appear when the artificial creature autonomously behaves in the different fluid environments. At first, we construct an approximate virtual fluid environment which enable us to do the behavior acquisition simulation with low computing costs. This environment is constructed by setting physics parameters such as the fluid density and drag coefficients. And we propose a simulation method for the artificial creature in consideration of the fluid environment. The artificial creature imitating a flat fish is modeled by connecting rigid bodies. This creature can behave by moving its bodies. In order to control bodies and learn the behaviors, an artificial neural network (ANN) is implemented with the creature. Genetic algorithm (GA) is applied to the ANN by its evolution. We experiment to examine how the artificial creature can acquire adaptive behaviors in some fluid environments. As a result of simulation, we verify that it is possible to ac-

Figure 1: Modeling buoyancy

Figure 2: Modeling drag

quire an adaptive behavior for the artificial creature in virtual fluid environments. And we analyze the acquired behaviors by examining a relation between fluid environments and acquired behaviors.

### Construction of the Virtual Fluid Environment

We assume that the buoyancy and drag act as the forces that virtual rigid objects (sphere, rectangular parallelepipeds) receive from the fluid effect. We construct a virtual fluid environment by modeling two forces acting on the object in the fluid environment. These two forces compare to the buoyancy and drag respectively. The simulation is performed by calculating objects' movement, which obeys a physics law, resulting in an animation. We employ "PhysX (offered by the NVIDIA Corporation)" as a physical calculating engine. PhysX is applied to calculate a basic physical operation, for example, a gravity, a friction force, and collisions among virtual objects. In the virtual fluid environment the acceleration of the gravity  $g$  is  $9.807[m/s^2]$ . We construct the fluid environments by changing the parameter of fluid density  $\rho$ .

#### Modeling Buoyancy

Based on Archimedes' principle, we model the buoyancy as a force whose strength  $F_B$  equals to the weight of the fluid volume which an object occupied in the fluid. This force acts on the center of the mass in the opposite direction of gravity (Fig.1). The strength of the buoyancy in the fluid environment,  $F_B$  [N], is given by equation 1,

$$F_B = \rho V g \quad (1)$$

where  $\rho[kg/m^3]$  is the density of the fluid,  $V[m^3]$  is the volume of the object, and  $g[m/s^2]$  is the acceleration of the gravity.

#### Modeling Drag

Based on fluid dynamics, we model the drag as uniformly distributed forces to the surface of the object in the opposite moving direction (Fig.2). In the field of fluid dynamics,

Figure 3: Artificial flat fish model

$F_D[N]$  is given by equation 2,

$$F_D = C_D \frac{1}{2} \rho v^2 S \quad (2)$$

by using dynamic pressure of a flow  $\frac{1}{2} \rho v^2 [kg/(m \cdot s^2)]$  derived analytically as the strength of the drag in the fluid, where  $C_D$  is a scalar quantity called the drag coefficient, and  $S[m^2]$  is the reference area of the object. The drag coefficient depends on the shape of the object. In this study, the drag coefficient of a rectangular parallelepiped is 1.50. The reference area of the object is the projection area of the object to the plane which is perpendicular to the flow.

An artificial creature can generate a propulsion force by moving its bodies because the modeled drag force is added to its bodies when this creature moves its bodies.

### Experiment for Acquisition Behavior in the Different Fluid Environment

We examine how the differences appear when an artificial creature autonomously behaves in some fluid environments. It is assumed that the model must move forward as efficiently as possible. Evolutionary computing is adopted to acquire the adaptive behavior.

#### Artificial Flat Fish Model

We model the artificial creature by connecting rigid bodies with actuators. The modeled artificial creature imitates a flat fish, which can behave by controlling its bodies. After evaluation of this model by evolutionary computing in fluid environments, this creature behaves effectively by using leverage fluid forces in each virtual environment. Figure 3 shows an artificial flat fish model. The fish model consists of three rectangular parallelepiped with same sizes. This model has two actuators with one degree of freedom (Fig.4). The density of the model is as same as that of fluid.

Figure 4: Model's actuator

Figure 5: Modeling behavior (to bend model's body)

Figure 6: Modeling behavior (to unbend model's body)

### Modeling Behavior for Flat Fish Model

We focus on one actuator, when the model bend upward its body, the center of gravity of its body received drag force  $F_1$  (Fig.5). The strength of the drag force  $F_1$  is given by 3,

$$F_1 = \frac{1}{2} C_D \rho S v_1^2 \quad (3)$$

where  $\theta$  is the bend angle,  $r_G$  is the distance between the actuator and the center of gravity of its body,  $\omega_1$  is the angular velocity of the actuator and  $v_1^2$  it the speed of the body.  $v_1$  is given by 4,

$$v_1 = r_G \frac{d\theta}{dt} = r_G \omega_1 \quad (4)$$

Therefore,  $F_1$  is expressed by 5

$$\begin{aligned} F_1 &= \frac{1}{2} C_D \rho S (r_G \omega_1)^2 \\ &= k \omega_1^2 \left( k = \frac{1}{2} C_D \rho S r_G^2 \right) \end{aligned} \quad (5)$$

In the same way, when the model unbends its body, the center of gravity of its body receives the drag force  $F_2$  (Fig.6), The strength of the drag force  $F_2$  is given by 6,

$$F_2 = k \omega_1^2 \quad (6)$$

where  $\omega_2$  is the angular velocity of the actuator.

In order to move the model forward, the equation 7 is satisfied.

$$\int_{\theta}^0 k \omega_2^2 \sin \theta d\theta - \int_0^{\theta} k \omega_1^2 \sin \theta d\theta > 0 \quad (7)$$

By solving 7, the following relation

$$k(\omega_2^2 - \omega_1^2)(1 + \cos \theta) > 0 \quad (8)$$

$k$ ,  $1 + \cos \theta$  are the positive value,

$$\omega_2 - \omega_1 > 0 \quad (9)$$

This equation 9 means that the model moves forward by the speed of unbending the body faster than that of bending the body. In the same reason, when the model bends its body downward, the model moves forward by the speed of unbending the body faster than that of bending the body, too.

Therefore, the model moves forward as efficiently as possible by the speed of unbending the body, which is faster than that of bending the body on each actuator.

### Control Method for Flat Fish

An artificial neural network (ANN) is introduced to move flat fish model's actuators autonomously depending on information given by its sensor and actuators. Actuators are controlled by outputs of the three-layer feed-forward ANN. Table 1 shows the input and output parameters of the ANN. A transfer function for the ANN  $f(x)$  is formalized by combining two sigmoid functions, given by equation 10.

$$f(x) = \frac{1}{1 + e^{(-\frac{x}{\alpha} - \beta)}} + \frac{1}{1 + e^{(-\frac{x}{\alpha} + \beta)}} - 1 \quad (10)$$

Figure 7 shows an example of the transfer function ( $\alpha = 0.1$ ,  $\beta = 5.0$ ). This function enables the ANN to output the zero value. The number of neurons in the hidden layer is the same as the number of neurons in the input layer. Synaptic weights of the ANN are initialized by a real random number at first. The model enables itself to behave more effectively by optimizing synaptic weights of the ANN and the gain of the transfer function.

### Experimented Condition

We experiment to examine how the differences appear when the artificial creature autonomously behaves in some fluid environments. The flat fish model must move forward as efficiently as possible within a definite period of time (Fig.8).

Table 1: Setting of input and output parameters of ANN

Input	Relative angle of actuator $i$ between rectangular parallelepiped in each time ( $\theta_i$ )
	Relative angular velocity of actuator $i$ between rectangular parallelepiped in each time ( $\omega_i$ )
Output	Object angle of actuator $i$ between rectangular parallelepiped in each time ( $A_i$ )

Figure 7: Transfer function for ANN ( $\alpha = 0.1, \beta = 5.0$ )

Figure 8: Initialize state of a experiment (Front view)

We artificially prepare six fluid environments for experiments. Table 2 shows the density  $\rho_n$  used for each fluid environment. The GA optimizes the synaptic weights of the ANN and the gain of transfer function by applying the RCGA. Table 3 shows ANN and RCGA conditions for this experiment. An evaluated value for the RCGA as a fitness function is set so that the creature moves forward as possible as it can. This evaluated value  $F_{eval}$  is given by 11.

$$F_{eval} = \sum_{t=0}^{Step} x(t) \quad (11)$$

where  $Step$  is the number of step used for the simulation at each generation,  $x(t)$  is a distance from a start position at each simulation step  $t$ .

Result and Discussion

$\rho_6$	998.20[kg/m <sup>3</sup> ] (Water environment)

creature acquires adaptive behaviors. Figure 9 shows a diagram which draws the position of best individual at each simulation time in each environment. The angle between rigid bodies on the best individual in each environment is shown in Fig.10-15. From these results, model's bodies oscillate periodically, and the angle between its bodies propagates from the front to back in each environment. This model moves forward by oscillating its tail much more than the bodies. And the smaller the density of model is, the faster the model oscillates its bodies in the fluid environment, because the creature in the environment whose density is larger needs more energy to move its bodies than that in the environment whose density is smaller. Therefore, the smaller the density of model is, the farer the model moves forward from the start position. In addition, the speed of fish's body generates the drag forces. The speed to unbend model's body ( $\omega_2, \omega_4$ ) is faster than that to bend its body ( $\omega_1, \omega_3$ ) as modeling behavior for flat fish model (Fig.16). Therefore, this model can generate propulsion by applying evolutionary computations (ANN and RCGA).

Figure 20: Relation of the generation and the distance from the start position in the water environment

Figure 21: Three Joints Model

Figure 22: Five Joints Model

In the air environment, the frequency of the elite creature's body in the middle of the experiment is larger than that of creatures's body after optimizing the ANN (Fig.17). However the creature on the way of the experiment cannot move more forward well (Fig.18). Similarly, the creature on the way of the experiment cannot move more forward well in the water environment (Fig.19, 20). This creature acquires an adaptive behavior in the each environment by using evolutionary computations (ANN and RCGA), moves forward as efficiently as possible.

### Additional experiment

Additionally, we examine how the topology of the artificial creature affects with the behavior ability through numerical simulation. To do so, we generate two types of the flat fish model. The modification is done by changing the number of actuators. We make a three joints flat fish model (Fig.21), and a five joints flat fish model (Fig.22). These models consist of rectangular parallelepipeds with the same size, keep-

Figure 23: Relation of the number of actuators and the distance from start position

ing the total length of flat fish model (two joint model). We investigate how far two models move forward as efficiently as possible from the initial position within a definite period of time. Evolutionary computation (RCGA) is applied to all generated creatures to adapt their ANNs, which are set as controllers for the behavior. The experimental conditions for the RCGA and the ANN are shown in Table 2. The density of the fluid and model is as same as that of the water.

Figure 23 shows the position of best individual of each model at each simulation time in the water environment. Figure 24 shows the angle between rigid bodies on the best individual of the three joints model. Figure 25 shows the angle between rigid bodies on best individual of the five joints model.

From these results, three joints model move forward further than two joints model from the start position. However, five joints model do not move forward further than two joints model from the start position. Bodies of two models oscillate periodically and the angle between the creature's bodies propagates from the front to back. This creature moves forward by oscillating its tail much more than the bodies like a two joints model. And the speed to unbend each model's body ( $\omega_2, \omega_4$ ) is faster than that to bend its body ( $\omega_1, \omega_3$ ) as modeling behavior for flat fish model (Fig.16).

In addition, the three joints model oscillates its bodies greatly and slowly, This model generates stronger drag forces because the surface drag area is large. On the other hand, the five joints model oscillates its bodies in a small range with a fast frequency. This model generates a small drag forces because the surface drag area is small. By these experiments, it becomes clear that the flat fish model needs a proper topology of the body to move forward, that is, the topology of the flat fish model effects behaviors.

Figure 24: Angles of the rigid bodies on the best individual (three joints model)

Figure 25: Angles of the rigid bodies on the best individual (five joints model)

## Conclusion

In this paper, we constructed the virtual environment with low computational costs by introducing two forces comparing to the buoyancy and drag calculated by using a physical calculating engine. And we examine how the differences appear when artificial creature model autonomously behaves in some fluid environments by applying evolutionary computing (ANN and RCGA). From the result, it is possible for the model to acquire behaviors in some fluid environment. After optimizing the ANN, this model behaves effectively by leveraging fluid forces in each environment. The model's bodies oscillate periodically, and the angle between the its bodies propagates from the front to back in each environment. This model moves forward by oscillating its tail much more than the bodies. Additionally, we examine how the topology of the artificial creature affects with the behavior ability through numerical simulation. From the result, it becomes clear that the flat fish model needs a proper topology of the body to move forward.

As a future work, we would like to explore "life-as-it-could-be" by controlling the artificial creature which has many wings.

# Autonomous Learning in an Information Stream through Autopoiesis

Nikolaos Nanas<sup>1</sup>

<sup>1</sup>Center for Research and Technology Thessaly, Greece  
n.nanas@cereteth.gr

## Abstract

Nootropia is a complex, self-organizing system, inspired by the Theory of Autopoiesis and successfully applied so far to the challenging problem of profiling a user's information interests. In this paper for the first time, Nootropia is studied in the context of Artificial Life, as an autonomous system that can learn without human intervention. A series of experiments demonstrate that Nootropia can autonomously learn to identify documents belonging to a specific topic with minimal training. This is achieved through a deterministic process of self-organization, which, when coupled with a complex and dynamic information environment, gives rise to rich and unpredictable behavior. Nootropia is open to its environment and operates far from equilibrium, while it tries to maintain its identity within an information stream. Our exploration of the dynamics behind Nootropia's autonomous learning capabilities lead to interesting insights, which may extend beyond its successful application to the problem of profiling and towards a new research stream that uses Nootropia as a means for studying computational autopoiesis.

## Introduction

Humberto Maturana and Francisco J. Varela's *Autopoietic Theory* describes a model of self-organisation (Varela et al., 1974; Maturana and Varela, 1980). In simple words, it states that a system's organisation is defined by its "structure" (its components (nodes) and their relations (links)) and the processes that this structure performs, which continuously regenerate the structure that produces them. Of particular interest to the current work is Varela's view of the immune system in the context of Autopoietic Theory. Varela treated the immune system as an *organisationally closed* network that reacts autonomously in order to define and preserve the organism's identity, in what is called *self-assertion* (Varela and Coutinho, 1991). Self-assertion is an on going process, since both the organism and the environment change over time.

Two types of change contribute to self-assertion. The network's *dynamics* refer to ongoing variations in the concentration of antibodies and play the role of reinforcement learning. The network's *metadynamics* are the result of the recruitment of new cells (produced by the bone marrow)

and of the removal of existing cells. The network's metadynamics play the role of a distributed control mechanism that allows the network to maintain its viability by shifting its immune repertoire (Bersini and Varela, 1994). It is also important, that due to the interactions between antibodies, it is essentially the network itself that chooses which new recruited cells will survive in the network. According to Vaz and Varela, self-assertion is the natural consequence of this *endogenous selection* process (Vaz and Varela, 1978).

Stewart and Varela used a computational model to explore self-assertion (Stewart and Varela, 1991). Like the original computer simulation of a cell-like autopoietic structure in (Varela et al., 1974), Stewart and Varela's model involved a discrete two dimensional grid representation of shape-space, where antibodies are randomly introduced. The survival of antibodies on this grid depends on their affinity to other antibodies, with affinity being a function of the distance between two antibodies. The simulation gave rise to stable (but not static) patterns that were the result of the network's metadynamics. Similar self-assertion models have also been studied in (De Boer and Perelson, 1991) and (Bersini, 2002).

Discrete, two dimensional spaces have been the basis of many computational models of autopoiesis. A comprehensive review can be found in (McMullin, 2004). Although cellular automata on two-dimensional grids are known to be capable of universal computation, in the case of autopoiesis and self-assertion models in particular, the simulated environments are relatively simple. For instance, in the original computational model of autopoiesis, the environment where the cell-like structure is formed comprises particles that bond in the presence of a catalyst to form the cell's membrane. Similarly, in Stewart and Varela's model of the immune system the external environment consists of randomly generated antibodies in the shape space. In both cases, the computer simulations demonstrate visually, that despite the stochastic nature of the environment stable structures progressively emerge and manage to maintain their identity over time.

This paper suggests an alternative scientific methodology

for exploring autonomous behaviour through autopoiesis. It uses the Web as a source of real-world data for simulating a complex and dynamic information environment. In this environment, a profiling system, which has been inspired by the autopoietic view of the immune system, has to autonomously learn to identify specific information, in order to maintain its identity. A series of experiments demonstrates that this system is capable of autonomous learning through a process of self-organisation that dynamically controls the profile's structure. Although, the adopted information environment cannot be easily visualised, depicting how certain macroscopic variables vary over time, reveals a complex system that, although deterministic, is unpredictable. Small variations in the initial conditions can cause significant variations in the structural pathways the system follows as it interacts with its complex environment. The results also reveal an interesting relation between energy consumption and autonomous behaviour that requires further investigation.

### Profiling with Nootropia

According to (Mireille, 2008), profiling could be generally defined as:

“The process of ‘discovering’ correlations between data in databases that can be used to identify and represent a human or nonhuman subject (individual or group) and/or the application of profiles (sets of correlated data) to individuate and represent a subject or to identify a subject as a member of a group or category.”

In practice, when profiling an individual's (or a group's) information interests, a profile is built and continuously learns from the user's interaction with information and is used to evaluate the relevance of new, incoming information to these interests. Profiling in this case, is a challenging problem with analogies to the immune system's self-assertion process. To maintain its viability a profile has to be able to define and preserve the identity of the user's interests. It has to be able to learn a variety of interests and continuously adapt to changes in them.

These analogies inspired the design and development of Nootropia<sup>1</sup>, a profiling system that so far, has been successfully applied for adaptive filtering of textual information according to a user's (or a group's) interests. In its current form, Nootropia was first introduced in (Nanas et al., 2004) and since then, it has been extensively described and experimentally evaluated (see for instance (Nanas and De Roeck, 2009; Nanas et al., 2009, 2010b,a).

In Nootropia, the profile is a weighted network of features, e.g., a network of words extracted from the content of text documents. The links in this network capture correlations between features that appear regularly in the same

context, e.g., correlations between words that appear close to each other in text. A feature's weight measures its importance within the profile and a link's weight the strength of the correlation between two features. The profile is built and continuously adapts to interest changes through a process of self-organisation that adjusts the network's structure in response to user feedback (explicit or implicit). For instance, if a document is identified as relevant to the user's interests, then words in the profile that also appear in the document get reinforced at the expense of the words they are linked to. These local competitions cause a redistribution of weight between the profile's words (dynamics). Words in the document that do not already appear in the profile are recruited and those profile words that run out of weight are purged (metadynamics). The exact self-organisation process is described in detail in (Nanas and De Roeck, 2009).

To evaluate the relevance of an information item (e.g., document), the profile deploys a directional spreading activation process. Profile features (e.g., words) that also appear in the item get activated. In order of increasing weight, each activated feature disseminates part of its current activation towards the activated features with larger weights that it is linked to. The relevance score is then calculated as the weighted sum of the final activation of profile features. This non-linear evaluation process, which is described in detail in (Nanas et al., 2010a), implies a hierarchy of features, as activation is being channeled from the majority of features with small weights towards the “elite” of features with large weights. The structure of this implicit hierarchy, which continuously self-organises in response to the environment, defines the profile's collective reaction to incoming information.

The autopoietic properties of Nootropia are discussed in detail in (Nanas and De Roeck, 2009), where it is argued that Nootropia exhibits the basic characteristics of self-assertion models. It is a non-linear, self-organising system, that is open to its environment and operates far from equilibrium, constantly adjusting structurally, and hence behaviourally. It also involves both network dynamics and metadynamics with endogenous selection. Experiments performed in (Nanas and De Roeck, 2009) and (Nanas et al., 2010b) demonstrate Nootropia's ability to effectively adapt to a variety of interest changes through self-organisation. Further experiments and analysis indicate that it is the network's non-linearity which allows the profile to store additional information regarding a user's interests and thus remain specific even within high-dimensional spaces (Nanas et al., 2010b,a). In such spaces, comparative experiments between Nootropia and a vector-based profile containing the same weighted words, show that the additional information encoded by Nootropia's links contributes to an increase in accuracy of up to 50% (Nanas et al., 2010a). Nootropia's advantageous properties have already boosted the development of real world prototypes, such as the Personalised

<sup>1</sup>Greek word for: “an individual's or a group's particular way of thinking, someone's characteristics of intellect and perception”.

Figure 1: Experimental Process

News Aggregator described in (Nanas et al., 2010c).

In all of the above cases though, it is the user (or a group of users) that explicitly, or implicitly, provides the profile with relevant information to learn from. So what if we take the user out of the equation and ask the profile to autonomously identify and choose information to learn from? Will the profile be able to maintain its identity and what lessons can be learned from its autonomous learning behaviour? This paper deals with these questions experimentally in the context of Alife in general and of the Theory of Autopoiesis in particular.

## Experimental Evaluation

The performed experiments are a continuation of those referred above and use a variation of their methodology to test the ability of a profile to autonomously learn to identify documents belonging to a specific topic category. Once more the dataset used in the experiments is the Reuters-21578 document collection<sup>2</sup>. It includes 21578 news stories from Reuters newswire in 1987, ordered according to publication date and classified by human experts into 135 topic categories. The experiments focus on the 23 topics with at least 100 relevant documents in the dataset.

### Autonomous Profile

As it is exemplified in figure 1, for each of the 23 topics, a “seed” profile is initialised using the first five<sup>3</sup> documents in the collection belonging to the topic. The seed profile is then released in the information stream and traverses the 21578 documents in the collection in chronological order. The profile evaluates every individual document and assigns to it a score. If the assigned score is over a threshold the profile chooses the document for “consumption” and self-organises accordingly. For the current experiments, the threshold is calculated for each individual document as the average score assigned to the documents “consumed” so far. The process is repeated until all 21578 have been accounted for. The

<sup>2</sup>available at <http://www.daviddlewis.com/resources/testcollections/reuters21578/>

<sup>3</sup>Experiments were also performed for 1, 10 and 50 initialisation documents, but are not reported here due to space limitations. With just 1 initialisation document the seed profile is not developed enough to achieve the desired behaviour. As the number of initialisation documents increases from 5 to 10 and then to 50 the profile relies more on its initial condition rather than the subsequent learning process.

profile’s accuracy is then measured by calculating the Average Uninterpolated Precision (AUP) of the list comprising the documents in the collection ordered by decreasing score. A topics AUP is defined as the sum of the precision<sup>4</sup> at each point in the ordered list where a relevant document appears, divided by the total number of relevant documents. The essence of this accuracy metric is that documents relevant to the current topic should receive larger scores than irrelevant documents.

The above methodology establishes a challenging experimental task. Based only on its initial training with a small number of documents relevant to a topic, the profile has to autonomously learn to identify documents belonging to that topic. Ideally, the profile should choose all relevant documents and ignore the rest<sup>5</sup>. However, as it is depicted in figure 1, there are typically both false negatives and false positives. Not all relevant documents are chosen and not all chosen documents are relevant. Both the percentage of relevant documents chosen and the percentage of chosen documents that are relevant affect the profile’s accuracy. If the first percentage is small the profile ignores valuable input. If the second percentage is small then the profile may deviate away from the current topic of interest. It should also be noted that since the content of documents relevant to a topic may change over time, the profile has to be able to follow this drift. Overall, the choices the profile made so far define its current structure and consequently its future choices. So even small changes in the initial conditions can cause the profile to follow a very different trajectory. Out of an infinite number of possible network configuration the profile has to self-organise in such a way that it manages to maintain its (topical) identity within a complex and dynamic environment.

### Supervised and Random Profiles

In the experiments the accuracy and behaviour of the autonomous profile are juxtaposed with those of a *supervised profile* and of a *random profile*<sup>6</sup>. In both cases we start with an initially empty profile. Like before the profile is released in the information stream and evaluates the 21578 documents in chronological order. Unlike the autonomous profile, these two types of profile do not choose the documents to learn from autonomously. Whenever the supervised profile evaluates a relevant document it will always use it for learning, while it ignores all non-relevant documents. In other words, it is provided a priori with complete knowledge of which documents are relevant to the current topic of

<sup>4</sup>i.e., the ratio of documents relevant to that topic.

<sup>5</sup>It is assumed that the categorisation of documents by Reuter’s experts has been accurate.

<sup>6</sup>All three types of profile are built using Information Gain to extract the most important words in the training documents and a sliding window of size 20 for identifying correlations between the extracted words.

topic code	relevant docs	docs chosen	relevant chosen	rel. chosen/ docs chosen	rel. chosen/ total rel.	AUP autonomous	AUP supervised	AUP random	auto/ supervised

interest. The random profile, on the other hand, is provided with an equal number of randomly selected documents from the collection.

## Accuracy

Table 1 summarises for each topic, the choices made by the autonomous profile and the resulting AUP score and compares it to those of the supervised and autonomous profile. The results lead to the following observations:

- The accuracy of the random profile is the lowest (table 1 col. 9). The profile must learn from relevant documents to be accurate.
- As expected the supervised profile achieves the best overall performance (table 1 col. 8).
- The performance of the autonomous profile is satisfactory (table 1 col. 7). It achieves on average 74% of the supervised profile’s accuracy (table 1 col. 10).
- The autonomous profile achieves this level of accuracy although on average it only identifies 10% of the existing relevant documents per topic (table 1 col. 6). It appears that not all of the available relevant documents are required for increased accuracy. In fact, it is interesting that there are four topics (corn, oilseed, nat-gas, soybean) for which the autonomous profile clearly outperforms the supervised profile although, after its initialisation with five documents, it chooses a very small number of documents to learn from. It may be the case, that for certain topics with relatively small number of relevant documents in

the collection and distinct content, this is a better strategy. The seed profile overspecialises to the initialisation documents, but these are representative enough of the remaining relevant documents that ignoring them leads to better accuracy. In any case, this is not always the best strategy (e.g., topics grain, ship, and livestock).

- The satisfactory accuracy of the autonomous profile is mainly due to the fact that, on average, 50% of the documents chosen are indeed relevant. There is a clearer correlation between the profile’s accuracy and the percentage of chosen documents that are relevant. In general, if the percentage is small the accuracy of the autonomous profile is small and increases as the percentage increases. For percentages close to one the accuracy of the autonomous profile approximates that of the supervised profile. It is clear that the profile has to be selective when choosing the documents to learn from. Too many false positives can cause the profile to drift away from the current topic of interest.

## Behaviour

Nootropia is a complex system and it is not easy to visualise, or to analyse, its dynamic behaviour. In this paper, an attempt is made to understand how self-organisation contributes to the above autonomous learning capabilities, by observing certain macroscopic variables related to the profile’s nodes and their weights. The analysis of the network’s connectivity is part of ongoing work and will be included in future publications. Furthermore, due to space limitations,

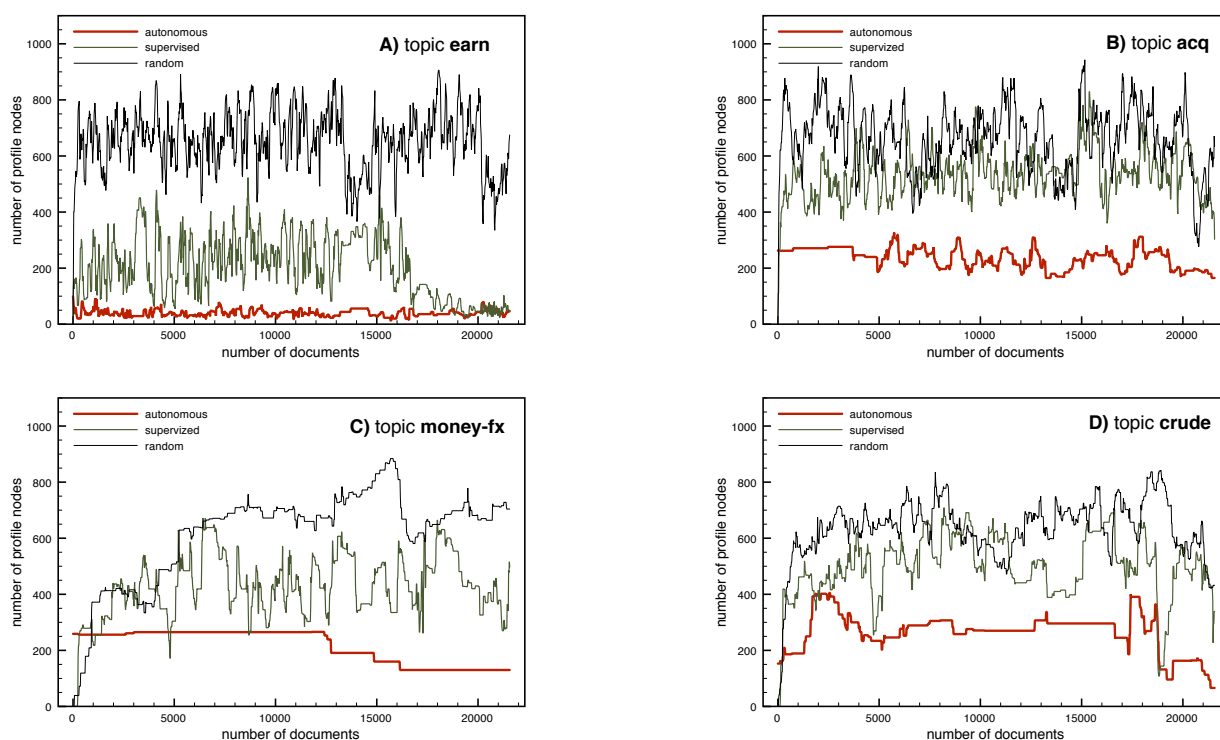

Figure 2: Fluctuations in the number of profile nodes along the information stream.

only the four topics with the largest number of relevant documents are indicatively chosen for this study.

The graphs in figure 2 depict for each of the topics earn, acq, money-fx and crude, how the number of nodes (words) in the profile (Y-axis) changes as it traverses the document collection (X-axis). These indicative graphs show that Nootropia is a dissipative, self-organising system that can dynamically control its size (and connectivity (Nanas et al., 2009)). Energy (word weight) flows through the profile with the addition of words and is dissipated when these words are purged. Although there are more than 20.000 unique words in Reuters-21578<sup>7</sup>, the number of nodes in the profile does not escalate above 1000. In all four cases, the three types of profile are easily distinguished based on the average number of words. The autonomous profile maintains the smallest number of words and the random profile the largest number of words, although it uses the same number of documents to learn from as the supervised profile. So these differences are not only due to differences in the number of training documents, but they also depend on the semantic diversity of these documents. The random profile is provided with randomly selected training documents from the collection, that may belong to any topic. These documents may include a greater variety of words and thus give rise to a profile

with a larger number of nodes. The supervised profile uses the same number of documents relevant to a specific topic and so their vocabulary is more focused. For the same reasons, the autonomous profile appears to be the most focused profile type, with the least number of profile words and the mildest fluctuations. Apparently, the profile has the ability to choose documents that are semantically close to its initial composition and their vocabulary is already reflected in the profile. These documents do not have many new words to contribute to the profile and cause as a result smaller profile perturbations. It is also evident from these figures that the average number of words in each profile type varies from topic to topic and depends not only on the number of relevant documents, but also on the semantic characteristics of each topic. Finally, it is clear that in the case of topic money-fx (fig. 2 C ), the profile does not successfully identify appropriate documents to learn from, causing a decrease in the number of profile words and the poorest relative accuracy out of the four cases (see tbl. 1).

To further investigate the behaviour of Nootropia, figures 3 and 4 depict respectively, the average and aggregate weight of profile nodes through out the 21578 documents<sup>8</sup>. With the exception of the unsuccessful topic money-fx, the autonomous profile has the largest average weight, which

<sup>7</sup>After stop word removal and stemming.

<sup>8</sup>Note that for visualisation reasons the Y-axis of the graphs in figure 3 has various scales.

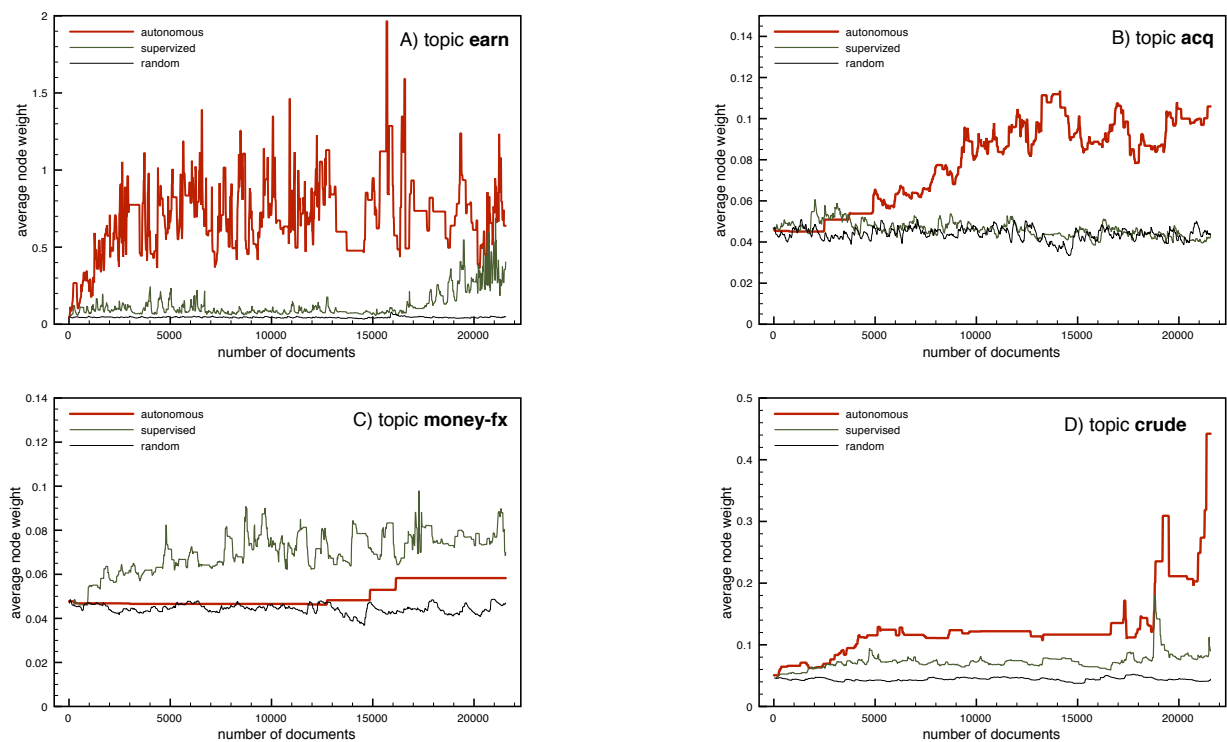

Figure 3: The average weight of profile nodes along the information stream.

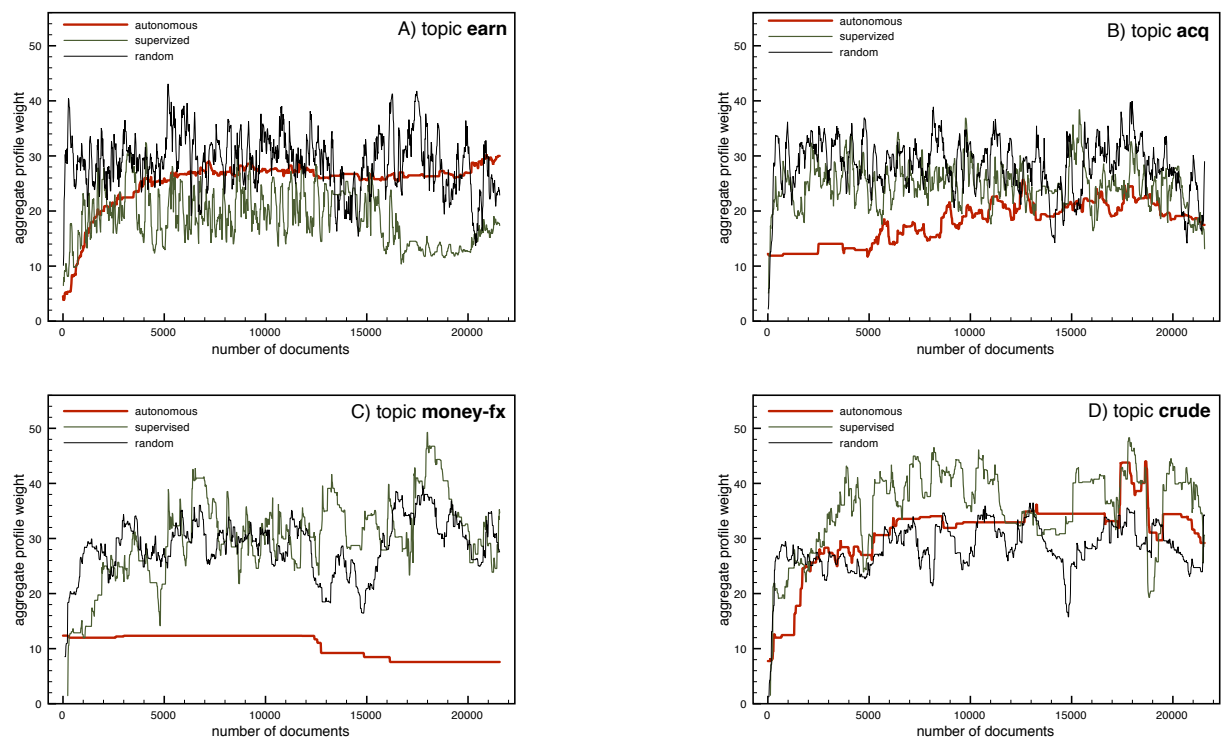

Figure 4: The aggregate profile weight along the information stream.

tends to increase along the process. There is also an apparent correlation between the scale of the average node weight and the accuracy of the profile (see table 1). Furthermore, the average weight does not depend only on the number of profile nodes. According to graphs B and D in figures 2 and 3, although the autonomous profile maintains in both cases approximately the same number of nodes, there is a significant difference in the average weight. This means that the average weight of profile nodes is possibly another macroscopic variable that characterises the behaviour and accuracy of the autonomous profile. It shows that the autonomous profile can effectively maintain and reinforce its identity. By choosing documents that are relevant to its initial semantic composition, the profile reinforces what has already been learned and remains specific to its area of interest, thus avoiding intense structural fluctuations.

The distinct behaviour of the autonomous profile is also reflected in the way it aggregates node weight. According to figure 4, with the exception again of topic money-fx, the autonomous profile progressively accumulates weight until it reaches a certain capacity, where it tends to stabilise. It is also interesting, that unlike the supervised and the random profile, the aggregation of weight by the autonomous profile is more progressive and with less fluctuations. Finally, it is notable that for topic earn, acq and crude the aggregate weight of the autonomous profile is comparable to that of the supervised and random profiles, despite the smaller number of documents used for learning (tbl. 1) and the smaller number of profile words (fig. 2).

## Discussion

The experimental results show that Nootropia is capable of autonomous learning within a complex information environment. The system's accuracy in itself is not the primary concern of this paper. It is already satisfactory enough, given the small amount of training data that are provided for initialisation and it can be further improved, e.g., through more elaborate thresholding mechanisms. What is important is that this unsupervised learning behaviour is the result of an autopoietic network's self-organisation in response to a diverse and changing information environment. The network "perceives" its environment through a non-linear spreading activation process that leads to increased specificity even within high-dimensional environments (Nanas et al., 2010a). As a result, the network can accurately identify and extract relevant information from the environment. The "cognitive", learning process is the result of the network's reaction to the extracted information and involves both the redistribution of node weights through local interactions (network dynamics) and the addition and removal of nodes (network metadynamics). The network becomes open to the environment: energy (weight) is absorbed from the environment, it is temporarily stored by the network and eventually, it is disseminated back to the environment. The distribution of

stored energy (weight) in the network imposes a hierarchy on the nodes that defines the network's response to the environment. When the network is forced to self-organise in response to random information then it becomes large (fig. 2), but the hierarchy of nodes remains shallow (fig. 3). The network is more volatile, because more nodes have small weights and can be more easily removed from the network, causing pronounced fluctuations in the number of nodes. On the contrary, relevant information reinforces what is already in the network with additional energy and the hierarchy of nodes grows higher. This increases the stability and specificity of the network and it becomes more likely that it will identify additional relevant information, leading to a positive feedback loop, which allows the profile to maintain its identity and to avoid strong perturbations.

Some interesting lessons can be learned from all the above:

- The World Wide Web can serve as a valuable source of real-world data, for simulating complex and dynamic environments to experiment in the domain of Artificial Life. These environments are multidimensional and cannot be visualised. They provide however a rich information world that lies somewhere in the middle of the range between the relatively simple 2D worlds of many computer simulations and the physical world. As in the case of Varela's 2D simulations (Varela et al., 1974; Stewart and Varela, 1991), the above experiments demonstrate that even in such a complex environment autopoiesis can still give rise to consistent, "meaningful" behaviour that can maintain a system's viability.
- If Nootropia is indeed an autopoietic system, or at least exhibits some autopoietic properties, then its experimental study highlights the importance of the environment during autopoiesis. Nootropia is organisationally closed, but it is the interaction with the environment that guides its structural and hence, behavioural development. It is structurally coupled to its environment and unlike existing 2D simulations, it is the richness of this environment that can give rise to a plethora of structural modifications and corresponding behaviours.
- It is even more interesting that the study of Nootropia's behaviour indicates a relation between energy and autopoiesis. The autonomous profile effectively accumulates energy per node, to reinforce its structure and hence its identity. As a consequence, even within a complex environment and despite the infinite number of possible structural pathways, the profile can be specific enough to choose the information that will lead to further energy aggregation and self-assertion. The role of energy during autopoiesis has been ignored by existing computational investigations and will become a major theme of the research endeavour that this paper initiates.

## Summary and Outlook

Computational Autopoiesis is already an established area of research in Alife. The most common approach involves simulating autopoietic (cell-like) structures on a discrete, two-dimensional space. The current work deviates from this practice. Nootropia is a profiling model that has been inspired by Varela's view of the immune system as an organisationally closed network of interacting antibodies, which reacts autonomously to define and preserve the host organism's identity. Nootropia has already been evaluated extensively and has produced significant results, both quantitatively and qualitatively. The past experimental work on Nootropia concentrated on supervised learning. In this paper for the first time, human intervention is kept minimal. A collection of news articles ordered according to publication date serves as an information stream and within this stream a profile, which has been initialised with a small number of articles relevant to a topic, has to autonomously identify and learn from more relevant articles. This autonomous profile is contrasted to a supervised profile that has complete knowledge of what is relevant and a random profile that chooses documents to learn from at random.

The accuracy of the autonomous profile is satisfactory. It clearly outperforms the random profile and achieves a level of accuracy that is on average 74% that of the supervised profile. What is important is that this level of accuracy is the result of self-organisation in response to the environment. The analysis of Nootropia's behaviour provides evidence that it can control its structure dynamically and in such a way that it effectively consumes and stores energy from the environment. The stored energy reinforces the network's structure and hence the profile's specificity. It becomes easier for the profile to identify more relevant information, leading naturally to self-assertion.

The experimental work in this paper demonstrates also that exploiting the web as a valuable source of real-world data for simulating complex and dynamic environments, can be a fruitful avenue of research in Alife. It is in such multidimensional information worlds that interesting complex structures and behaviours may arise as a natural consequence of autopoiesis. This paper is only a first step in this research avenue. Future steps involve a more extensive experimentation and analysis, including statistical analysis of the network's properties (e.g., degree distribution and clustering coefficient), but also, a more comprehensive exploration of the background theories and philosophies. This paper brings to our attention the relation between information, energy and life and creates one more connection between Alife and the domains of Thermodynamics and Energetics in general. Nootropia is a possible means for exploring this relation through computational autopoiesis and some interesting insights have been gained with the current work. Much more is of course required to be able to make bolder claims, or to draw more general conclusions.

adam@cs.york.ac.uk

## Abstract

We address the process of *copying* in Artificial Life organisms. Copying is a source of mutations, a crucial component in evolution. We propose that rich copying mechanisms, and thereby rich evolutionary systems, can be obtained by *embodying* the copying process in a lower-level simulation.

We demonstrate an embodied copying process that has the potential to alter its own mutation rate, without having the concept of a mutation rate parameter explicit in the system.

## Introduction

In computing, the concept of copying is important. Many programs copy data during computation. So programming languages often have the concept of copying as a primitive instruction. For example, all high-level imperative languages have an assignment operator;  $a := b$  copies the contents of  $b$  and puts the result in  $a$ .

In Artificial Life (ALife), the concept of copying is also important. To reproduce, life-forms (whether biological or artificial) need to copy themselves. ALife organisms in computers can make use of the copy operations in programming languages, using these to copy themselves. But the requirements of ALife organisms and traditional computer programs are different. Copying in ALife is a source of mutations. It is a novelty-generation process driving evolution.

In biological organisms, copying is not an abstract concept implemented by a defined instruction. It is an emergent property of lower level processes. Copying is *embodied* within the biological systems that are being copied, and so mutations caused by the copying process can change the copying process.

We propose that ALife organisms should not blindly use the copy operations provided by programming languages. Here, we focus on copying as an embodied *process*, rather than as a computational *result*.

Artificial Chemistry (AChem) is the medium we use to embody the copying process. We explain how existing work has started to implement embodied copying reactions in AChem. We build on this by designing an AChem and using it to implement an embodied copying process.

## Crisp, stochastic, and embodied copying

In normal computer programs, copying should happen *crisply*, without any errors. If a programmer writes  $a := b$  in their code, they expect the copy to work perfectly. They expect  $a$  to contain an exact copy of  $b$ .

However, this is not the case in ALife. When biological life-forms (such as bacteria) clone themselves asexually, the clones are not exact copies of their parents (see any biology textbook, e.g. [1]). The biological ‘copy operation’ does not work perfectly. But this is not a mistake. Biology would not be improved by a perfect copy operation. Imperfect copying in biology causes the mutations and novelty that allow evolution to happen.

*Stochasticity* is a way of introducing variation into computer programs (or more generally, any systems). ALife organisms can use this variation to explore the design space of possible organisms. Stochastic programs are crisp programs with variation introduced via pseudo-random number generators. Stochastic programs can influence ALife organisms, allowing the organisms to vary. But the variation originates outside the simulation of the organisms, so the organisms can not influence the variation process. They can not change the stochastic programs. If the programs are to be changed during a simulation, they must be changed by another abstract process, operating on a higher level. This process, in turn, can only be changed by a process operating on an even higher level. This chain of meta-processes and meta-parameters can be broken by *embodying* the process in the simulation.

*Embodying* means implementing one system (the process) within another (the environment). It is frequently used in robotics to refer to building physical robots rather than simulated ones, thus embodying the robot system (process) in the physical world (environment). But the environment within which a process can be embodied is not limited to the physical world [6]. All processes are embodied within some environment, but stochastic programs are embodied in a trivial environment outside the simulation of the ALife organisms. This is why the ALife organisms can not change the stochastic programs.

---

**Algorithm 1** Deconstructing the string copy operation, as a prerequisite to embodying it

---

```
result string_A := string.B

i := start(string.B)
while i not at-end(string.B) do
  string_A(i) := char-copy(string.B(i))
  i := next(i)
end while
```

---

In order for an ALife organism to change a stochastic process, the process must be implemented in the same language as the organisms: the process must be embodied within the simulation of the organism. A stochastic copying process allows the organisms in a simulation to vary, and so evolve. If the copying process is itself part of the simulation, then it too will be able to vary and evolve.

### Copying as a process

In writing an embodied copying program, we must think about the *process* of copying a string, rather than the *result* of the copy. Algorithm 1 breaks down this process into four parts, each involving a particular function: *start*, *at-end*, *char-copy*, and *next*. Each of these four functions can be either crisp, stochastic or embodied. If all four are crisp, then the overall copying process is crisp, and exact copies are always produced.

If any of these four functions are stochastic, then the overall copying process will be stochastic. Making different combinations of these four functions stochastic introduces different kinds of variation into the copying process. For example: making *char-copy* stochastic could cause some characters to be copied incorrectly; making *at-end* stochastic could cause the copy to be truncated.

We can embody the copying process in different ways, and to different degrees. We must implement a simulation of a system where at least one of these functions can happen as a consequence of lower-level events. But we do not need to embody all four of the functions. We can implement some of them as crisp or stochastic functions in the definition of our simulation. Thus there are many different ways in which we can embody the copy operation. Each of these ways leads to different systems with different properties and different degrees of self-modification and novelty generation.

### Example: the Stringmol AChem

The Stringmol AChem [3, 2, 4] has been used to implement an embodied copy operation. In terms of algorithm 1, it has embodied *start* and *at-end* functions, a stochastic *char-copy* function and a crisp *next* function.

Stringmol's embodied copying process has been shown to produce interesting behaviour [3]. Because the process of copying is embodied in a 'replicase' chemical, evolution

can change the process when the replicase copies (another instance of) itself. One sequence of changes observed in Stringmol (described in detail, in [3]) is the emergence of an unprogrammed 'macro-mutation' that chops off the first few characters of a chemical. The emergence of the macro-mutation exploited the two embodied stages of Stringmol's copying process: the *start* and *at-end* functions.

Stringmol produced something different from what would normally be expected of a copy operation: an unprogrammed type of mutation. The emergence of a new type of mutation is not possible using just a stochastic copy operation. Embodiment is needed to allow the intermediate stages of the copying process to be exploited and changed. This shows the potential power of embodying the copying process (or more generally, any process).

Our hypothesis is that by embodying different stages of the copying process, we will be able to observe different, unprogrammed types of mutation emerging from our ALife simulations.

## The Graphmol AChem

In our Graphmol AChem, the chemicals are graphs, and reactions change the topology of the graphs. We use Graphmol to build an embodied copy operation that has an embodied *next* function. Here we use crisp *start*, *at-end* and *char-copy* functions, because we are interested in investigating the effect of embodying the *next* function. However, Graphmol has been designed so that the *start*, *at-end* and *char-copy* functions can (in the future) be made stochastic or embodied.

We embody the *next* function by building a "walker" chemical in Graphmol. This chemical is a graph that can change its own topology by running short computer programs. Some of its graph nodes are "feet" that walk along the string being copied (which is also represented as a graph). The *next* function (incrementing a pointer) is broken down into two stages: (1) lifting up a foot; and (2) putting that foot down in the 'next' place. A stochastic process controls where the feet are put down, allowing them to be put down in the "wrong" place and so causing mutations in the copied string (variations in the copying process). The *next* function is embodied because the stochastic process depends on the composition of the walker chemical. Changing the walker chemical changes the stochastic process, and so an evolving walker chemical can change the way in which it performs its *next* function.

We show that this embodiment allows the walker chemical to change its mutation rate through evolution. This demonstrates the usefulness of an embodied *next* function (increment operation) used to make an embodied copy operation.

## Definition of Graphmol

The chemicals in Graphmol are represented by graphs. Each graph is both a data structure and a program. The execution of the program changes the structure of the graph.

A Graphmol chemical is defined by a string of atoms over an alphabet (figure 1). This string is parsed into three types of nodes (binding sites, which can be *shown* or *hidden*; functions; and junk), and folded into a graph with three types of edge (program edges, fold edges, and bind edges). Distances through the graph are used in a stochastic binding process (distances are calculated using the number of atoms in each node).

Reactions are defined by the Graphmol programming language, which has two parts: a declarative part (binding process) and an imperative part (instruction pointers).

The declarative part defines how chemical graphs bind to each other, implemented by a simple aspatial physics engine. This continually changes the graph structure by adding bind edges between *shown* binding sites. The process is stochastic, and the chance of two binding sites binding (having a bind edge added) depends on: (1) how closely their binding site patterns match; and (2) their distance apart, through the graph (measured as the length of the shortest path between the two binding sites).

The function nodes in the graph are the imperative language instructions. Instruction pointers move through the graph, executing the function nodes. This changes the graph structure by *showing* and *hiding* binding sites. When binding sites are *shown*, new binds become possible; when binding sites are *hidden*, some binds become impossible.

Junk affects how programs run in two ways: (1) it acts as a no-op for instruction pointers moving through the graph, slowing down execution of programs with respect to the timescale of the binding process; (2) it affects the graph distance between nodes, used to calculate binding probabilities.

**Parsing and Folding** There are two steps in converting a string of atoms into a chemical graph. These are (1) parsing atoms into nodes and (2) folding: connecting function nodes to their binding site nodes (figure 2).

A sequence of non-functional atoms enclosed in brackets [nnnnn] (with no internal brackets) defines a *binding site*. So the string [hdfgdd[icsd]bdgd[dhdhd]ixr]ss defines two binding sites, *icsd* and *dhdhd*. The string of

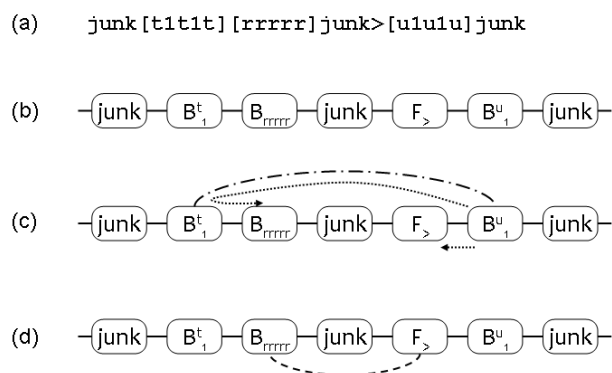

Figure 2: Parsing and folding: (a) a string of atoms; (b) the parsed graph of nodes connected by program arcs (solid edges); (c) temporary edge between *u1u1u* binding node and *t1t1t* binding node (dash-dotted edge), used to find closest functional node and binding site (dotted arrows); (d) resulting fold edge between the function node and its binding site (dashed edge).

atoms is parsed into a linear graph (figure 2 (b)) of binding site nodes, function nodes, and junk (everything else).

When executed, each < or > function *shows* or *hides* a particular binding site. The folding process connects these functions to the sites they affect. A temporary graph edge is added between a binding site node of the form *uxuxu* and its matching *txtxt* binding site node (where *x* is any non-functional atom). The closest *show* or *hide* function node, and closest the binding site node (measured along edges including the temporary edge), to the *uxuxu* node, are joined by a fold edge, and the temporary edge is removed. The result is the folded chemical graph (figure 2 (d)).

The fold edge is a form of indirect addressing. Instead of the function node specifying explicitly which binding site it *shows* (or *hides*), it instead specifies a template: *uxuxu*. During folding, this template is ‘dereferenced’ to locate the binding site: the closest binding site to the matching *txtxt*. Indirect addressing makes the system more evolvable, because the templates can change independently of the pattern of the target binding site.

**Chemicals** Once strings have been parsed and folded into chemical graphs, the graphs can start to react. The physics engine starts binding matching sites (here, we use exact string matching, so two binding sites either match or they do not; binding is a crisp process). When more than two sites match, the choice of which to bind is made stochastically, based on the graph distances between the sites.

When two binding sites bind, a bind edge is created between them, and an instruction pointer is created at each binding site. These instruction pointers move along their respective chemicals, executing any functions they reach.

As Graphmol runs, the graph states change because of two

processes: (1) instruction pointers move along the chemicals, executing functions that `show` and `hide` binding sites; (2) the physics engine makes binds happen between binding sites that match and are close together, which creates new instruction pointers.

**Reactions** There are two different concepts of ‘reaction’ in Graphmol: (1) a micro-scale interaction between two binding sites; (2) a macro-scale interaction between two chemicals, either designed into the chemicals, or an emergent property of the system.

(1) In the micro-scale case, a ‘reaction’ is the same as a bind between two binding sites. If two binding sites have patterns that match, then they have a probability of binding that depends on their distance apart through the graph. If the two binding sites are on different chemicals (that are not bound), then their distance apart is not defined, and they have a (pre-specified) low probability of binding.

When a bind happens, a bind edge is created between the two binding site nodes. This changes the topology of the chemical graphs, changing the probabilities of other binds happening. This new edge remains in place until one of its binding site nodes is `hidden`, at which point the edge is removed. When the bind happens, two instruction pointers are created, one at each binding site node. They move along their respective chemical’s program edges, executing any function nodes they encounter, until they reach either the end of the chemical, or a `stop`, (!), function, at which point the instruction pointer is removed.

The immediate result of this type of reaction is a graph topology change. The two chemicals are now connected together, and so the distances between binding sites have changed. A longer-term result of this reaction is that two computer programs are now running, represented by the two instruction pointers that are created. If another bind happens before these programs finish running, then further programs start executing in parallel.

This definition of ‘reaction’ views Graphmol as a simulation of nodes in a graph. Graphmol simulates these nodes by continually iterating the instruction pointers that exist (running the programs), and checking if any new binds happen (starting new programs). As the programs run, new binding sites become visible and so new binds can happen.

(2) In the macro-scale case, a ‘reaction’ is not defined explicitly as part of the Graphmol program: instead, it is a property of a running system. This can be an emergent property, produced by an evolutionary system. But in order to bootstrap evolutionary systems, we can design macro-scale reactions by hand-crafting Graphmol chemicals.

In traditional AChems, a reaction is a process whereby two chemicals are chosen to enter a black box, something happens, then one or more chemicals emerge from the box. Viewing Graphmol as a simulation of graph nodes does not fit this black box definition of a reaction. But we can use the

```
[start] junk
[lllll] ! junk [xxxxx] ! junk [rrrrr] ! junk
[lllll] ! junk [xxxxx] ! junk [rrrrr] ! junk
...
[lllll] ! junk [xxxxx] ! junk [rrrrr] ! junk
[lllll] ! junk [xxxxx] ! junk [rrrrr] ! junk
[stop]
```

Figure 3: The Graphmol DNA as a string of atoms (white-space added for readability only). The `xxxxx` binding sites are the bases that carry the information. The DNA chemical can be of arbitrary length.

simulation to implement *white* box reactions instead.

We can design two chemicals that have binding sites with matching patterns. We can set up the internal states of these chemicals so that only the two matching binding sites are `shown` (the rest being `hidden`). When we put these chemicals into the simulation, they will bind and start executing their programs. The execution of their programs might cause other binding sites to become `shown` and other binds to happen, but eventually all the programs will stop and no more binds will be possible. The individual programs cannot go into an infinite loop, since they execute along the program edges of a linear graph. The whole simulation could go into an infinite loop, but we assume not, for this argument.

We can think of this whole process as one ‘reaction’, and the system now looks like a traditional AChem, but with a complicated reaction mechanism. The chemicals that now exist in the simulation are the products of the ‘reaction’. Macro-reactions of this type are white boxes, because they are embodied in the simulation. This means that other chemicals can interfere with the process of the reaction.

## Embodied copying in Graphmol

Binding and program execution change the topology of chemical graphs. We use this to make one chemical graph move, relative to another. We make a long linear chemical graph composed of binding sites separated by regions of junk. This chemical contains no function atoms, so will not change its own topology. We make a second, smaller, chemical that ‘walks’ along the long chemical by alternately `showing` and `hiding` its six binding site ‘feet’. We add a special `crisp char-copy` instruction to the Graphmol language, specifically for the purpose of the experiments reported here.

The idea of a small chemical moving along a long, linear chemical is analogous to the way in which DNA is copied in biology. DNA is a long linear chemical. The chemical ‘DNA polymerase’ moves along the DNA and copies it. The actual process in biology is much more complicated than this, but making a simplified abstraction of the process allows us to implement an embodied copy operation in an AChem. Furthermore, many chemicals in biology move along DNA or RNA chemicals (not just to copy them). For example: (see

```

[t1t1t] [yyyyy] junk >[u4u4u] junk <[u2u2u] !
[t2t2t] [magic] junk >[u5u5u] junk <[u3u3u] !
[t3t3t] [eeeeee] junk >[u6u6u] junk <[u4u4u] !
[t4t4t] [yyyyy] junk >[u1u1u] junk <[u5u5u] !
[t5t5t] [magic] junk >[u2u2u] junk <[u6u6u] !
[t6t6t] [eeeeee] junk >[u3u3u] junk <[u1u1u] !

[tstst] [fgneg] junk <[u1u1u] junk >[ususu] !

[tetet] [fgbc] junk junk junk junk
junk >[u1u1u] junk >[u2u2u] junk >[u3u3u]
junk >[u4u4u] junk >[u5u5u] junk >[u6u6u]
junk <[ususu] junk >[ueueu] !

```

Figure 4: The Graphmol walker as a string of atoms. There are six feet (t1t1t–t6t6t), a ‘start’ site (tstst) and a ‘stop’ site (tetet). The length of the junk sections is varied in the experiment (see later).

any biology textbook for details, for example [1]) helicases (that unwind the two strands of DNA), ligases (that glue together sections of DNA) and ribosomes (that transcribe RNA into protein).

So, if we are interested in simulating analogies of biology, then movement of one chemical along another is a useful type of process to have in general.

**Graphmol DNA** We design a Graphmol chemical analogous to biological DNA. DNA stores information as a sequence of DNA bases attached to a common “backbone” structure.

Graphmol DNA has a sequence of ‘base’ nodes containing different information, interspersed with backbone nodes (figure 3). A ‘base’ node is a binding site, whose pattern is five information-carrying atoms (shown generically as xxxxx). Two backbone nodes [l1l1l1] and [r1r1r1] give the DNA a direction. (The stop atoms, !, are for efficiency, to remove the instruction pointer that is created on the DNA when a bind occurs.)

The junk regions add distance between the binding sites, which controls the probability of binding to different sites. In the implementation reported here, the DNA’s junk regions are each 40 atoms long.

The DNA chemical also has a start and a stop binding site. These allow the walker chemical to begin copying from the start of the DNA and to unbind when it reaches the end. This allows us to program the copy operation as a ‘macro-scale reaction’, as described above.

**Graphmol Walker** The walker chemical is shown in figure 4 as a sequence of atoms; its walking behaviour is shown schematically in figure 5. The walker chemical moves along the DNA chemical using six ‘feet’ (binding sites) alternating their visibility in a cycle. Feet 1 and 4 bind to [l1l1l1] on the DNA, feet 2 and 5 to [xxxxx], and feet 3 and 6 to [r1r1r1]. In this paper, binds happen if sites match exactly, where alphabet atoms match their complements (rotated 13 characters through the alphabet), and digits do not match.

Figure 5: The walking process. Feet 1–3 are shown and bound (triangles), foot 4 is shown and unbound (dark circle), feet 5 and 6 are hidden (white circles). **bind**: The physics engine binds foot 4 (which is now shown with a triangle). **show/hide**: The bind starts a program running, which hides foot 1 (which therefore unbinds), and shows foot 5 (which is unbound). The cyclic process is ready to start anew.

Figure 6: Low probability mis-stepping: (a) stepping over a site; (b) stepping backwards.

For the purposes of this paper, the Graphmol language is extended with magic binding sites that match and bind to any of the DNA’s [xxxxx] information-carrying binding sites. It performs a crisp copy of the bound node (a crisp char-copy function, from algorithm 1).

The walker has a ‘start’ [fgneg] region and a ‘stop’ [fgbc] region. The start region sets up the walker’s feet ready to begin moving along the DNA. The end region unbinds the walker from the DNA and sets the walker up ready to start another copy. This is a crisp start and at-end function, from algorithm 1.

Each foot has a short program associated with it. These programs show and hide the walker’s six feet in a cyclic pattern, making it walk along the DNA (figure 5).

Each of the walker’s feet has a pattern that matches multiple binding sites on the DNA. Because the probability of binding depends stochastically on graph distance, the walker’s feet will always be more likely to bind to sites on the DNA that are close to where the walker is currently bound. As three of the walker’s feet are always bound at the same time, the next matching binding site along the DNA will always be closer to the walker’s shown foot than earlier or later DNA sites. The walker usually steps to the correct next binding site, but can sometimes (with a low probability controlled by the amount of junk) jump forwards or step backwards (figure 6). Thus the walker implements an embodied next function (from algorithm 1).

Because the walker is copying the chemical it walks over. These jumps forwards and backwards correspond to insertions and deletions in the copied chemical.

Through the same binding process, the walker can also occasionally get its feet tangled, and fall off, resulting in a truncated copy. So the walker also implements an embodied `at-end` function. It has two `at-end` functions: a crisp one ('stop' region) and an embodied one (fall off early).

## Experiment

The Graphmol walker chemical, described in the previous section, can copy a DNA chemical, making insertion, deletion and truncation errors. But the way in which it makes these errors is not a collection of arbitrary choices written into an equation or a piece of stochastic code. It is a collection of arbitrary choices written into a machine (chemical) implemented in a lower-level stochastic programming language (Graphmol). If this machine/language combination is evolvable, then these arbitrary choices can be changed by evolution, and adapted to the problem being solved.

This paper is a feasibility study, testing that the embodied copying process implemented by the walker is evolvable. We show that, due to the design of the walker and of Graphmol, there is evolutionary pressure for the walker to evolve. It can trade off its accuracy against its speed of copying, by altering its level of junk. With more junk, the walker copies more accurately but also more slowly. With less junk, the walker copies less accurately but also more quickly.

### Experiment design

We want to test the hypothesis that changing the walker's junk level changes its speed and accuracy of copying.

To test this hypothesis, we run multiple simulations of the walker copying the DNA chemical. The length of the DNA chemical (number of bases) is the same as the length of the walker (number of atoms). This simulates the fact that if the walker was evolving, then changing its junk level would change the length of its encoding on the DNA.

We set up the DNA chemical by showing all of its binding sites. We set up the walker chemical by hiding all of its binding sites except the 'start' site [`fgneg`]. We then bind the walker's 'start' site to the DNA's 'start' site and simulate the (macro-scale) reaction until the walker unbinds from the DNA, thus finishing its copy. When the walker unbinds from the DNA, we compare its copy to the original DNA. The pattern of bases on the original DNA is randomly generated each time.

We repeat this copying process for walker chemicals containing different levels of junk. The junk regions in the walker chemical (see figure 4) are varied in length from one atom to 20 atoms. In this experiment, all of the junk regions within the walker are the same length as each other, for simplicity. If the walker was evolving, it would not need to enforce this. Indeed, unless there was evolutionary pressure

for it, evolution would probably not maintain 26 different regions at the same length. So this experiment shows a coarse view of the evolutionary options the walker has. In reality, the walker has a much finer level of control over its junk regions than this experiment shows.

For each different level of junk, we measure the time taken for the walker to make a copy (figure 7(a)) and the accuracy of its copying (figure 7(b)). Since the walker can make insertions, deletions and truncations of the DNA it is copying, there are many ways to define accuracy. We use the following. We care about the walker copying the DNA almost perfectly: we want perfect copies most of the time, but occasionally we want small mutations for evolution to exploit. So we define an 'almost perfect copy' as a copy that differs from the original by at most three bases, i.e. any combination of three insertions or deletions. To determine if a copy is almost perfect, we use Smith-Waterman alignment [5]. The Smith-Waterman algorithm measures the length of the longest common subsequence between two strings, taking into account (and penalising) short insertions and deletions. We set the penalty for an insertion or deletion to be 1, to measure the number of errors in the copy (subtracting the length of the original DNA, and taking the absolute value). If the number of errors is three or less, the copy is 'almost perfect'. Values other than three give qualitatively similar results, but larger values are more noisy so more experiments would need to be run to obtain the same error bars.

We run 80 copies per junk level, counting the number of nearly perfect copies to measure accuracy. We then repeat this process 20 times, to determine the error in these measurements (shown as notched boxplots in figure 7).

## Results

As the junk level increases, the walker takes longer to copy its DNA (figure 7(a)). This is for two reasons: (1) more junk makes the graph distance between binding sites longer, so the probability of the walker binding (and hence taking a step) is reduced; (2) more junk means the walker's encoding on the DNA is longer, so takes more steps to copy.

As the junk level increases, the walker becomes more accurate at copying its DNA (figure 7(b)). This is in spite of there being more DNA to copy at higher junk levels. As junk increases, the probability of binding is reduced in such a way that the probability of an erroneous bind (either jumping forwards or stepping backwards, figure 6) is reduced more than the probability of it making a correct bind (the probability is a non-linear function of distance,  $p(d) = (20/d)^{77}$ , chosen to give good behaviours over a range of chemical sizes). This makes the walker more accurate with more junk.

A walker with a low junk level is fast but error-prone; a walker with a high junk level is slow but reliable. So, the walker can trade off accuracy against speed. We can see this tradeoff by graphing the rate of copying for each junk level (figure 7(c)). This is the number of nearly perfect copies

made, divided by the time taken to make them. The graph is noisy at low junk levels because few nearly perfect copies are made here (as can be seen from the accuracy graph, figure 7(b)). The tradeoff can be seen in this graph as a peak at a moderate amount of junk. Too much junk and the walker copies too slowly, making its *rate* of accurate copying low. Too little junk and the walker makes too many errors, making its rate of *accurate* copying low.

## Discussion

When the walker is put into a simulation where it can evolve, it will be able to control its own junk level through mutations that add or remove junk. These results show that changing the walker's junk level changes its speed/accuracy tradeoff for copying. Thus the walker will be able to find, for itself, the tradeoff between speed and accuracy that optimises its survivability in its environment.

Because it finds this tradeoff for itself, it will be able to re-optimize if its environment changes. We have taken a quantity that is normally a parameter in ALife simulations, the mutation rate, and embodied the process that requires this parameter. This means that the ALife organisms can change this parameter, by manipulating the underlying processes that give rise to the parameter. The mutation rate has changed from being an external parameter, to an observed property of the system.

## Future work

This experiment has demonstrated that it is possible to build an AChem with an embodied copying process that can be exploited by the system to adapt its mutation rate. But because the whole *process* of mutation is embodied (not just the rate), the system should be able to change the copying process, generating novel *types* of mutation. When we run the embodied copying process in a evolutionary system, we will be looking for such changes.

To make systems that can change their mutation process in different ways, different parts of the copying process can be embodied:

## Copying a character

The walker chemical takes the process ‘iterate over a string’ and implements this as an embodied process in Graphmol. Here we have used a crisp `char-copy` function to copy each character of the string (so the only copying errors are insertions and deletions). The `char-copy` function could instead be made stochastic, to explore the effect of point mutations on the walker. More interestingly, the `char-copy` process could be embodied, by implementing a `char-copy` mechanism in Graphmol. Just as we broke the string copy process into components (algorithm 1), we can break the character copy process into components to be embodied (algorithm 2):

(a) Copying time increases with junk level (so speed decreases).

(b) Accuracy of copying increases with junk level.

(c) Rate of copying has an optimum junk level, trading off speed against accuracy.

Figure 7: How the walker's junk length affects its copying. A “nearly perfect copy” is a copy that differs from the original by at most three bases (three insertions or deletions). The notches show the 95% confidence intervals.

---

**Algorithm 2** Deconstructing the character copy operation, as a prerequisite to embodying it

---

**result** char\_A := char\_B

```
x := read(char_B)
y := repn(x)
char_A := write(y)
```

---

1. **Read the character** `read` This could be implemented as a set of binding sites with patterns that match each of the DNA bases. When one of these sites binds to a DNA base, a program on the walker changes the walker's state.
2. **Represent the character** `repn` The walker needs to know which site has been bound, so needs a change of state to signify this. For example, it could show a binding site corresponding to the base that it is currently copying.
3. **Write the character** `write` The walker needs to maintain a chemical representing the copy it is making of the DNA chemical. The binding site it shows in the step above, could bind to a free-floating chemical base, at which point the walker would attach this base to the copy.

After attaching the copied character to the result string, the walker needs to move on to the next character on the string being copied. The walker already does this to walk along a DNA chemical, but it will also need to do this with the copy it is producing.

### Making binding evolvable

In this paper, binding requires an exact (complementary) match between binding sites. We need to allow 'soft' binding, so that evolution can modulate binding affinities to give complex behaviours [3]. This will make the `start` and `at-end` functions embodied (and `char-copy`, if used with the previous section).

In this paper, the folding sites `[uxuxu]` and `[txtxt]` (figure 2a) were chosen arbitrarily. In future, the folding process will be implemented by a folding chemical, with binding sites matching `[uxuxu]` and `[txtxt]`. This makes the folding process embodied, rather than hardcoding folding in the definition of Graphmol. Thus evolution will be able to exploit the folding process and potentially change it.

### Conclusions

We have discussed how ALife simulations can be made more evolvable by making their copying process embodied rather than stochastic. An existing example of where an embodied copying operation has led to interesting behaviour is the Stringmol AChem [3].

We have embodied copying in a new way, by making an embodied `next` function (increment operation). This involved designing the Graphmol AChem and implementing

an embodied `next` function in Graphmol. We attached a crisp `char-copy` function to this embodied `next` function, creating an embodied string copy operation. This embodied string copy operation can make insertion and deletion mutations on the copied string.

We have run a feasibility experiment (figure 7) to show that the embodied copy operation is evolvable, and has the potential to adapt its own mutation rate to its environment. But more experiments are needed to find the environments in which it will show this. The copying process adapts by changing the level of junk in its embodiment, which changes its probability of incrementing correctly versus incrementing erroneously. In this way, the embodied copy operation can adapt its own mutation rate without there being an explicit mutation rate parameter in the system.

This is the crucial difference between embodied systems and stochastic systems. Stochastic systems are crisp systems with parametrised variation added in. Embodied systems are evolvable machines that can evolve their own parameters and processes, because they are implemented in a lower-level language.

### Acknowledgements

## Abstract

Artificial evolution of robot behavior is commonly conducted in environments containing a single robot or multiple robots that are all controlled by evolving behavioral logic. In this paper, we take a novel approach and study how the presence of preprogrammed robots affects the evolutionary process and the solutions evolved. We evolve behavioral control that enables robots to forage. The robots are situated in an environment that contains a nest and a number of prey. The robots must either push or carry the prey to the nest. We analyze the behaviors evolved in mixed setups in which one or more preprogrammed robots are present. We compare these behaviors to behaviors evolved in non-mixed setup in which no preprogrammed robots are present. The results show that although the evolved robots do not use their capacity to communicate, they do collaborate with the preprogrammed robots. We find that the performance of some of the solutions evolved in the mixed setup is higher than the performance of homogeneous groups of robots.

## Introduction

In this paper, we take a novel approach to the evolution of behavioral control for robots. We report on experiments in which we evolve behaviors for robots that share the environment with preprogrammed robots. The preprogrammed robots are (aside from their behavior) indistinguishable from the evolving robots. Mixing evolving robots with preprogrammed robots is interesting for several reasons: from an engineering perspective, artificial evolution may be used to fill in the gaps between partially known (easily preprogrammable) solutions to complex tasks and/or to optimize the performance of a robot collective. From an evolutionary perspective, it is interesting to evaluate how the presence of robots programmed with a solution influences the evolutionary process and the solutions evolved – such as determining whether the evolving robots adopt the preprogrammed solution and/or whether they learn to communicate with the preprogrammed robots.

We use a multirobot foraging task for our experiments. A robot can push prey or it can pick up and carry a prey. If a prey-carrying robot collides with another robot, it loses

the prey. Thus, the robots must avoid collisions when carrying prey. The preprogrammed robots have the same sensory and actuation capabilities as the evolving robots. Each robot can control the color of its body. Whenever carrying prey, a preprogrammed robot sets its body color to red. When not carrying a prey, a preprogrammed robot sets its body color to green. Thus, nearby robots can see when a preprogrammed robot is carrying a prey or not and give way in order to avoid collisions. Since evolving robots have control over their body color too, they have the potential to communicate to nearby teammates in the same way as the preprogrammed robots do.

In this study, we analyze and discuss the fitness trajectories and the solutions obtained in evolutionary runs where one preprogrammed robot and two evolving robots are present. We discuss if and how the robots collaborate and communicate. We setup an experiment in which we take an incremental approach to evolution in order to increase the rate of solutions with a high average fitness. Finally, we report on experiments in which three preprogrammed robots and six evolving robots are present during evolution.

The contribution of this paper is three-fold: i) We demonstrate that evolving robots can learn to collaborate with preprogrammed robots. ii) We demonstrate how a basic incremental approach to evolution can increase the rate at which collaborative solutions are evolved when preprogrammed robots are present. iii) We show that heterogeneous groups of preprogrammed robots and evolved robots can achieve a better performance than homogeneous groups of preprogrammed robots.

## Related work

Interest in evolutionary robotics started in the early 90s (Cliff et al., 1993; Nolfi and Floreano, 2000). Initially, focus was on evolving a controller for a single robot to perform relatively simple tasks such as obstacle avoidance, exploration, and navigation (see for instance Nolfi et al. (1994)). Recently, there have been several studies on the evolution of controllers for multirobot systems—particularly those systems in which control is decentralized

and in which individual robots have limited sensory capabilities. In swarm robotics research (Şahin, 2005), it has been demonstrated how the application of evolutionary robotics can overcome the fundamental design problem of deriving microscopic rules for the individuals such that the desired macroscopic behavior emerges. When artificial evolution is applied to swarms of robots, the designer can specify a fitness function that scores the collective behavior and let evolution search the space of individual behaviors. Using this approach, Dorigo et al. (2004) demonstrated how a group of homogeneous robots could be evolved to aggregate and to display coordinated-motion when physically connected to each other. In another study, Trianni et al. (2006) demonstrated how a group of evolved homogeneous robots could cooperatively avoid holes.

Evolutionary robotics has been applied to heterogeneous multirobot systems: Tuci et al. (2008) evolved homogeneous controllers for heterogeneous robots. Nolfi and Floreano (1998) co-evolved a predator agent and a prey agent. The fitnesses of the two types of agents were co-dependent although each had a different genome.

It has also been demonstrated that heterogeneity can arise in a homogeneous system (identical agents with identical neuro-controllers). Quinn et al. (2003) evolved controllers for a team of three robots with minimal sensory capabilities. The robots' task was to aggregate and then travel a distance of one meter as a group. Interestingly, the team members dynamically adopted roles and moved in a line formation. The robot that would adopt the role as the leader, moved backward in order to perceive the middle robot. The middle and rear robot, on the other hand, moved forward. Ampatzis et al. (2009) evolved homogeneous controllers for two real robots that allowed them to *self-assemble*, that is, physically connect to one another. However, the robots first had to allocate roles so that one would be the gripping robot, while the other would be the gripped robot. The roles were allocated during what can be described as a dance: the robots would circle each other while performing oscillatory movements until one would approach the other to perform the grip.

In this study, we use a novel evolutionary setup. We explore the effect of the presence of preprogrammed robots on the evolved behaviors. We find that the heterogeneity in the group composition leads to role allocation and collaboration.

## Robot Model and The Task

Below, we start by presenting the robot model that we use. We go on to describe the foraging task and the environment. Finally, we briefly discuss the software simulator in which we conduct our experiments.

### The Robot Model

We use a differential drive, cylindrical robot model. Each robot has a diameter of 10 cm. The set of actuators is composed of two wheels, a prey carry mechanism and a change-

able body color. The two wheels can be controlled independently allowing a robot to move and to turn. Gaussian noise with standard deviation of 5% is added independently to the left wheel speed and to the right wheel speed set by the robot controller in order to simulate issues such as slippage, slightly uneven ground and so forth. The prey carry mechanism enables a robot to pick up a prey within a distance of 5 cm. The body color actuator has three possible settings: green, red, and black. Whenever green or red, a robot can be detected by other nearby robots, while when black, the robot is invisible to other robots.

The robots are equipped with several sensors that allow them to perceive i) whether they are currently carrying a prey or not (prey-carried sensor), ii) whether they are inside the nest or not (in-nest sensor), and iii) the presence of nearby objects: eight nest sensors, eight prey sensors, eight red robot sensors, and eight green robot sensors.

Aside from the prey-carried sensor and the in-nest sensor, all the sensors operate in a similar way, but register different types of objects. The nest sensors only register the nest. The prey sensors only register prey. The green robot sensors only register green robots. The red robot sensors only register red robots. The sensors are distributed evenly around the robot's body.

A sensor only registers objects within a certain distance and angle with respect to its orientation. All sensors have an opening angle of  $135^\circ$  and a range of 1 meter, except for the nest sensors which have a range of 10 meters. If there are no sources within sensor's range and opening angle, its reading is 0. Otherwise, the reading is based on distance to the closest source ( $c$ ) according to the following equation:

$$s = \frac{\text{range} - d_c}{\text{range}}, \quad (1)$$

where  $\text{range}$  is the sensor's detection range and  $d_c$  is the distance between the closest source  $c$  and the sensor.

### The Foraging Task

Our experiments are conducted in the arena shown in Figure 1. The robots must search for prey and transport them to the circular nest area with a diameter of 0.50 m centered in the arena. The nest can be perceived by the robots using their nest sensors. The prey are scattered in the foraging area around the nest. The foraging area is circular and has a diameter of 4 meters. Whenever a prey is dropped in the nest, it is immediately redeployed to a random location in the foraging area. 13 prey are present in the environment which results in a prey density of 1 prey/m<sup>2</sup>. When a prey-carrying robot collides with another robot, it loses the prey that it was carrying. The lost prey is randomly redeployed in the environment in order to keep the prey density constant.

Figure 1: Foraging arena.

## Simulation Environment

We have implemented the robot model and constructed the environment discussed above in JBotEvolver (see <http://sourceforge.net/projects/jbotevolver>). We have implemented our own neuro-evolution framework that allows for distributed, fault tolerant fitness evaluation.

## Controller Architecture

Below, we present the control logic for the preprogrammed robot and the artificial neural network used for the evolving robots.

### Preprogrammed Robots

A finite state machine representation of the control program for the preprogrammed robots is shown in Figure 2. A preprogrammed robot starts of in the “Search” state in which it locates and moves towards the nearest prey. If the preprogrammed robot detects the presence of a red robot in its way, it assumes that the red robot is carrying a prey and therefore turns around (180°) and moves out of the way (state “Make way”). When a prey is encountered, the preprogrammed robot attempts to pick it up (state “Pick up”). If the prey is picked up successfully, the preprogrammed robot becomes red and starts moving towards the nest (state “Transport”). When the nest is reached, the preprogrammed robot drops the prey (state “Drop”) and returns to the “Search” state. If the preprogrammed fails to pick up a prey or if it loses the prey (due to a collision), the preprogrammed robot returns to the “Search” state.

In the finite state machine in Figure 2, we have colored the states with the color that a preprogrammed robot has when in the respective states. Whenever a prey is carried, the preprogrammed robot is red. Otherwise, the preprogrammed

Figure 2: Preprogrammed controller.

robot is green. Preprogrammed robots are never black.

### The Evolving Robots

The evolving robots are controlled by a continuous time recurrent neural network (Beer and Gallagher, 1992). The network consists of three layers of neurons: an input layer with 34 neurons, a hidden layer with 5 neurons, and an output layer with 4 neurons. The input neurons  $I_i$  are reactive. The prey-inputs ( $I_1$  to  $I_8$ ), the nest-inputs ( $I_9$  to  $I_{16}$ ), the green-inputs ( $I_{17}$  to  $I_{24}$ ), and the red-inputs ( $I_{25}$  to  $I_{32}$ ) are all set based on sensor readings from the respective sensors. The prey-carried-input ( $I_{33}$ ) is 1 if a prey is currently carried and 0 otherwise. The in-nest-input ( $I_{34}$ ) is 1 if the robot is in the nest and 0 otherwise. The neurons in the hidden layer are fully connected and governed by the following equation:

$$\tau_i \frac{dH_i}{dt} = -H_i + \sum_{j=1}^{34} \omega_{ji} I_j + \sum_{k=1}^5 \omega_{ki} Z(H_k + \beta_k), \quad (2)$$

where  $\tau_i$  is the decay constant,  $H_i$  is the neuron's state,  $\omega_{ji}$  the strength of the synaptic connection from neuron  $j$  to neuron  $i$ ,  $\beta$  the bias terms, and  $Z(x) = (1 + e^{-x})^{-1}$  is the sigmoid function.  $\tau$ ,  $\beta$ , and  $\omega_{ji}$  are genetically controlled network parameters. The possible ranges of these parameters are:  $\tau \in [0.1, 32]$ ,  $\beta \in [-10, 10]$  and  $\omega_{ji} \in [-10, 10]$ . Cell potentials are set to 0 when the network is initialized and circuits are integrated using the forward Euler method with an integration step-size of 0.2.

The output layer is fully connected to the neurons in the hidden layer. The activation of the output neurons is given by the following equation:

$$O_i = \sum_{j=1}^4 \omega_{ji} Z(y_j + \beta_j); \quad (3)$$

The first two outputs  $O_1$  and  $O_2$  control the speed of the left and the right wheel, respectively. Their output is linearly mapped to speeds in the range  $[-50 \text{ cm/s}, 50 \text{ cm/s}]$ . The third output  $O_3$  is mapped to the prey carrying mechanism: if  $O_3 > 0.5$ , the robot attempts to pick up the closest prey or to hold a prey if one is already carried. If  $O_3 \leq 0.5$ , any prey

carried will be dropped. The fourth output  $O_4$ , controls the color of the robot. For values in the range  $[0, 0.33]$  the robot becomes invisible to other robots, for values in the range  $]0.33, 0.66[$ , the robot becomes green, and for values in the range  $[0.66, 1.00]$ , the robot becomes red.

## Evolutionary Algorithm

We use a simple generational evolutionary algorithm (Schwefel, 1995; Goldberg, 1989). Each generation consists of 100 genomes. Each genome consists of a vector of 228 real valued numbers. These values encode the weights of the synaptic connections between neurons, the bias terms and the decay constants for a neural network with the topology described in the previous section. After sampling the fitness of each genome in a generation, the 5 best genomes are retained and the rest are discarded. These 5 genomes are the parents of the subsequent generation. From each parent an equal number of children (19) are created and the parents are copied to the new generation. The genotype for a child is obtained adding a random Gaussian offset to each real-valued gene with a probability of 15%.

We compute the fitness at the group-level. Thus, in the experiments where a preprogrammed robot is present, its behavior and its performance contribute to the fitness of the group in the same way as the behavior of the evolving robots. The fitness function  $F(i)$  is given below:

$$F(i) = P_i + \sum_{s=1}^{\text{time-steps}} f_{i,s} \quad (4)$$

where  $i$  is the genome being evaluated,  $P_i$  is the number of prey foraged and  $f_{i,s}$  is computed at every time-step,  $s$ . The term  $f_{i,s}$  is computed in the following way:

$$f_{i,s} = 10^{-3}c_s + 10^{-4}d_s \quad (5)$$

where  $c_s$  is the number of robots carrying a prey at time-step  $s$  and  $d_s$  is a prey distance reward that depends on the distance between each prey and the nest at time-step  $s$ . The prey distance reward is computed using the formula:

$$d_s = \frac{1}{n^{\circ} \text{ prey}} \sum_{j=1}^{n^{\circ} \text{ prey}} \frac{1.75 \text{ m} - \text{dist}(p_j, \text{nest})}{1.75 \text{ m}}. \quad (6)$$

We sample the fitness of each genome five times and selection is based on the average fitness obtained.

## Results and Discussion

We initially experimented with two different evolutionary setups: a *mixed* setup in which two evolving robots and one preprogrammed robot were present, and a *non-mixed* setup in which three evolving robots were present. In each setup,

we performed 30 evolutionary runs with different initial random seeds for 2000 generations each. Each generation consisted of 100 genomes. The fitness of each genome was sampled in five trials of five minutes of virtual time (3000 control steps) each.

Below, we provide an overview of the results obtained. We then describe the different types of behaviors evolved in the *non-mixed* setup and the *mixed*, respectively. We go on to discuss cooperation and communication. We then experiment with incremental evolution in order to speed up evolutionary learning. Finally, we experiment with setups in which nine robots are present.

## Fitness Trajectories

The plot in Figure 3 summarizes the results of the evolutionary runs conducted in the *mixed* setup and in the *non-mixed* setup, respectively. The figure shows the average fitness of the best genome in each generation in all the 30 runs conducted in the *mixed* setup and in the *non-mixed* setup, respectively. We have included the fitness trajectory for the single highest scoring *mixed* run and for the single highest scoring *non-mixed* run. The horizontal line at  $y = 119.9$ , shows the average fitness obtained by three preprogrammed robots alone in the environment.

Figure 3: The fitness scores of the best and the average the best genomes in all the runs in the *mixed* setup and in the *non-mixed* setup. The horizontal line at  $y = 119.9$  indicates the average performance of a team of three preprogrammed robots.

The results in Figure 3 show that the fitness of the best genome in the *mixed* setup is on average higher than the best genomes in the *non-mixed* setup. The higher fitness in the beginning of an evolutionary run in the *mixed* setup is explained by the presence of the preprogrammed robot. The preprogrammed robot finds and transports prey to the nest from the onset of an evolutionary run whereas the evolving robots first have to learn to forage.

When a preprogrammed robot is alone in the environment, it obtains an average fitness of 60.0. When three preprogrammed robots are present in the environment, they interfere with one another. Furthermore, as a trial progresses, prey tend to be distributed further from the nest since more preprogrammed robots tend to forage the prey close to the nest faster. Interference and the increased prey distance both have negative impacts on the fitness score. Three preprogrammed robots therefore obtain a fitness (119.9) that is less than three times what a single preprogrammed robot obtains on average (60.0). In the beginning of an evolution run when the evolving robots are not yet foraging, the preprogrammed robot can often forage undisturbed in the *mixed* setup. The average fitness in the beginning of an evolutionary run in the *mixed* setup is therefore close to the fitness obtained by a single preprogrammed robot operating alone.

## Behavioral Analysis

In this section, we analyze the evolved robots' behaviors. A summary of the post evaluation scores for the 30 evolutionary runs conducted in the *non-mixed* setup and the 30 evolutionary runs conducted in the *mixed* setup can be seen in Figure 4. In the plot, we have grouped the evolutionary runs according to their foraging behaviors and fitness.

Figure 4: Summary of the post evaluation of the best behavior evolved in each evolutionary run in the *non-mixed* setup and in the *mixed* setup. We have divided the evolved solutions into groups A to E based on fitness and behavior.

In the *non-mixed* evolutionary runs, we observed behaviors that can be divided into three groups: A, B and C. All the solutions in all groups successfully forage prey, however, they forage in different ways. The behaviors group A all rely on pushing prey towards the nest. An example of the pushing behavior can be seen in Figure 5. The pushing behavior requires the robots to move in small circular patterns to constantly get behind the prey and the behavior is thus not very efficient.

The behaviors in group B rely on continually picking up and dropping prey. When a prey is picked up, it is often dropped after a single or a few control cycles, only to be picked up again immediately. One of the behaviors in group B is particularly interesting: often the robots transport two or

Figure 5: An example of a behavior in group A evolved in the *non-mixed* setup (two screenshots from the same experiment). The robots forage by pushing prey towards the nest. As can be seen on the figure, this behavior results in a lot of small circular movements and is thus not very effective.

more prey at a time by repeatedly picking up, dropping different prey. An example can be seen in Figure 6. Transporting multiple prey, however, comes at a cost: since a robot can only carry one prey at a time, it has to constantly make small circular movements to pick up the prey left behind. This means that the average fitness of the behavior in group B is lower than the average fitness of the behaviors in the last group of behaviors evolved in the *non-mixed* setup, group C.

In group C, the robots pickup prey and transport the prey back to the nest. The differences in fitness between the different solutions are due to a number of factors: how the robots search for prey, how efficient they are in moving to a prey once they have located the prey, and if and how much they interfere with one another. Some robots move away from the nest in a straight line to search for prey, some robots circle away from the nest, while in other cases, the robots move in more irregular patterns. Most of the robots move only forward or only backward, however, for some behaviors, the robots change direction once a prey is picked up. Changing direction is especially efficient for those robots that move directly from the nest to a prey: when a prey is picked up, they change direction (without having to turn around) to transport the prey back to the nest. Examples of some of the behaviors in group C can be seen in Figure 7.

We have divided the behaviors evolved in the *mixed* setup into two groups: D and E (see Figure 4). Group D contains the lowest scoring behaviors evolved in the *mixed* setup. The evolving robots in this group do not contribute to the foraging, but instead move away from the nest in order to let the preprogrammed robot forage undisturbed. In some cases, the evolving robots move beyond the foraging area, in some cases the evolved robots remain in the foraging area, and sometimes they even pickup prey.<sup>1</sup> However, in none of the cases do the evolved robots attempt to move prey closer to

<sup>1</sup>Carrying prey is rewarded in the fitness function (see the "Evolutionary Algorithm" section).

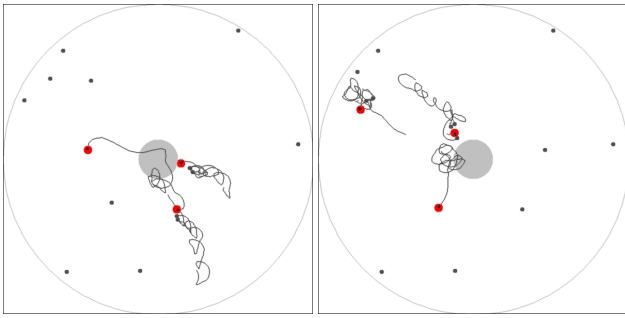

Figure 6: An example of the behavior in group B evolved in the *non-mixed* setup (two screenshots from the same experiment). By continually picking up and dropping prey, the robots are able to transport multiple prey towards the nest at the same time.

the nest.

The evolved solutions in group E all obtained an average post evaluation fitness of more than 70. In all of these solutions, the evolved robots actively forage. The difference in performance is due to the way in which the evolved robots search for prey: some of the evolved robots move directly towards prey close to the nest while others circle the foraging area and forage mainly prey located far away from the nest (thereby leaving the prey close to the nest for the preprogrammed robot to pickup). This type of behavior indicates that the evolved robots collaborate with the preprogrammed robot.

**Collaboration** To examine the level of collaboration (if any) between the evolving and preprogrammed robots, we analyzed if there is some evidence of division of labor: we recorded the number of prey foraged by evolved robots and the number of prey foraged by the preprogrammed robot in the *mixed* setup. We ran 100 trials with each of the highest scoring genomes from the 30 evolutions conducted in the *mixed* setup. For 16 of the 30 genomes, the preprogrammed robot forages significantly more prey when the evolved robots are present compared to when it is the only robot in the environment (Mann-Whitney,  $p < 0.05$ ).

When the preprogrammed robot is alone, it forages 57.9 prey on average during a five minute trial, while when three preprogrammed robots are present, each forages on average 38.7 prey. When evolved robots are present, the preprogrammed robot forages an average of 75.3 prey per trial for the best solution in the *mixed* setup. These results indicate that the evolved robots have learned to collaborate with the preprogrammed robot. For the best solution in the *mixed* setup, the average distance (over 100 five minute trials) of the preprogrammed robot from the center of the nest was 0.54 m, while the average distance of the each of the two evolved robots from the center of the nest was 1.06 m.

The evolving robots forage prey that are located far from the nest and leave the prey close to (but not always in) the nest. The preprogrammed robot (which prioritizes prey located close to the nest) then transports the prey left by the evolving robots the rest of the way to the nest. The division of labor is efficient because the evolved robots in general operate far from the nest, while the preprogrammed robot operates close to and in the nest – collisions are therefore avoided.

**Communication** The robots in both the *non-mixed* and the *mixed* setups have the capacity to change their body color and to detect the body color of nearby teammates. This capacity potentially allows the robots to communicate. However, in 22 out of 30 evolutionary runs in the *non-mixed* setup, the evolved robots remain mainly black (invisible to one another) during experimental trials. In the remaining 8 runs, the robots either remain mainly red (5) or constantly change color (3) during a trial.

In order to determine if communication plays a major role in the evolved solutions, we ran three sets of experiments in the *non-mixed* setup, where we fixed the body color of all the robots to black, red and green in 100 trials each. The differences in terms of performance when the body color is fixed and when the neural network has the control over the body color were minimal. The average performance difference was only 0.5%, with the largest drop being 3.7% and the largest increase in performance being 5.4%.

In a similar set of experiments in the *mixed* setup, we fixed the color of the preprogrammed robot and the two evolving robots. Fixing the body color to red results in an average performance drop of 22.6%. This drop is explained by the fact that the preprogrammed robot attempts to make way each time it encounters a red robot. The average difference in performance when the body color is fixed to either black or green and when the controllers have control over the body color was 0.6% with the largest difference being 3.2%. This indicates that the performance of the evolved robots does not depend on their capacity to change their body color.

It is surprising that the robots did not evolve to exploit their capacity to change color in the *mixed* setup to communicate with the preprogrammed robot (which already communicates its internal state by changing color depending on whether it is carrying a prey or not). A probable explanation for the lack of communication is that the robots can forage efficiently in the *mixed* setup without communicating. As discussed in the previous section, the evolved robots do in most cases learn to collaborate with preprogrammed robot by transporting prey located far from the nest closer to the nest for the preprogrammed transport the rest of the way to the nest. The robots operate in different regions of the environment and they do therefore not need to communicate in order coordinate their actions or to avoid collisions.

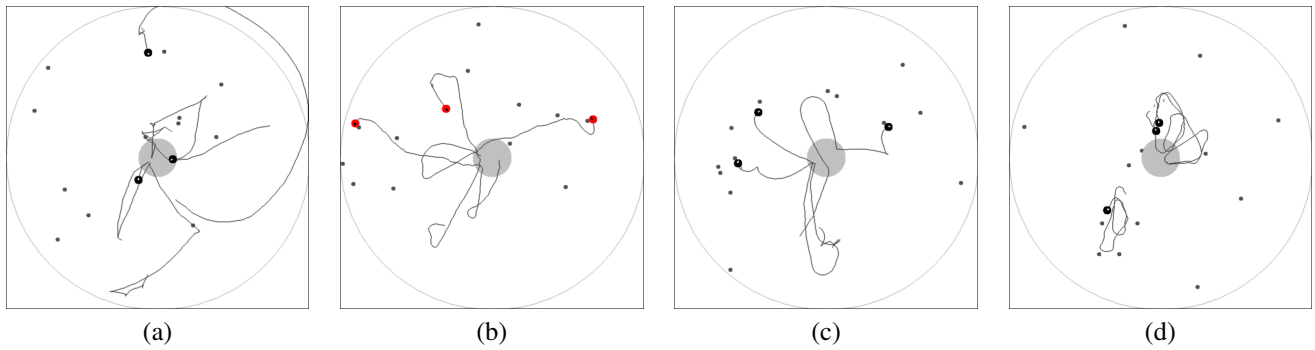

Figure 7: Examples of the behaviors from group C evolved in the *non-mixed* setup (screenshots from different experiments with different controllers). (a) the robots move directly to prey or start circling the foraging area in case no prey is found. (b) the robots have set their body color to red and turn around once a prey is picked up. (c) the robots move to prey in arcs. (d) robots pick up and carry prey, but they often interfere with one another.

**Incremental Evolution in the *mixed* setup** Of the 30 evolutionary runs conducted in the *mixed* setup, the 12 runs in group D did not evolve foraging behaviors, but instead, the evolved robots move away from the nest in order to avoid interfering with the preprogrammed robot. This solution is a local maximum in the fitness landscape because the preprogrammed robot is an efficient forager from the onset of the evolutionary process and any interference – a lost prey due to a collision for instance – would result in a lower collective fitness. We set up a series of experiment in which we tried to increase evolutionary pressure towards solutions in which the evolving robots participate in the foraging by initially reducing the speed of the preprogrammed robot. When the preprogrammed robot moves at a reduced speed, it forages less than when moving at full speed. Evolutionary pressure towards solutions in which the evolving robots actively forage is thus increased because any contribution made by the evolving robots proportionally is higher with respect to the fitness obtained by the team than when the preprogrammed robot is moving at full speed. In a new *incremental mixed* setup the preprogrammed robot initially moved at 50% of the full speed. Once a collective fitness of 50 was reached by the highest scoring individual in a generation, the speed of the preprogrammed robot was increased to full speed.

We performed 30 evolutionary runs in the *incremental mixed* setup. Out of the 30 evolutionary runs, only 6 produced non-foraging behaviors compared to 12 in the normal (non-incremental) *mixed* setup. The average of the post evaluation fitness of the best genome from each run in the *incremental mixed* was 90.0 compared to 84.7 in the *mixed* setup. For 24 of the 30 genomes, the preprogrammed robot forages significantly more prey when the evolved robots are present compared to when it is the only robot in the environment (Mann-Whitney,  $p < 0.05$ ). Hence, in the *incremental mixed* setup, the evolving robots learn more frequently to collaborate with the preprogrammed robot than in the non-

incremental *mixed* setup. Visual inspection of the successful solutions evolved in the *incremental mixed* setup confirmed that they are similar to the successful solutions evolved in the non-incremental *mixed* setup (that is, the behaviors in group E in Figure 4).

**Performance in larger *mixed* groups** In order to determine if and how the mixture of preprogrammed and evolved could benefit larger groups of robots, we conducted experiments in which nine robots were present in the environment: three preprogrammed robots and six evolving robots. We conducted the evolution in the same environment and with the same fitness function as used above. We used an incremental setup with four increments:

- 1st increment:* Only the six evolving robots were present [Fitness limit: 20].
- 2nd increment:* The three preprogrammed robots were introduced but moving at 25% of full speed [Fitness limit: 100].
- 3rd increment:* The speed of the three preprogrammed robots was increased to 50% of full speed [Fitness limit: 200].
- 4th increment:* The speed of the three preprogrammed robots was increased to full speed.

We conducted 30 evolutionary runs till the 2000th generation. The average fitness obtained in a post evaluation (100 samples) of the best chromosome from each run was 358. The average fitness score obtained in 100 samples with a homogeneous group of nine preprogrammed robots was 363. The average post evaluation fitness obtained by the larger mixed groups was thus slightly lower than the fitness obtained by nine preprogrammed robots. However, 12 out of the 30 evolutionary runs produced solutions for mixed groups that obtained a higher post evaluation fitness than nine preprogrammed robots (Mann-Whitney,  $p < 0.02$ ).

The average post evaluation fitness of the best mixed group was 403, thus well above the score obtained by a homogeneous group of nine preprogrammed robots.

We also observed collaborated between the six evolved robots and the three preprogrammed robots just like in our previous experiments. For the best solution evolved, the average distance from the center of the nest to each of the preprogrammed robots was 0.58 m, whereas the average distance to each of the evolved robots was 1.23 m.

## Conclusions

In this paper, we evaluated how the presence of preprogrammed robots affects the evolutionary process and the behaviors evolved in a multirobot foraging task. We conducted evolutions in which a preprogrammed robot was present and evolutions in which it was absent. Without the preprogrammed robot, three different kinds of foraging behaviors were evolved: one in which robots push prey to the nest, one in which robots continually pickup and drop prey, and one (much more efficient) in which robots pickup and carry prey to the nest.

In the setup in which the preprogrammed robot was present, we only observed the pickup and carry behavior. To increase the rate at which foraging solutions are evolved, we conducted a series of incremental evolution experiments in which the preprogrammed robot initially moved at a lower speed and only after the evolved robots had learned to forage did the preprogrammed robot start to move at normal speed. We applied a similar incremental approach for a mixed group of nine robots. We found that when preprogrammed robots were present, the highest performing evolving robots had learned to collaborate with them: the evolving robots targeted prey far from the nest and dropped them close to the nest for the preprogrammed robots to pickup and deploy in the nest. As a result, the robots occupied different regions of the environment and avoided collisions.

The results demonstrate that robots can be evolved to collaborate with preprogrammed robots. The evolving robots did not adopt neither the preprogrammed solution nor the preprogrammed communication protocol, but instead assumed different roles and collaborated with the preprogrammed robots.

In this study, the preprogrammed robots had a complete solution: they were able to forage on their own. In ongoing work, we are evolving robots to fill in the behavioral gaps between robots preprogrammed with different partial solutions to complex tasks.

## Abstract

In the natural world, performing a given task which is beneficial to an entire group often requires the cooperation of several individuals of that group who often share the workload required to perform the task. The modeling toolkit to address problems related with the dynamics of collective action and other conflict of interests is game theory, often combined with its dynamical counterpart, Evolutionary Game Theory [1]. In this context, the last decades have witnessed the discovery of key insights into the emergence and sustainability of cooperation at different levels of organization. Special attention has been paid to two-person dilemmas such as the Prisoner's Dilemma (PD), the Snowdrift Game (SG) and the Stag-Hunt game (SH), which constitute powerful metaphors to describe conflicting situations often encountered in the natural and social sciences.

Yet, unlike two-person games, current models of collective action have typically overlooked the necessity of some form of coordination among individuals, pervasive in biological and social collective dilemmas [2]. From social organization to the salvation of the planet against environmental hazards [3, 4], examples abound where a minimum number of individuals, which does not necessarily equal the entire group, must simultaneously cooperate before any outcome (or public good) is produced. With this abstract we intend to discuss the predictions of evolutionary game theory for the emergence of collective action, whenever a minimum threshold of individuals must cooperate simultaneously in a group before any viable public good is achieved. These conclusions were previously reported in Refs [2, 3, 5, 6].

We have concentrated on two of the most important collective dilemmas: the N-person snowdrift game (NSG) [5] and N-person prisoner's dilemma (NPD) [2]. In doing so, we uncover a new framework in which the advantage or not of cooperators depends sensitively on group and population size, as well as on the threshold for collective action. Such interplay leads to rich evolutionary scenarios of simultaneous co-existence and bi-stability, impossible to anticipate based on the traditional assumption of infinite populations, providing valuable insights into the variety and complexity of many person social dilemmas, inescapable especially among Humans.

In addition, it is noteworthy that irrespective of the distinctive features of the N-person Prisoner's dilemma (a defector's dominance dilemma) and the N-person Snowdrift game (a

coexistence game) [5], the existence of a coordination threshold is able to produce a unifying framework associated with a generalized stag-hunt game [2]. Moreover, the necessity of coordination is shown to increase the equilibrium fraction of cooperators, even if this enhancement comes together with a strong dependence on the initial level of cooperation, since coexistence between cooperators and defectors only emerges when a minimum number of cooperators is already present in the population. This result is of particular relevance given that the existence of coordination thresholds constitutes a rule, rather than the exception. In addition, we shall also discuss how the chances of collective cooperation are strongly dependent on the perception that individuals have of the collective risk of failure [3]. In this context, we are able to show how global cooperation is better achieved within *i*) small groups, addressing *ii*) highly risky situations characterized by *iii*) stringent condition to meet goals [3]. This result has strong implications on our current understanding of various collective problems, from collective hunting, voluntary adoption of public health measures and other prospective choices, to the mitigation of the effects of global warming. Overall, our results reinforce the idea that even minor differences in the nature of collective rewards and/or costs can have a profound effect in the final outcome of evolution.

## Abstract

In biological systems, whole genome duplication and subsequent diversification constitute powerful mechanisms for the discovery of new phenotypes and for the protection of these phenotypes against environmental perturbation. Here, we use Random Boolean Networks to investigate the influence of these genetic mechanisms on the relationship between evolutionary innovation and environmental robustness in gene regulatory networks. We find that whole genome duplication is highly deleterious in ancestral environments, but provides fitness advantages in novel environments, which come at the cost of reduced environmental robustness. We then show that the subsequent diversification of duplicated networks, via the loss of regulatory interactions, can partly negotiate this trade-off, improving evolutionary innovation and environmental robustness. We conclude by discussing the implications, limitations, and future directions of our research.

## Introduction

Biological systems exhibit two crucial and seemingly antagonistic properties: robustness and evolvability (Wagner, 2005). Regardless of the level of biological organization, living organisms display remarkable resilience to changing conditions, and at the same time, they are able to respond to these changes by developing novel phenotypes. At first glance, these qualities seem paradoxical, yet both empirical (Bloom et al., 2006; Ferrada and Wagner, 2008; Isalan et al., 2008) and theoretical (Aldana et al., 2007; Wagner, 2008; Draghi et al., 2010) analyses suggest their compatibility.

The relationship between robustness and evolvability has been investigated in biological systems ranging in scale from the molecule (Schuster et al., 1994; Cowperthwaite et al., 2008) to the cell (Aldana et al., 2007; Ciliberti et al., 2007a,b). At the cellular level, gene expression patterns are robust to changing environmental conditions, such as alterations in growth medium or the concentration levels of transcription factors (Alon, 2007). This insensitivity to environmental perturbation is largely influenced by the structure of the underlying gene regulatory network (GRN) (Aldana and Cluzel, 2003). A GRN consists of a set of genes, represented as vertices, linked by directed edges if the gene-product (e.g., protein, mRNA, microRNA) of the source gene has

a regulatory influence on the target gene. Recent analyses of model GRNs have revealed that robustness is often correlated with the capacity for evolutionary innovation (Ciliberti et al., 2007a; Aldana et al., 2007).

One major form of structural change in GRNs comes from whole genome duplication (WGD) events, wherein the entire gene repertoire of an organism, including regulatory interactions, is doubled (Sémon and Wolfe, 2007). WGD has long been recognized as a driver of evolutionary innovation (Ohno, 1970) and recent genetic analyses have demonstrated that several major evolutionary transitions resulted from ancient WGD events (Kellis et al., 2004; De Bodt et al., 2005; Taylor et al., 2003). For example, the origin of the budding yeast *Saccharomyces cerevisiae* (Kellis et al., 2004) and the radiation of the angiosperms into over 250,000 species (De Bodt et al., 2005) have both been attributed to WGD. The duplication of genetic material has implications for environmental robustness, as redundant genes diverge to compartmentalize the original function of the ancestral gene (subfunctionalization) (Sémon and Wolfe, 2007). In *S. cerevisiae*, for example, this occurs through the differential expression of redundant genes under various growth conditions (Kafri et al., 2005). WGD also has implications for evolutionary innovation, as duplicate genes diverge to acquire new functions (neofunctionalization) (Sémon and Wolfe, 2007). In *S. cerevisiae*, the ability to consume glucose and grow anaerobically have both been attributed to the genetic diversification that followed a WGD event (Piškur, 2001).

Despite the known importance of WGD events for evolutionary processes, their influence on environmental robustness and evolutionary innovation in GRNs is not thoroughly understood. Here, we use Random Boolean Networks (RBNs) (Kauffman, 1969) to model the dynamics of GRNs. We simulate WGD events in RBNs and quantify their effect on environmental robustness and evolutionary innovation.

This paper is structured as follows. In the subsequent section, we present the key concepts of this work. We then present our model and the details of our simulations, ana-

lyze and discuss our results, and conclude with an outline of future research directions.

## Background

### Random Boolean Networks

Random Boolean Networks (RBNs) are abstract dynamical models of gene regulatory networks (GRNs) (Kauffman, 1969). RBNs consist of  $N$  nodes, which represent genes, and directed edges, which represent regulatory interactions. Node states are binary, representing the expression (1) or repression (0) of gene products. Node states are also dynamic, such that the state of a node in time step  $t + 1$  is dependent upon the states of its regulating nodes in time step  $t$ . To model this dependence, each vertex is associated with a Boolean update function, which is captured by a look-up table that explicitly maps the output expression state for all possible combinations of input states. These output expression states are drawn at random with probability  $p_{\text{expr}}$  and are held fixed throughout the system's dynamics.

Node states are updated synchronously and in discrete time. The dynamics of a RBN begin with a prespecified initial configuration of node states, which represents regulatory factors upstream of the GRN (Ciliberti et al., 2007a). After at most  $2^N$  time steps, the system will encounter a configuration previously visited, thus entering a cycle of one or more configurations, which is referred to as an attractor.

An important aspect of RBNs is that their dynamical behavior falls into one of three regimes: ordered, critical, or chaotic. Systems in the ordered regime exhibit short attractors that are relatively insensitive to environmental perturbation. At the other end of the spectrum, systems in the chaotic regime possess longer attractors that are highly sensitive to environmental perturbation. The critical regime lies at the transition between the ordered and chaotic regimes, offering a balance between the ability to withstand environmental perturbation (robustness) and the ability to utilize these perturbations for evolutionary innovation (evolvability) (Aldana et al., 2007).

### WGD and Subsequent Diversification

Immediately following whole genome duplication (WGD), organismal stability is generally reduced, leading to a decrease in fitness (van Hoek and Hogeweg, 2009). However, duplicate genes supply new genetic material, which can be shaped via mutation and selection to produce novel functions. These functions may allow for more rapid adaptation if a new environment is encountered, providing potential fitness benefits (van Hoek and Hogeweg, 2009). The genetic reorganization that accompanies such diversification may occur via gene loss, gene rearrangements, or alterations in the circuitry of genetic regulation (Sémon and Wolfe, 2007).

## Methods

In this section, we separately present our implementations of RBN generation, duplication, and diversification. We then quantify environmental robustness and evolutionary innovation, outline the evolutionary processes used in our analyses, and provide the details of our simulations.

### RBN Topology

The degree distribution of a RBN has an important influence on system dynamics (Aldana and Cluzel, 2003; Oikonomou and Cluzel, 2006; Aldana et al., 2007). Here, we consider RBNs with Poisson input degree distributions and power-law output degree distributions, as empirical evidence suggests that such topologies are representative of the GRNs of several organisms (Aldana and Cluzel, 2003; Albert, 2005). RBN topologies are generated as described by Darabos et al. (2009).

### Duplication

WGD is simulated by first creating a mirror-image of the original RBN and then linking the duplicate and original components by drawing edges from the source nodes in one component to the targets in the other (Fig. 1a,b). Each node in the duplicated RBN has twice as many inputs as the corresponding node in the non-duplicated RBN. As a result, the number of entries in the look-up table is squared. To populate the entries of each table, we follow Aldana et al. (2007): when the duplicate regulatory inputs are not expressed, the Boolean rules remain identical to those prior to duplication. However, when the duplicate regulatory inputs are expressed the Boolean rules are assigned at random with probability  $p_{\text{expr}}$ .

### Diversification

To simulate the genetic diversification that follows a WGD event, we take a conservative approach and assume that only regulatory interactions can be lost (akin to structural simplification algorithms for neural networks (Le Cun et al., 1990)). This represents a mutation to the promoter region of a gene that prohibits the binding of one of its regulating gene products. While this type of mutation represents only a small subset of all possible forms of genetic reorganization, it offers a useful and parsimonious starting point. Further, empirical data suggest that (i) interactions are lost at a rate that is three orders of magnitude larger than the rate at which they are gained (Wagner, 2001) and (ii) rates of alternative forms of reorganization, such as gene loss, are significantly reduced among transcription factors (De Bodt et al., 2005), which are the primary gene products modeled by RBNs.

In our simulations, diversification occurs through the removal of all non-functional regulatory edges (Fig. 1c,d). These edges link a source to a target, where the state of the source does not influence the expression of the target. Such edges are referred to as canalized (Kauffman et al., 2004),

Figure 1: Schematic of whole genome duplication (WGD) and the subsequent diversification of a Random Boolean Network (RBN). The (a) non-duplicated RBN (b) undergoes WGD, wherein its entire gene repertoire is copied. Additional edges (gray) are drawn from the source nodes of one component to the target nodes of the other. The look-up tables of each node are expanded as described by Aldana et al. (2007). As an illustrative example, we depict one possible expansion of the look-up table of node  $a$ . (c) Diversification occurs via edge loss. E.g.,  $a \leftarrow b$ . (d) All edges are removed where the state of the target node is independent of the state of the source node. The diversification process continues throughout the evolution of the population, resulting in RBN topologies that differ markedly from those that immediately followed WGD.

and their removal does not immediately affect the dynamics of the RBN.

## Environmental Robustness

Environmental perturbations come in many forms, including alterations in temperature, growth medium, or biotic environment. A RBN is environmentally robust if its phenotype is insensitive to these non-genetic perturbations. We measure environmental robustness as the sensitivity of a RBN to the perturbation of a single, randomly chosen configuration of its attractor. Specifically, we systematically perturb the state of each node in the randomly chosen configuration, one at a time, and measure the proportion of perturbations in which the RBN returns to its original attractor.

## Evolutionary Innovation

An evolutionary innovation can be thought of as a change in phenotype that confers a fitness advantage. To assess evolutionary innovation, we measure the fitness of a RBN as the ability of its attractor to match a randomly generated target attractor. This target attractor represents the gene expression pattern required for optimal adaptation to a given environment. Fitness thus provides a proxy for evolutionary innovation.

For each RBN, we randomly select a single output node and record the sequence of output states  $\sigma_{\text{out}}$  during its attractor. The fitness  $F$  of a RBN is then calculated as the Hamming distance between the output and target sequences

(Oikonomou and Cluzel, 2006),

$$F = \max \left\{ 1 - \frac{1}{\text{lcm}(L, L_c)} \sum_{t=1}^{\text{lcm}(L, L_c)} |\sigma_{\text{out}}(t) - \sigma_{\text{target}}(t)| \right\}, \quad (1)$$

where  $L$  is the length of the output sequence,  $L_c$  is the length of the target sequence, and  $\text{lcm}$  denotes the least common multiple. To facilitate the comparison of sequences with  $L \neq L_c$ , both sequences are concatenated onto themselves until they are of length  $\text{lcm}(L, L_c)$ . To ensure that fitness is independent of the starting position of the output sequences, we take the maximum fitness over all cyclic permutations of  $\sigma_{\text{out}}$ .

## Evolution

We simulate the evolution of randomly initialized populations of RBNs in discrete, non-overlapping generations. In every generation, the fitness of each RBN is assessed according to Eq. 1. RBNs are then selected with uniform probability, with replacement, to compete in binary tournaments. Within a tournament, the RBN with the highest fitness is selected to move on to the next generation, after undergoing mutation. Mutation only affects the RBN's look-up tables, such that the entries in the look-up tables associated with each vertex undergo bit-flip mutation with probability  $p_{\text{mut}}$ . This process of selection and mutation is repeated until the next generation is fully populated.

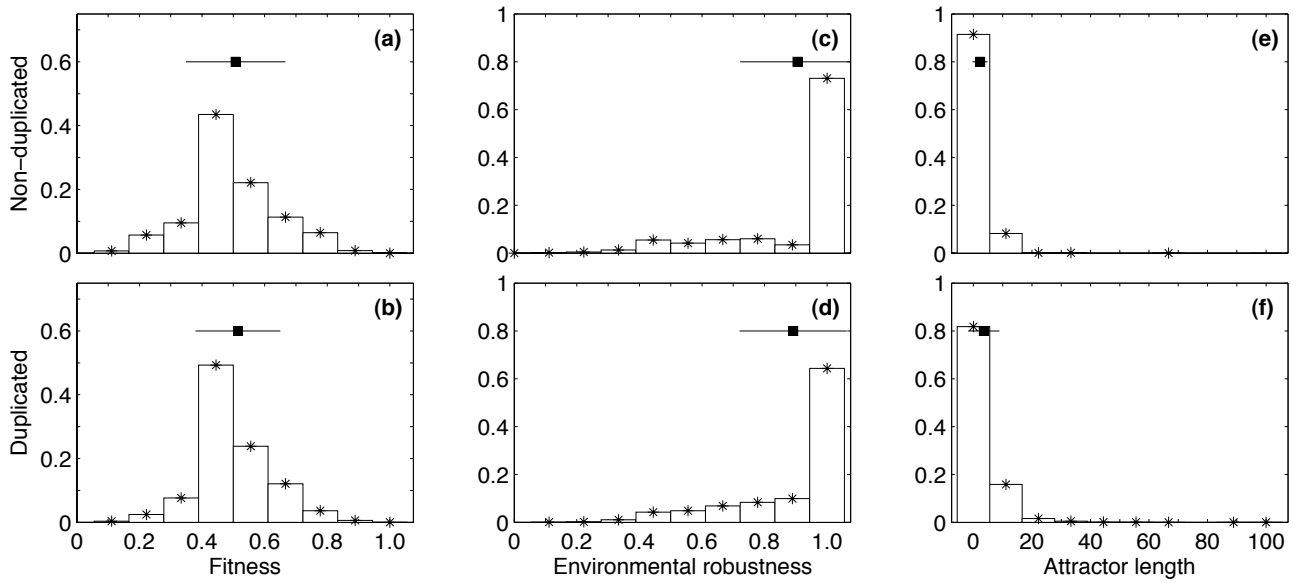

Figure 2: (a,b) Fitness, (c,d) environmental robustness, and (e,f) attractor length of non-duplicated (top row) and duplicated (bottom row) RBNs in novel environments. Each panel depicts the frequency distribution of data across 10,000 independent replications. The filled squares depict the mean of those data and the horizontal lines depict one standard deviation. The asterisk symbols are placed atop each non-empty bin as a visual aid. In (f), there was a single outlier with an attractor length  $L = 254$ , which is not shown.

## Simulation Details

We consider RBNs with  $N = 10$  nodes prior to duplication and  $N = 20$  nodes after duplication. RBNs are initialized near the critical regime by setting the probability of gene expression to  $p_{\text{expr}} = 0.5$  and the scaling exponent of the output degree distribution to  $\gamma = 1.894$ , which yields criticality in RBNs with  $N = 10$  (Aldana et al., 2007).

Evolutionary analyses are conducted with a population size of 500, wherein each RBN is paired with its own, randomly chosen initial state which does not change throughout the evolutionary trajectory of its lineage. In each experiment, we consider 100 independent replications that each consist of 5,000 generations. Mutation occurs with probability  $p_{\text{mut}} = 0.002$  per look-up table entry. In the experiments that include diversification, the deterministic edge-loss process only occurs every 10 generations, due to computational constraints.

## Results

We present our results in four successive phases. First, we compare the immediate effects of WGD on the fitness of RBNs in their ancestral environments. Second, we compare the immediate effects of WGD on the fitness and robustness of RBNs in novel environments. Third, we consider the evolutionary dynamics of fitness and robustness for non-duplicated and duplicated RBNs. Fourth, we compare the evolutionary dynamics of these same quantities when dupli-

cated RBNs are allowed to undergo diversification.

### WGD in an Ancestral Environment

To simulate an ancestral environment, we simply assume that the expression profile of a randomly generated RBN is optimally adapted. To do this, we choose a random node from the RBN and define it as  $\sigma_{\text{target}}$ . We then simulate a WGD event, designate the expression profile of the same node in the duplicated RBN as  $\sigma_{\text{out}}$ , and compute its fitness (Eq. 1). To collect meaningful statistics, we repeat this process 10,000 times.

WGD is highly deleterious in an ancestral environment. Optimal fitness is maintained in only  $\sim 42\%$  of WGD events. Of the remaining  $\sim 58\%$  of duplicated RBNs, average fitness decreases to  $0.37 \pm 0.002$ .

### WGD in a Novel Environment

To simulate a novel environment, we randomly generate  $\sigma_{\text{target}}$  of length  $L_c = 10$  (Oikonomou and Cluzel, 2006). We then generate a RBN, choose a random node, designate its expression profile as  $\sigma_{\text{out}}$ , and compute the RBN's fitness (Eq. 1). In addition, we measure the RBN's environmental robustness. We then collect these data for the same RBN after WGD. As in the previous analysis, this process is repeated 10,000 times.

Duplicated RBNs exhibit a marginal fitness advantage over their non-duplicated counterparts (Fig. 2a,b; Stu-

dent's t-test,  $p = 5.43 \times 10^{-4}$ ). However, this advantage comes at the expense of a marginal decrease in environmental robustness (Fig. 2c,d; Kolmogorov-Smirnov test,  $p = 3.46 \times 10^{-74}$ ). These subtle differences can be attributed to the increased attractor length of the duplicated RBNs (Fig. 2e,f; Student's t-test,  $p = 8.9 \times 10^{-9}$ ), which have a higher probability of matching  $\sigma_{\text{target}}$  and exhibit a greater sensitivity to perturbation.

### Evolutionary Dynamics of Duplicated RBNs

We now turn from a static analysis of environmental robustness and fitness to an evolutionary analysis of these quantities for populations of non-duplicated and duplicated RBNs. As in the previous section, we consider novel environments by randomly generating target sequences  $\sigma_{\text{target}}$  of length  $L_c = 10$ .

As observed in our previous analysis, the duplicated RBNs have an immediate, albeit slight, fitness advantage in a novel environment (Fig. 3a), but are marginally less robust (Fig. 3b). These differences in fitness and robustness become more pronounced throughout the evolutionary process. Duplicated RBNs reach a plateau of average fitness at  $0.92 \pm 0.006$  (Fig. 3a, squares) while the non-duplicated RBNs stagnate at an average fitness of  $0.89 \pm 0.008$  (Fig. 3a, triangles). Simultaneously, the duplicated RBNs drop to an average environmental robustness of  $0.73 \pm 0.042$  (Fig. 3b, squares), while the non-duplicated RBNs retain a higher environmental robustness of  $0.83 \pm 0.018$  (Fig. 3b, triangles). Thus, WGD in the absence of subsequent diversification leads to a trade-off between environmental robustness and evolutionary innovation.

### Evolutionary Dynamics of Diversified RBNs

To investigate the effects of diversification after WGD, we conduct an evolutionary analysis of paired populations of duplicated RBNs, wherein diversification can only occur in one of the initially identical populations.

Diversification promotes evolutionary innovation, with populations reaching an average fitness of  $0.95 \pm 0.013$  (Fig. 4a, open circles), a significant improvement over the fitness obtained with WGD alone (Fig. 4a, closed squares). Simultaneously, diversification increases environmental robustness (Fig. 4b, open circles), though not to the same levels observed prior to WGD (Fig. 3b, triangles). Thus, diversification allows for the partial negotiation of the trade-off between environmental robustness and evolutionary innovation that is induced by WGD.

The diversification process also leads to appreciable structural changes in RBN topologies, with average connectivity dropping rapidly (Fig. 4a, inset). RBN dynamics are also affected, with attractor lengths of diversified networks settling to an average of  $9.48 \pm 0.174$ , as compared to  $9.92 \pm 0.112$  for non-diversified networks (Fig. 4b, inset). The probability of gene expression  $p_{\text{expr}}$  remains approximately constant

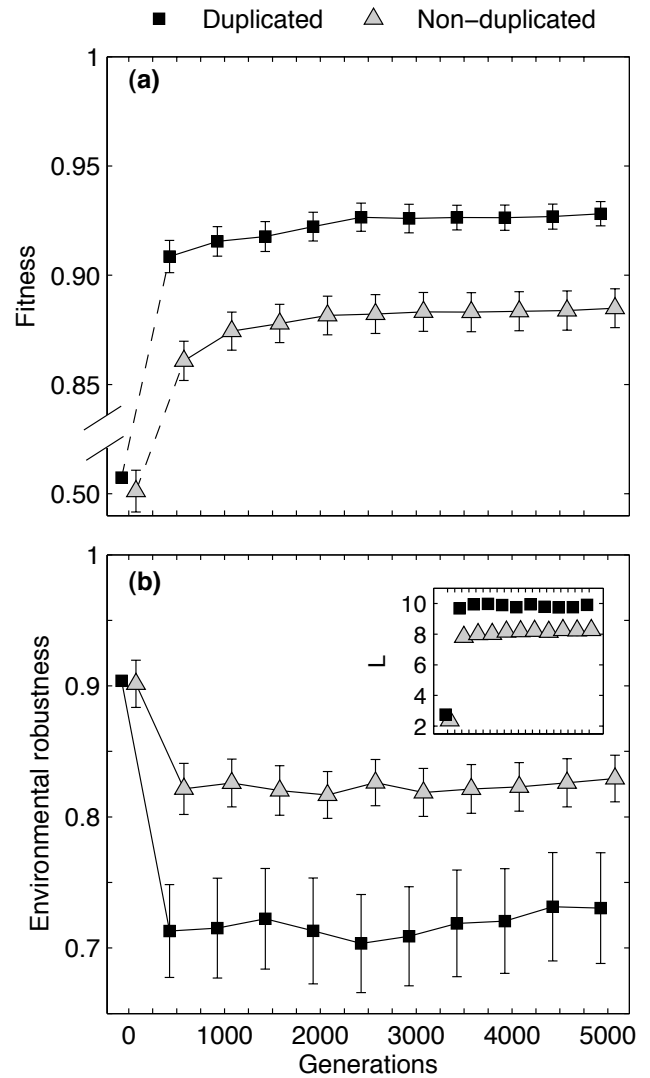

Figure 3: Evolutionary dynamics of (a) fitness and (b) environmental robustness for populations of duplicated and non-duplicated RBNs in novel environments. Data represent the mean of 100 independent replications and error-bars denote a single standard deviation. The inset in (b) depicts the average attractor length  $L$ . Data are deliberately offset in the horizontal dimension for visual clarity. Note the break in scale on the y-axis of (a). The scale of the x-axis is the same in all panels, including insets.

at 0.5 throughout the evolutionary process (data not shown).

### Discussion

We have used Random Boolean Networks (RBNs) to investigate the influence of whole genome duplication (WGD) and subsequent diversification on evolutionary innovation and environmental robustness in gene regulatory networks (GRNs). There are some limitations to our approach that

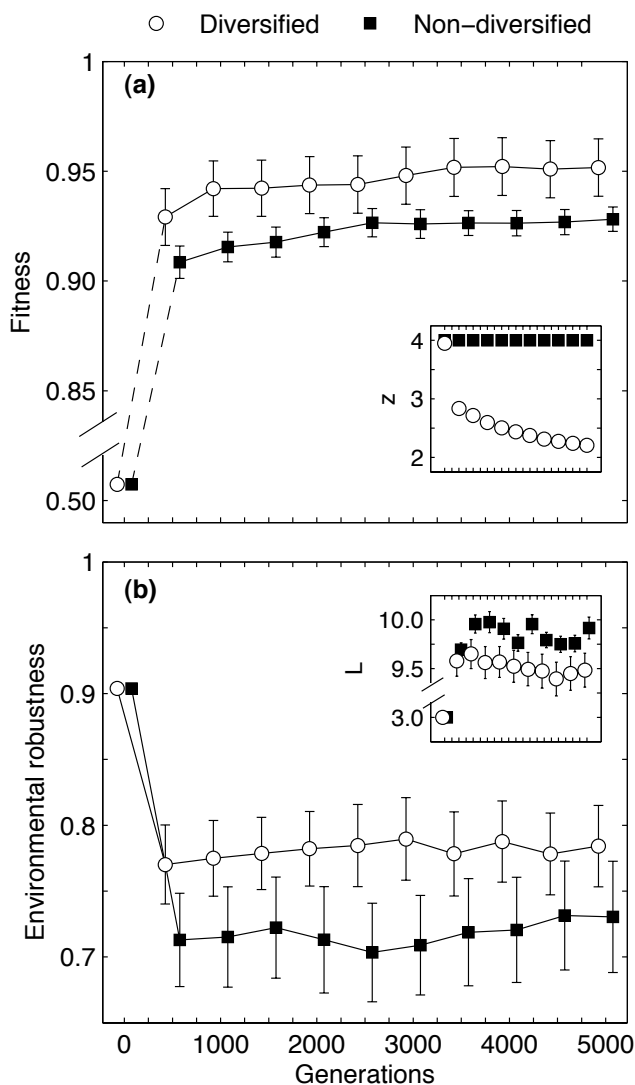

Figure 4: Evolutionary dynamics of (a) fitness and (b) environmental robustness for populations of RBNs following WGD in novel environments, with (open circles) and without (closed squares) subsequent diversification. Data represent the mean of 100 independent replications and error-bars denote a single standard deviation. The inset in (a) depicts the average network connectivity  $z$  and the inset in (b) depicts the average attractor length  $L$ . Data are deliberately offset in the horizontal dimension for visual clarity. Note that the data represented by the closed squares are the same as in Fig. 3. Also note the break in scale on the y-axis of (a) and the inset of (b). The scale of the x-axis is the same in all panels, including insets.

are worth highlighting. First, while the genotype produced by a WGD event is purely redundant, its resulting phenotype may differ immediately from that of the non-duplicated genotype. This occurs because both the original and du-

plicated nodes acquire new regulatory connections, necessitating the random initialization of entire segments of the expanded look-up tables. Further, the duplicated node cannot, under most circumstances, act as a “backup” because alterations to the original node may lead to phenotypic alterations that are not easily compensated for by the duplicate. Second, because many phenotypes yield identical fitness, and the phenotypic contribution of a single gene cannot be separated from its interaction partners, it is not possible to discern whether the observed changes in environmental robustness and evolutionary innovation are due to subfunctionalization, neofunctionalization, or a combination thereof (He and Zhang, 2005).

Despite these limitations, our analyses have helped to clarify the influence of WGD and subsequent diversification on environmental robustness and evolutionary innovation in GRNs. While deleterious in ancestral environments, WGD provided marginal fitness benefits in novel environments, coming at the expense of reduced environmental robustness (Fig. 2). Over evolutionary time, these differences magnified, with duplicated RBNs achieving significantly higher fitness and significantly lower environmental robustness than their non-duplicated counterparts (Fig. 3). Genetic diversification, via the loss of non-functioning regulatory interactions, was able to partly negotiate this trade-off, leading to improvements in both fitness and environmental robustness (Fig. 4).

Environmental robustness and evolutionary innovation were therefore inversely related in this system. This occurred because fitness assignment was based solely on the ability of a RBN to match a target expression profile  $\sigma_{\text{target}}$  (Eq. 1). This induced selection pressure for longer attractors (insets in Figs. 3b and 4b), because increasing the duration of the expression profile of the output node increased the probability that some segment of that profile matched  $\sigma_{\text{target}}$ . In turn, environmental robustness decreased, because longer attractors were more sensitive to perturbation. Thus, while some aspects of robustness and evolvability are positively correlated in RBNs (Aldana et al., 2007), robustness to environmental perturbation and the ability to match a target phenotype are not amongst them.

Diversification increased environmental robustness (Fig. 4b) through a reduction in network connectivity (Fig. 4a, inset). This shifted the RBN dynamics closer to the critical regime and therefore reduced the average attractor length (Fig. 4b, inset), yielding more environmentally robust attractors. It is notable that this reduction in attractor length did not lead to a corresponding reduction in fitness (Fig. 4a). How the diversified RBNs were able to attain increased fitness using shorter attractors is not yet known. An analysis of the structural properties of evolved RBNs, such as network excitation (Draghi and Wagner, 2009) or degree distribution (Aldana et al., 2007), may provide more insight into the mechanisms by which diversification can simultaneously

increases fitness and environmental robustness.

In the absence of diversification, the selective advantage of WGD may depend heavily on the frequency with which environmental perturbations occur. Selection may favor phenotypes that consistently yield expression profiles of average fitness over those that inconsistently yield expression profiles of high fitness. By placing non-duplicated and duplicated RBNs in a head-to-head competition under varying levels of environmental perturbation, future work will seek to determine how selection moderates the trade-off between environmental robustness and evolutionary innovation, and to discover the conditions under which selection leads to the “survival of the flattest” (Wilke et al., 2001).

The environments considered in this study were static, meaning that the target gene expression profile did not change over time. Several studies have demonstrated the importance of dynamic environments in shaping a population’s potential for evolutionary innovation (Kashtan et al., 2007; Draghi and Wagner, 2009). Future work will seek to understand how WGD and subsequent diversification influence evolutionary innovation and robustness in dynamic environments.

Future work will also seek to expand upon our usage of fitness as a proxy for evolutionary innovation. It may prove insightful to analyze not only the ability to move toward a specific fitness optimum, but also the ability to move toward arbitrary fitness optima. Such measurements of the diversity of accessible phenotypes are common in studies of evolvability (Ciliberti et al., 2007a; Cowperthwaite et al., 2008; Wagner, 2008), and could be incorporated into our analysis (Draghi and Wagner, 2009). In addition, we will also investigate alternative forms of genetic diversification, with a particular focus on gene loss, which will allow for a more direct comparison with alternative models of WGD and diversification in GRNs (Wagner, 1996). These extensions, among others, will lead to a more thorough understanding of how various genetic mechanisms influence the relationship between robustness and evolvability in gene regulatory networks.

## Abstract

By using Aevol, a simulation framework designed to study the evolution of genome structure, we investigate the effect of homologous rearrangements on the course of evolution. We designed an efficient model of rearrangements based on an intermittent search algorithm. Then, using experimental *in silico* evolution, we explore the effect of rearrangement rates on the genome structure. We show that the effect of homologous rearrangements is quite complex. At first glance they appear to be dangerous enough to trigger an indirect selective pressure leading to short genomes when the rearrangement rate is high. However, by analyzing the successful lineage in the best runs, we found that there is a positive correlation between the number of homologous rearrangements and the fitness improvement in these lineages. Thus the impact of homologous rearrangements on evolution is rather complex: dangerous on the one hand but necessary on the other hand, to ensure a sufficient level of evolvability to the organisms. Moreover, our results show that the spontaneous rate of small mutations influences the relative proportions of homologous versus nonhomologous rearrangements.

## Introduction

Chromosomal rearrangements are known to play a major role in evolution. Their most visible effects are quite straightforward: duplications and deletions account for numerous gene acquisitions or losses while translocations and inversions have a direct influence on gene order. However, these direct effects are flanked by other indirect selective pressures. The rates and mechanisms of rearrangements indeed influence the evolvability (Kirschner and Gerhart, 1998) of the lineage and, as it was stated by Earl and Deem (2004), evolvability itself can be subject to evolution. In the long term, more evolvable lineages are more likely to produce beneficial mutations and hence to overcome lineages with lower evolvability. Similarly, Wilke et al. (2001) showed a second-order selective pressure on mutational robustness. The selection of a specific level of evolvability or robustness is said to be indirect because they do not influence the fitness of the organism, but that of its descendants.

Unraveling these second-order pressures is a very challenging matter. Indeed, the underlying processes are complex and act on a very long time scale. It is hence difficult

to tackle such questions either *in vivo* or *in vitro*. Comparative genomics approaches are a way to circumvent this difficulty. However, they are based upon the static snapshots of the contemporary sequences and have to *infer* their evolutionary past.

Artificial life and *in silico* simulations are very useful in such cases, providing us with insights into complex mechanisms and shedding light onto second-order pressures that would have been difficult to identify otherwise (Wilke et al., 2001; Adami, 2006; Misevic et al., 2006; Knibbe et al., 2007; Beslon et al., 2010). They offer a dynamic view of the evolutionary process and provide the experimentalist with a very good control over parameters as well as a perfect fossil record throughout the evolution.

The Aevol model was developed specifically to study the evolution of genome structure. Experiments using this model underlined the major importance of chromosomal rearrangements in the evolutionary process. For a start, we observed that in total absence of chromosomal rearrangements, evolution can hardly occur at all because gene duplications are necessary to acquire new genes and thus new functions. Secondly, it has been shown that, because of rearrangements, non-coding sequences can become mutagenic for the surrounding genes. The consequence is a clear trend for organisms having evolved under high rearrangement rates to own shorter and denser genomes than those having evolved under lower rates of rearrangement (Knibbe et al., 2007; Parsons et al., 2010). As we have already shown, this effect is the consequence of the long-term selection of a specific level of mutational variability (Knibbe et al., 2007).

Unlike point mutations and indels that produce local variations, chromosomal rearrangements can involve huge sequences and turn a very fit individual into an ill-adapted one in a single event. Chromosomal rearrangements can hence be very dangerous. However, rearrangements are usually not fully random. Most rearrangements are the consequence of error-repair mechanisms such as the RecA mediated double strand break repair mechanism (Neidhardt, 1996). These mechanisms usually require that the sequences be similar (at least around the breakpoints) to be rearranged. Such rear-

After an overall presentation of the AevoL model, focusing particularly on the way we take sequence homologies into account in the rearrangement process, we will present our results regarding the different effects of homologous and nonhomologous rearrangements. We will discuss the intricate relationship that exists between homologous and non-homologous rearrangements, and their impact on evolvability.

The AevoI model was developed in our team to study the evolution of genome structure. It simulates the evolution of a population of  $N$  artificial haploid organisms with flexible genomes. Although a description of the model has already been published (see Knibbe et al. (2008) and its supp. mat.), we thereafter provide an overview of the most important principles that are necessary to have a good understanding of the results presented here.

At each generation,  $N$  new individuals are created by reproducing preferentially the best individuals of the parental generation which is then completely replaced. During the replication process, the chromosome can undergo different kinds of modifications: local mutations (point mutations, small insertions and small deletions), but also large chromosomal rearrangements (duplications, deletions, translocations and inversions). At the beginning of the run, all the organisms are initialized with the same random sequence (of 5,000 base-pairs here) which contains at least one gene.

**Transcription** In prokaryotes, transcription initiates at particular sites, called promoters, where the RNA-polymerases recognize a consensus sequence to which they can bind and begin the RNA synthesis. In Aevol, we defined a long consensus sequence, a promoter being a sequence whose Hamming distance  $d$  with this consensus is less than or equal to  $d_{max}$ . In the experiments presented here, the consensus was a 22-base-pairs (bp) sequence and up to  $d_{max} = 4$  mismatches were allowed. This consensus sequence is long enough to ensure that random, non-coding sequences have a low probability to become coding by a single mutation event.

The expression level  $e$  of an RNA is determined according to its promoter sequence:  $e = 1 - \frac{d}{d_{max} + 1}$ . This modulation of the expression level models in a simplified way the basal interaction of the RNA polymerase with the promoter, without additional regulation. It provides duplicated genes with a way to reduce temporarily their phenotypic contribution while diverging toward other functions.

**Translation** Transcribed sequences (RNAs) do not necessarily result in a protein. The translation process of an RNA takes place when a Shine-Dalgarno-like sequence is found, followed, a few base-pairs away, by a START codon (see genetic code on figure 2). Whenever this signal 011011\*\*\*\*000 is found, the following sequence is read three bases (one codon) at a time until the STOP codon (001) is found on the same reading frame. Each codon lying be-

tween the initiation and termination signals is translated into an abstract “Amino-Acid” using an artificial genetic code, therefore giving rise to the protein’s primary sequence (figure 2). As in real organisms, genes can be found on six different reading frames (three on each strand), giving the possibility for the organisms to evolve overlapping genes, which are commonly found in virus and bacteria.

**Protein “folding” and phenotype computation** To model the activity of proteins and the resulting phenotype, we defined a simple “artificial chemistry” (Dittrich et al., 2001) that describes the organism’s metabolism in a mathematical language. In our simplified artificial world, we assume that there is an abstract, one-dimensional space  $\Omega = [0, 1]$  representing all the possible metabolic processes (that is, in this model, a metabolic process is just a real number). In this “metabolic space”, each protein is involved in a subset of processes (either realizing it or preventing other proteins from realizing it) which is described using the fuzzy set formalism: a given protein can be involved in a metabolic process with a possibility degree lying between 0 and 1. A protein is thus fully characterized by a mathematical function that associates a possibility degree to each metabolic process, describing the fuzzy subset of metabolic processes it is involved in. For simplicity, we use piecewise-linear functions with a symmetric, triangular shape (figure 2). In

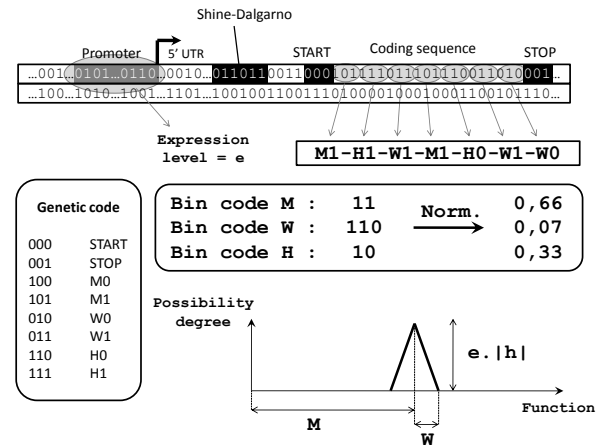

Figure 2: Overview of the transcription-translation-folding process in Aevol. Transcribed sequences are those that start with a promoter (consensus sequence) and end with a terminator sequence (stem-loop structure), not shown on the figure. Coding sequences (genes) are searched within the transcribed sequences; They begin with a Shine-Dalgarno-START sequence and end with a STOP codon. An artificial genetic code (right) is used to convert a gene into the primary sequence of the corresponding protein and a “folding process” enables us to compute the metabolic activity of this protein (functional abilities).

this way, only three numbers are needed to characterize the metabolic activity of a protein: the position  $m$  ( $m \in \Omega$ ) of the triangle on the axis, its half-width  $w$  and its height  $h$  (positive when realizing a function, negative when inhibiting it). This means that the protein contributes to the range  $[m-w, m+w]$  of metabolic processes, with a preference for the processes closest to  $m$  (for which the highest efficiency,  $h$ , is reached). Thus, various types of proteins can co-exist, from highly efficient and specialized ones (small  $w$ , high  $h$ ) to polyvalent but poorly efficient ones (large  $w$ , low  $h$ ).

In this framework, each protein’s primary sequence is decomposed into three interlaced binary subsequences that will in turn be interpreted as the values for the  $m$ ,  $w$  and  $h$  parameters. For instance, the codon 010 (resp. 011) is translated into the single amino acid  $W0$  (resp.  $W1$ ), which means that it contributes to the value of  $w$  by adding a bit 0 (resp. 1) to its binary code. Small mutations in the coding sequence (point mutations, indels, possibly causing frame shifts) will change these parameters, resulting in a modification of the protein’s metabolic activity.

Once all the proteins encoded on the genotype of the organism have been identified and characterized, their activities are combined into a fuzzy set representing the individual’s phenotype  $P = (\cup A_i) \cap (\cup I_j)$ , using Lucasiewicz’ fuzzy operators, with  $A_i$  being the fuzzy subset of the  $i$ -th activating protein ( $h_i > 0$ ) and  $I_j$  the fuzzy subset of the  $j$ -th inhibiting protein ( $h_j < 0$ ). Intuitively, this means that

metabolic processes achieved by the organism are those that are activated and not inhibited. The phenotypic fuzzy set  $P$  indicates to what extent the individual can realize each metabolic process in our abstract metabolic space.

### Environment, adaptation and selection

In Aevol, the environment is represented by a phenotypic target: the fuzzy set  $E$  defined on  $\Omega$  that represents the optimal degree of possibility for each “biological function”. To evaluate an individual, we compare its phenotype  $P$  to the optimal phenotype  $E$ . The “metabolic error”  $g$  is computed as the geometric area between these two sets (figure 3). The lower the metabolic error, the better the individual. This measure penalizes both the under-realization and the over-realization of each function.

Figure 3: Measure of individual adaptation. Dashed curve: environmental target  $E$ . Solid curve: phenotypic distribution  $P$  (resulting metabolic profile obtained after combining all the proteins). Dark grey filled area: metabolic error  $g$ .

In the current version of Aevol, the population size is constant (here  $N = 1,000$  individuals) and the population is entirely renewed at each generation. A probability of reproduction is assigned to each individual according to its metabolic error and a multinomial drawing determines the actual number of offsprings each individual will have. In the experiments presented here, we used an exponential ranking selection (Blickle and Thiele, 1996). The individuals are sorted by decreasing metabolic error so that the worst individual has rank  $r = 1$  and the best  $r = N$ . The probability of reproduction of an individual is then given by  $\frac{s-1}{s^N-1} s^{N-r}$ , with  $s = 0,998$  being the intensity of selection in all the experiments presented here.

### Genetic operators

During their replication, genomes can undergo different modifications: local mutations (point mutations, insertions or deletions of 1 to 6 bp) and chromosomal rearrangements (duplications, deletions, translocations, inversions).

Mutations and rearrangements affect the genome but do not necessarily have a phenotypic effect. For instance, a mutation that takes place in an untranscribed region will be completely neutral unless it creates a new promoter, which is reasonably rare given the size of the consensus sequence.

The rates at which each type of local mutation occurs are parameters of the model. They are defined as the per-base, per-replication probability of each type of mutation to take place. The chromosomal rearrangement rates however, can not be a direct parameter of the model. Indeed, in this version of the model, a rearrangement is all the more likely to occur that the sequences at the breakpoints are similar. The probability of a chromosomal rearrangement to occur hence depends on the sequence itself and consequently, is subject to evolution. Details about how we modeled these homology-driven chromosomal rearrangements are provided in the next section.

Genetic exchange (crossover) between individuals was not allowed in the simulations presented here, because we first needed to assess the impact of similarity-based intra-chromosomal rearrangements in the simple case of an asexual population. We plan to allow for similarity-based genetic exchange in future experiments.

### Homology-driven chromosomal rearrangements

Taking homologies into account in the chromosomal rearrangement process requires some knowledge regarding sequence repeats on the chromosome. A naive approach would be to compute a complete alignment search of the genome on itself and then to proceed to the rearrangements if any. However, searching for alignments between sequences is known to be a computationally costly problem. In our particular case, where we deal with millions of genomes (classically 1,000 genomes per generation for thousands of generations), even a heuristic search such as BLAST (Altschul et al., 1990) would be forbiddingly long to compute. Another possible approach, chosen here, is to use intermittent searches (Bénichou et al., 2005), that provide us with a partial yet sufficient knowledge of sequence alignments within the genome.

In bacteria, several mechanisms can result in a rearranged chromosome. All these mechanisms have a basic prerequisite of spatial proximity: two sequences must be physically close together in the cytoplasm, at least at the breakpoints, for them to rearrange. As the chromosome is supercoiled, two sequences that are very distant from each other on the chromosome can very well be next to each other in the three-dimensional conformation. Since the mechanisms that constrain the spatial conformation of the genome according to its sequence are still poorly understood in bacteria, here we simply picked random pairs of sequences on the genome and consider them to be neighbours.

How many pairs of points are to be drawn depends on both the genome length and its degree of supercoiling. Consider any given sequence on the genome. The number of other sequences that are localized in its surroundings depends on how densely packed the genome is. In a highly supercoiled genome, for instance, all the sequences are very

Figure 4: (a) For each pair of points that are candidate for a rearrangement to occur, a local alignment search is performed between the surrounding sequences either in direct or indirect sense. (b) The searching zone is defined by 2 parameters: the *half\_length* of the searching zone and the maximum slippage *max\_shift* authorized between the sequences. In the experiments presented in this paper, we used values of respectively 50 for *half\_length* and 20 for *max\_shift*. (c) Solid line: probability to find a sequence of the given score on a random sequence. Dashed line: the function  $p_{rear}(score)$  used to map scores to rearrangement probabilities in our experiments.

tightly packed together so any sequence has many neighbours and thus many rearrangement opportunities. We thus introduced a specific parameter in the model, the “neighbourhood rate” ( $\mu_n$ ), that expresses this degree of supercoiling. The number of pair of points to consider for a possible rearrangement will then be given by  $L * \mu_n$ , with  $L$ , the genome length in bp. Here,  $\mu_n$  is a parameter defined for the whole population and cannot change during its evolution.

For each candidate pair of points, a basic local alignment search will be performed to determine the existence of similarities between the surrounding sequences either in a direct or indirect sense (figure 4(a)). To that end, we defined a simple scoring function (+1 per match, -2 per mismatch) that allows us to quantify the similarity of two sequences<sup>1</sup>, and associated each score to a probability of rearrangement. The kind and number of rearrangements are computed thanks to algorithm 2.

Preliminary experiments allowed us to adjust the function  $p_{rear}(score)$ , that maps alignment scores to probabilities of rearrangement. To favour homologous over non-homologous rearrangements, alignment scores that are seldom found on random sequences (high scores) are associated with very high rearrangement probabilities (homologous rearrangements). Low score alignments on the other hand, are likely to result from contingency, and will hence be given low probabilities of rearrangement (nonhomologous rearrangements). Figure 4(c) shows the probability of finding an alignment of a given score on a random sequence as well as the function  $p_{rear}(score)$  we used in the following experiments. This particular function yields a reasonable tradeoff between homologous and nonhomologous

rearrangements.

```

initial_nb_pairs ← L * μn
nb_pairs ← initial_nb_pairs
while nb_pairs > 0 do
    Draw 2 random positions pos1 and pos2
    Draw type of rearrangement
    if Inversion then sense ← indirect
    else sense ← direct

        Update L
    end
    nb_pairs ← nb_pairs - 1
    nb_pairs ←  $\frac{nb\_pairs}{initial\_nb\_pairs} * L * \mu_n$ 
end

```

**Algorithm 2:** Aevol Rearrangement Process Algorithm

## Results

Our model being quite complex, our experimental methods are very similar to those used in “wet” experimental evolution. We let 60 populations of 1,000 asexual individuals evolve during 20,000 generations in near identical conditions where the only changing parameters were the mutation rate (one common rate  $\mu_m$  for the three different types of local mutations, 4 values ranging from  $5.10^{-6}$  to  $1.10^{-4}$  were tested) and the neighbourhood rate ( $\mu_n$ , 4 values ranging from  $1.10^{-2}$  to  $5.10^{-1}$ ). During the evolutionary process, the organisms progressively acquire new genes by duplication and modify them in such a way that the whole gene repertoire fulfills the task the organisms are selected for.

<sup>1</sup>Even though it is possible to allow for gaps within alignments, the computation cost would be too important. Hence, in the experiments presented here, no gaps were allowed.

All the simulations proceed qualitatively in a similar way, evolving quickly in the first stage of evolution (rapid gene acquisition mostly by duplication-divergence) then slowing down the process of gene acquisition while optimizing the sequence of existing genes and promoters.

In the experiments presented here, the rate at which rearrangements occur is not constant, it depends on both the neighbourhood rate  $\mu_n$  and on the presence of repeated sequences on the chromosome. It is hence free to evolve and could well be selected for or against. Yet, despite this added degree of freedom, the rearrangement rate remains a very strong determinant of genome size and content (figure 5). These results confirm those obtained with previous versions of the model in which the rearrangement rates were direct parameters of the model (Knibbe et al., 2007). Even with homologous rearrangements, we find again that the spontaneous rate of rearrangement has a negative impact on fitness (figure 5(d)) because it sets an upper bound on genome size and hence on the number of genes (figure 5(c)). However, rearrangements are also mandatory for evolution to be efficient. An organism whose genome would have lost its capacity to rearrange would hardly be evolvable at all.

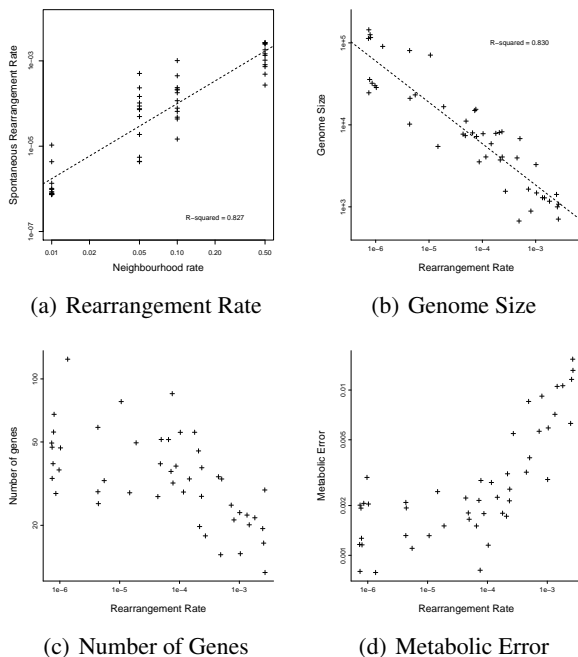

Figure 5: (a) Average spontaneous rearrangement rates observed for each simulation during the whole evolution. (b,c,d) Genome Size, Genes Number and Metabolic Error of the best organism after 20,000 generations for each simulation, as a function of the spontaneous rearrangement rate.

Because homologies are created by rearrangements (duplications) and gradually destroyed by local mutations, there must be some sort of complex interactions between the mutation rate, the neighbourhood rate and the rates of both ho-

mologous and nonhomologous rearrangements.

The distribution of the scores of the alignments that led to rearrangements (figure 6) can help us understand this intricate relationship. If we consider this data vertically, we can clearly observe that the proportion of homologous rearrangements is higher when the neighbourhood rate is high. However, as we progress downwards, the distributions behave differently: while it remains nearly unchanged on the left hand side, nonhomologous rearrangements become way more frequent on the right. A noteworthy observation is that there is a great variation in the number of rearrangement events. In fact, it is not the number of nonhomologous rearrangements that raises (it actually remains stable), but rather the number of homologous rearrangements that collapses when the neighbourhood rate decreases.

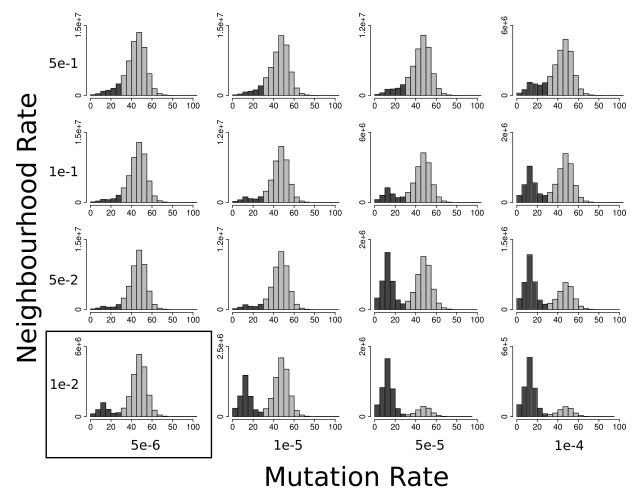

Figure 6: Distribution of the scores of the alignments that caused a rearrangement to occur in the whole population and during the entire evolutionary process, for each value of  $\mu_n$  and  $\mu_m$ . Light grey: homologous rearrangements, dark grey: nonhomologous rearrangements. For computational performance reasons, the given values are minimal bounds to the corresponding alignment score (cf. Algorithm 2).

The underlying phenomenon is best understood when looking at the data in a top-left to bottom-right fashion. One can then identify a phase transition between a regime of mainly homologous rearrangements at high  $\mu_n$  and low  $\mu_m$ , and a regime of almost exclusively nonhomologous rearrangements at low  $\mu_n$  and high  $\mu_m$ . In fact, for the possibility of homologous rearrangements to be maintained along the evolutionary process, homologies must be created (by either homologous or nonhomologous duplications) at least as fast as they are destroyed by local mutations. At high neighbourhood rates, this condition is always achieved because rearrangements are numerous. However, at low neighbourhood rates, the damage caused by local mutations can overcome the creation of homologies and stall the whole process.

The four histograms at the bottom of Figure 6 are hence the most interesting. Within this line, throughout which  $\mu_n = 1.10^{-2}$ , the change in rearrangement mode from mainly nonhomologous to mainly homologous is particularly clear when the spontaneous rate of small mutations decreases. To better understand the dynamics of homologous/nonhomologous rearrangements, we further analysed the simulations from the left hand side, that display both the greatest proportion of homologous rearrangements (within the bottom line) and, interestingly, the best final fitness of all parameter sets. For the three runs of this parameter set ( $\mu_n = 1.10^{-2}$  and  $\mu_m = 5.10^{-6}$ ), we kept track of the family ties during the evolution. We then retrieved the line of ancestry of the final best individual and analyzed the mutational events that occurred on this successful lineage. Except for those that occurred during the very last generations, the events on this lineage are those that went to fixation, either by selection or by genetic drift. In addition, every other 10 generations, we used the standard bioinformatic tool Mummer (Kurtz et al., 2004) to find the most significant repeated sequences in the ancestral genome. Mummer uses an approach similar to that of BLAST, it first searches for exact short repeats and then tries to join them together, allowing for gaps and mismatches. An example of Mummer output is shown in Figure 7. In this example, there are both direct and inverted repeats, and most of the repeated sequences are located in non-coding parts of the genome. This suggests that non coding DNA plays a major role in genome evolvability by providing breakpoints for chromosomal rearrangements. The emergence of repeated sequences having little or no direct impact on fitness has already been observed in genetic programming (Langdon and Banzhaf, 2008) though in that particular case, these repeated sequences could be thought to participate in robustness rather than evolvability.

Figure 8 shows the results of the analysis of the whole lineage of ancestors. It shows that fitness improvements are strongly correlated with the presence of repeats in the genome and, consequently, with the occurrence of chromosomal rearrangements. The impact of chromosomal rearrangements on evolvability is thus rather complex: on the one hand, a very high rate of spontaneous rearrangements has a negative impact on the final fitness (Figure 5(d)), but on the other hand, in these simulations where the rate was low and the final fitness high, we find that the presence of rearrangements is correlated with fitness improvement (Figure 8). This suggests that a minimal amount of chromosomal rearrangements is required for evolution to be efficient.

A closer look to the rearrangements that went to fixation in these simulations (see Figure 9) reveals that (i) most of the fixed rearrangements were based on homologous breakpoints (*score* > 40), (ii) most of the fixed translocations and inversions were neutral, (iii) most of the fixed deletions were beneficial and (iv) most of the fixed duplications were deleterious. This last result is surprising at first sight: one would

Figure 7: Example of Mummer “dot plot” for the best individual at  $t = 2000$  generations, for  $\mu_n = 10^{-2}$  and  $\mu_m = 5.10^{-6}$ , seed 2. Both the x- and the y-axis represent the genome of this individual. Long and strongly similar sequences appear as runs of diagonal lines across the matrix (exact match length = 15 bp, min. cluster length = 200 bp, max. gap between adjacent matches = 6 bp). Grey areas: coding sequences.

expect fixed events to be mostly neutral or beneficial. Our hypothesis is that despite their immediate negative impact, duplications can be indirectly selected because they allow for the creation of new gene copies (which can then undergo small mutations and ultimately realize new functions) and new repeats (which can then mediate other rearrangements).

## Conclusion

These experiments of *in silico* evolution with similarity-based rearrangements confirm our previous results regarding the influence of rearrangements on genome compactness. In large genomes, repeated sequences (located mostly in non-coding regions) promote rearrangements that are, most of the time, deleterious. There is thus an indirect selective pressure to limit the number of rearrangements, which is done by eliminating repeats (fewer homologous rearrangements) and by reducing genome size (fewer nonhomologous rearrangements). However, we have also shown that the absence of rearrangements is correlated with fitness stasis, suggesting that rearrangements can sometimes be directly beneficial or provide appropriate genetic background for subsequent beneficial mutations. A minimal amount of rearrangements is thus required for evolvability. Here, most of the rearrangement kept by evolution are homologous ones. For them to be possible, repeats must be created at least as fast as they are destroyed by small mutations. In the end, the best conditions for evolvability seem to be a small basal rate of nonhomologous rearrangement combined with a low-enough mutation

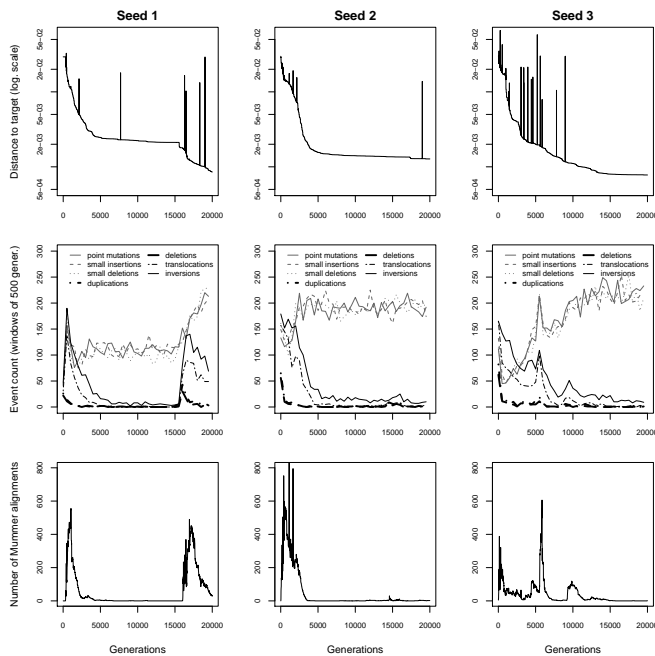

Figure 8: Analysis of the line of ancestry of the final best individual for  $\mu_n = 10^{-2}$  and  $\mu_m = 5.10^{-6}$ . First row: evolution of the fitness (the smaller the distance to the target, the higher the probability of reproduction). Second row: evolution of the number of mutational events, by windows of 500 generations. Third row: number of alignments found by Mummer on the genome (parameters: see Figure 7).

rate, thus leading to a few stable repeats and to an intermediate degree of variability by homologous rearrangements.

## Abstract

In this paper we propose a new computational model of cell cycle to study the dynamics of cells population in 2-D monolayer culture. Whereas most of the models are phase-orientated our model deals with a checkpoint orientated paradigm and uses the phase orientation as an output to provide the biologists with a relevant view of the simulation result. Through this paper we will present the genericity of our model, able to reproduce the exponential growth phase of different cellular processes.

## Introduction

Exploring, designing, understanding the complexity of the living world is of tremendous importance. The accurate assessment of its malfunction, especially those related to human diseases is a high stake venture. *In silico* simulation provides new means of studying and exploring living systems. In complementarity with experiments or when they are difficult to address *in vitro*, virtual environments can prove to be of interest. The latest computation capacity explosion allows us to tackle these questions with new approaches and new methods. System modelling may therefore use fitted methodologies to represent living systems at a systemic level. To this aim, the bottom-up approach tends to be the general paradigm for system modelling, focusing on each functional component of the system and in their interactions.

Cancer is often considered as the result of perturbation in cell cycle regulation associated with mutations that can appear in key regulators that result in abnormal proliferation, leading to tumorigenesis. Increasing the understanding of the cell cycle control is therefore central in cancer research and there are high issues in finding new regulatory mechanisms. The pharmacological issues foreseen with the *in silico* simulation of cellular systems let think that prospective research of new therapies could be addressed *in silico*.

In the different fields of computational and molecular biology, the focus on aspects of the cell cycle differs. Molecular biology models focus on the modelling and simulation of the molecular regulatory network of cycline-dependent kinase (CDK) (Novak and Tyson, 2004). These models can

be classified into two kinds of models, the discrete and the continuous. Continuous models basically describe the evolution of concentration of proteins using a set of ordinary differential equations, whereas discrete models focus on the activation state of each regulatory protein thanks to a predefined genetic regulatory network (GRNs) (Kauffman, 1969; Chavoya and Duthen, 2008). These models have been commonly used to simulate the cell cycle in yeast (Chen et al., 2004; Novak et al., 2001), frog eggs (Novak and Tyson, 1993; Pomerening et al., 2005), fruit flies (Calzone et al., 2007) and different mammals cells (Aguda and Tang, 1999; Singhania et al., 2011). These models are molecular-based models and do not account for behavioural considerations at a macro-level, their aims being to focus on the regulatory mechanisms.

The other family of models used to simulate cell proliferation are called Individual Cell-Based Models (IBMs) (Loeffler and Roeder, 2004). These are a subset of the agent-based models. Agent-based models have mainly proved their relevance in the simulation of different complex systems from social networks to the social behaviour of hive insects. Basically, individual cell based models come under two classes: cellular automaton (CA) models and off lattice models. On the one hand, CA are described by a discretization of the proliferative environment in 2-D/3-D evolution grid, and the cell shape is reduced to a lattice site. In this case, cell behaviour is composed of the different update rules set up (Patel et al., 2001; Moreira and Deutsch, 2002). On the other hand, off-lattice models have the advantages of letting evolving cells in a continuous media with continuous shapes. They can introduce topological aspects based on *in vitro* observation or knowledge. This involves high stakes for some investigative considerations. The IBMs have been successfully used to study the pattern formation in multicellular cultures (Galle et al., 2005; Gerlee and Anderson, 2007), avascular tumour growth (Hoehme and Drasdo, 2010) and the spatio-temporal organisation of tissues (Meineke et al., 2001; Drasdo and Loeffler, 2001). These models generally consider the cell cycle as a single time unit decision and the update frequency is the global scheduler of the cell cycle.

Basically, this representation does not allow any consideration on the cell cycle phases.

Moreover, IBMs and hybrid representations with GRNs have been widely used in Artificial Life to study the mechanisms of morphogenesis (Cussat-Blanc et al., 2010; Doursat, 2006). In these studies the cell cycle has to be seen as the cell behaviour with a bio-inspiration paradigm.

Whereas molecular-based models well express the dynamics of advancement of cells in each phase of the cell cycle, the individual-based models often do not, due to their description of the cell cycle. Expressing these dynamics reveals interest to simulate some *in vitro* culture where external compounds are introduced to study their effect in the dynamics of advancement. In this work, our goal is to simulate as closely as possible the population response to an external stress expressing the dynamics of progression of the cells at a population scale. For that purpose, we use the simplicity of IBM representations to describe the cellular behaviour and to introduce temporal considerations thanks to an accurate description of the cell cycle. This approach leads us to build a hybrid representation of the cell cycle with a hand coded regulation network and probabilistic-based cellular processes. In this paper we will show the preliminary results obtained simulating a particular stage of the cell's population dynamics: the exponential growth phase, allowing us to focus on the population dynamics for the sequencing of the different phases.

The following sub-section presents the biological background of this study. Section 2 extends the model proposed in (Pascalie et al., 2010), presenting its computational aspects with a formal representation. Section 3 shows preliminary results of cell proliferation in an exponential growth phase. Finally, the last section concludes and discusses the problem of parameters tuning based on the results presented in section 3.

## Biological Background

The cell cycle is often drawn as a circular timeline with different phases starting in G1 and ending at mitosis when a cell divides into two daughter cells. The study of the cell cycle by the biologists puts major emphasis on the essential role of the checkpoints (Elledge, 1996). They are the warrants of the cell's genomic stability and their integrity ensures a good progression on the cell cycle timeline. By the end of the G1-phase, at the commitment point (R), the cell integrates environmental signals before proceeding towards the G1/S transition. A lack of these signals will lead the cell to enter a quiescent (G0) state. If pro-apoptotic signals are detected the cell will undergo death, called apoptosis. Alternatively, differentiation signals will drive the cell out of the cell cycle to a differentiation programme. If the cell progresses in the cell cycle, it must duplicate accurately all its internal material (DNA, centrosome etc) and double its mass before preparing for division. Before entering into

S-Phase where DNA synthesis occurs, the cell must check for the integrity of its genetic material. This is called the G1/S DNA integrity checkpoint. Providing that DNA synthesis is fully completed, the cell switches to G2-phase and it finishes doubling its mass. During S-phase and G2-phase, centrosome duplication and maturation occurs thus building the two platforms that will allow the assembly of the mitotic spindle required for mitosis to occur. However, before proceeding from G2 to mitosis, the cell must ensure the integrity of its genetic material again. This is called the G2/M checkpoint. At mitosis, when cells are dividing, in order to ensure even segregation of the genetic material in the two daughter cells, the mitotic checkpoint (iM) prevents division until the chromosomes are perfectly aligned on the equatorial plan. Any alteration in these checkpoint mechanisms (for instance a mutation in a key regulator) leads to a genetic instability often associated with transformation and cancer. For these reasons it is essential to integrate checkpoints as artefacts (or essential milestones) of our simulation model. Figure 1 shows a cartography of the cell cycle with the localisation of each cellular processes and checkpoint.

## Modelling Cell Behaviour

This work focuses on the temporal behaviour of cells and the different regulatory mechanisms (i.e the checkpoints) are emphasized to study their influence over population scale. This problematic drives the modelling process. For that purpose, the cell cycle specificities are described and embedded in our representation as closely as possible to *in vitro* cell cycle.

The study of the cell cycle points out the cleavage between the functional level and the regulation level. Simulation models often focus on one of these aspects, however the effective cell behaviour depends on the interaction between these two levels. In fact, the changes made on the cell's internal state by the functional level (e.g. doubling the DNA)

Figure 1: Localization of different cellular processes and checkpoints on the cell cycle timeline. Red simple-lined boxes represent checkpoints with iM being the intra-mitotic one; blue dotted boxes are processes that could be executed during the associated checkpoint; in black with arrows are represented the different processes executed during the cell cycle; the ringed R is the commitment point, another regulator, and the green double-dotted box represents the three exiting points

Figure 2: The defined regulators are connected to each other to build a finite state machine (FSM) which embed the regulatory mechanisms of the cell cycle. The schema also indicates in which position of the FSM are executed each processes.

drive the cell on a specific regulatory pathway. To represent these mechanisms and their interaction with the best accuracy possible it is necessary to observe and describe both levels in a cell cycle accurate modelling.

The two next parts will first present how we designed the cellular behaviour and its computational implementation.

## Cell Cycle Instance

The behaviour of the cell described in the introduction induces a split in sub-behaviours which represents specific cellular processes. The good sequencing and scheduling of these processes is therefore managed by the different checkpoints and/or regulators clarified above.

Figure 2 shows the network of regulators we have defined to manage the cell behaviour at a high level. The cell starts its lifecycle with as first goal to try to pass the restriction point (R). The cell cycle is therefore defined by the  $R \Rightarrow G1/S \Rightarrow G2/M \Rightarrow iM$  sequence of regulators. This pathway ends with the mitosis of the cell and represents the proliferative behaviour of the cell.

This modelling approach allows us to build a generic cell cycle model which could be used to design specific cells by instantiating specific checkpoints and processes. The following list describes the different cellular processes we designed in this study. These cellular processes have to be seen as the behaviour of the cells *during* the transition between two nodes:

- **Initialisation:** this action matches the G1-phase of the cell cycle. All cells starting their cell cycle observe this phase, which culminates at the R restriction point. During this phase, the cells have not yet been committed to proliferation, differentiation nor entry into quiescence. This process is more a delay prior to commitment point (R) than a cellular process.
- **Commitment:** this action is the planning behaviour of the cell. It occurs when the cell has ended its initialisation

and when it decides which behaviour it will execute.

- **DNA Synthesis:** this activity represents the S-phase of the classical cell cycle. It starts at the end of DNA repair - if necessary - when DNA integrity has been verified at the G1/S transition. During this action the cell replicates its DNA.
- **Growth:** this action represents the cell's mass doubling. It starts at the beginning of the S-phase and ends during the G2-phase.
- **Centrosome Duplication:** this action represents the duplication of the centrosome. It occurs simultaneously with Growth during the S- and G2-phases.
- **Mitosis:** it is the last action of the cell cycle. It requires prior checking of genomic activity at the G2/M transition. If all pre-conditions are met, mitosis occurs in the final stage of the cycle and ends with the beginning of the two new cycles of the daughter cells. Completion of mitosis requires chromosome alignment at the equatorial plan (mitotic checkpoint).

A cell is thus considered to be in G1 phase until it has passed the G1/S checkpoint (if it is executing *initialisation* or *commitment* activities to be precise). A cell is considered in the S-phase while it is executing *DNA synthesis* regardless of *growth* and *centrosome doubling*. Therefore the cell is considered in the G2 phase when it has ended its DNA synthesis and while it is ending its *growth* and its *centrosome doubling*.

The proliferation is not the only behaviour observable in this model. The regulatory network presents alternative behavioural functions of the pathway followed by a cell:

- **Differentiation** represents one of the exit points of the cell cycle. If specific conditions are met the cell will differentiate. This exiting point is available at the R node (Restriction Point) of the regulatory network.
- **Quiescence**, also named G0-Phase, is an active survey loop used when environmental factors are insufficient for the cell proliferation. The quiescent cells are able to return to the cell cycle at any time if the growing conditions are met. This alternative behaviour occurs when the cell is at the G0 node.
- **Apoptosis** represents cellular death. Apoptosis happens if apoptotic factors or signals are delivered to the cell or if the cell spends too much time in a specific stationary situation of its cell cycle. Apoptosis can occur at any time of the cell cycle.

To process the cell behaviour, the regulators (i.e the nodes of the network) are composed of a list of activities along with the preconditions of their activation. The regulators are

global schedulers for the cell cycle and have the same role as the checkpoints in real cells. They regulate the cell cycle and activate the different processes if their preconditions are fulfilled. If several activities are activated at the same time the cell executes them simultaneously. The preconditions are two sets of boolean flags:

- one representing the internal state of the cell or its disponibility of environmental factors,
- the other indicating which activities are done; under progress or planned.

The following list presents the different regulators we defined in our computational cell cycle model:

- The **R commitment point**: cell has to choose between commitment to the proliferation pathway, the quiescent stage, or the differentiation process.
- The **G1/S checkpoint**: here the cell checks its DNA for lesions. If lesions are found, the cell repairs them or else it starts DNA Synthesis, Growth and Centrosome cycle.
- The **G2/M checkpoint**: to pass through this checkpoint the cell must have replicated its DNA, should not have detected any DNA damage, have duplicated its centrosome and doubled its mass.
- The **intra-mitotic checkpoint**: to pass this checkpoint and to divide into two daughter cells, the cell needs to have aligned its chromosomes on the mitotic plan and placed its centrosomes on the mitotic spindle poles.
- The **G0 regulator**: we choose to model the G0 state as a regulator because it represents an active survey loop of environmental factors for proliferation. In order to uncorrelate the cell functional level and its regulation, we consider this particular state as a regulatory element of our cell cycle model.

DNA repair has also been added as an activity to include and study the influence of the timings of DNA damages repair.

## Computational Model

A natural population of cells presents heterogeneous features. Owing to the variability of the duration of each cell cycle phase, two cells born at the same time will not divide simultaneously even if environmental conditions were equivalent. This property is extracted from *in vitro* cultures. To represent this heterogeneity we choose to let the parameters embedded in each cell be generated according to a distribution law. Our cell cycle model is thus defined to produce a population of a specific cell type and not a single cell. If the population of cells was only represented as a population of clones of a given cell, the dynamics of the cell population

would suffer from phasing in the sequencing of the different phases, each sister cell going to division at the same time.

To represent the cellular activity in a temporal manner and remain at a macroscopic level of representation<sup>1</sup>, we based the cellular process modelling on their scheduling. In this context, 3 parameters are used for each cellular process  $i$ : the optimal time of realisation, the maximum time before it eventually results in cell death, and the probability of success. A cellular process  $i$  is thus modelled using the following parameters:

- the average optimal time of a process  $i$ :  $\mu_{avg}^i \in \mathbb{R}^+$
- the standard deviation at the population scale of the average optimal time:  $\sigma_{avg}^i \in \mathbb{R}^+$
- the average maximal time of a process  $i$ :  $\mu_{max}^i \in \mathbb{R}^+$
- the standard deviation for the average maximal time:  $\sigma_{max}^i \in \mathbb{R}^+$
- the probability of success for the process  $i$ ,  $P_s^i \in [0; 1]$ , which has to be interpreted as an efficiency potential.

To integrate the population heterogeneity the previous parameters are defined for a population. Using these parameters, we generate a set of parameters which are used for the computation. Our processes are represented over time as Bernoulli processes. The average optimal time determines the number of successes needed to consider the process as achieved. The success rate is used to define the probability of success of one trial.

We can then specify for a given cell and a specific process  $i$ :

- the optimal time to finish the process  $i$ :

$$T_{opt}^i \sim \mathcal{N} < \mu_{avg}^i, \sigma_{avg}^i >$$

- the maximal time to finish the process  $i$  before death:

$$T_{max}^i \sim \mathcal{N} < \mu_{max}^i, \sigma_{max}^i >$$

These parameters are chosen to vary over the population thanks to a normal law that follows the probability density function with  $\mu$  as mean and  $\sigma$  as standard deviation:

$$\forall t \in \mathbb{R}, \quad \phi(t, \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp^{-\frac{1}{2}\left(\frac{t-\mu}{\sigma}\right)^2}$$

This definition does not allow a zero valued  $\sigma$ . To ensure the availability of building simulation without heterogeneity, a standard deviation set up to 0 affects the specified  $\mu$  as the value of the parameter for all the cells of the population. This kind of parametrisation could be used to compare

<sup>1</sup>we do not want to model molecular interaction nor the genetic regulatory network yet

Figure 3: Example of the configuration of mean probabilities for a given process with variation of the probability  $p$  with different values of the standard deviation  $\sigma$ . The mean value for the process is defined with  $\mu = 10$ . (a)  $\sigma = 1.5$ . (b)  $\sigma = 3.5$ . (c)  $\sigma = 6.5$

the influence of the different parameters or to study specific abstract behaviours.

These generated parameters help us to customise the Bernoulli process, which takes place to compute cellular activity. Parameters that have to be defined to map the cell model on the computational model are the frequency of the Bernoulli experiences over time. This frequency will allow us to have an accurate temporal model of cells behaviours, allowing the modeller to express heterogeneity regardless of the duration of the cellular process. The last parameter that needs to be defined to end this mapping is the duration of a simulation step. This has to be done during the setup of a specific simulation and not during the cell modelling because the cell model must be as scalable as possible beside the simulation step. The Bernoulli process  $i$  taking place to simulate a cell behaviour is parametrised as follows:

- the number of successes a cell has to reach to consider its process  $i$  as well terminated:  $n_s^i \in \mathbb{N}$ ,
- the probability of success for the bernoulli experience of the process  $i$ :  $P_s^i \in [0; 1]$ ,
- the maximum number of attempts to reach  $n_s^i$  successes:  $n_{max}^i \in \mathbb{N}$ .

To help the biologist in cell cycle modelling it is important to provide him with a representative view of the parameter's influence. In this case, formal representation can help us to give a relevant view of the initialisation population. As the temporality of the cell's activities is at the centre of the modelling process, the mean probability of success over time is defined so as to characterise the dynamics of the population over time.

The probability of success in a specific process  $i$ , at the  $k$ -th trial with the probability  $p$ , for a specific cell is given by the

negative binomial law:

$$\forall k \in \mathbb{N}, \forall p \in ]0; 1[ \\ \Lambda(k; n = T_{max}^i, p = P_s^i) = C_{n+k-1}^{n-1} \cdot p^n \cdot (1-p)^k$$

This law models the probability of failure (*resp.* success) that can appear before reaching a number of successes (*resp.* failures) defined by  $n$  with each attempt associated with a probability of success  $p$ . More generally the probability of success of a process  $i$  for a given cell is given by the repartition function applying to the maximum number of attempts  $T_{max}^i$ :

$$P_s(k = T_{max}^i) = 1 - q^{k+1} \sum_{i=0}^{n-1} C_{K+i}^i \cdot p^i$$

The generalisation of the previous equations at a population scale needs to take into account the distribution of the parameters of the binomial law. The following equation computes the mean probability of success of the process  $i$  at a given Bernoulli trial  $k$  with  $\mu$ :

$$\forall k \in \mathbb{N}; \forall \mu, \sigma \in \mathbb{R}^+; \forall p \in ]0; 1[ \\ \Phi(k, \mu, \sigma, p) = \frac{1}{k} \sum_{i=0}^k P(i, \mu, \sigma) * \Lambda(k-i; i, p)$$

Figure 3 shows the interpretation of the previous equation. It can be observed that a high granularity of representation for the different cellular processes is offered to the biologists. This granularity gives to the model its genericity properties. The next section presents the preliminary results obtained with an abstract model of cell cycle based on *in vitro* observations.

## Simulation of Cells in exponential growth phase

In this paper we will study the dynamics of the cell population in an exponential growth phase. In this part we will take

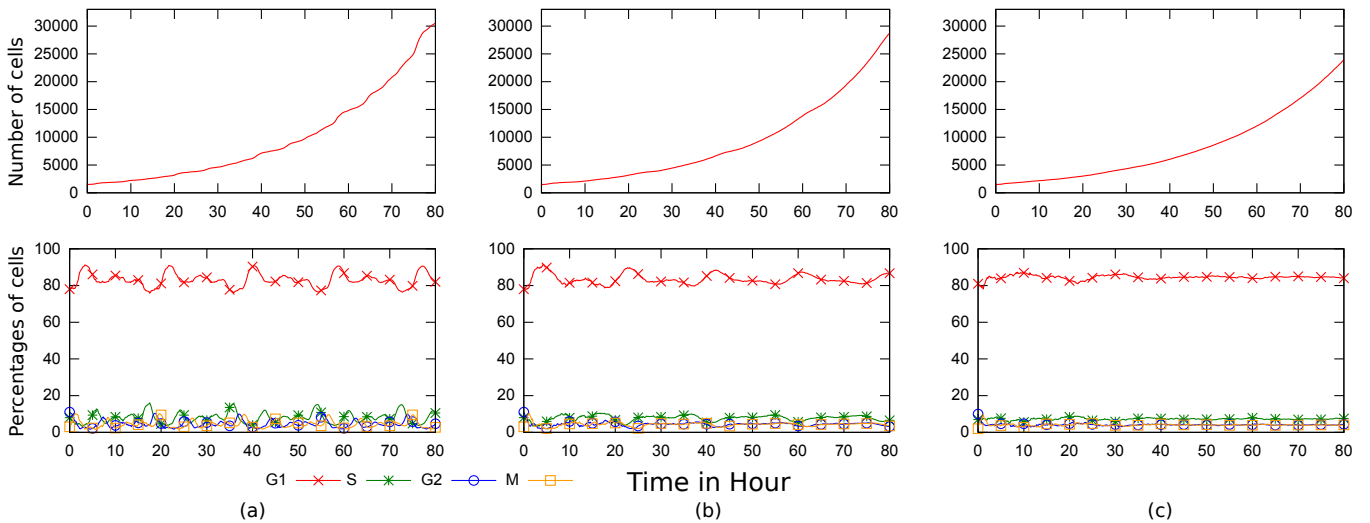

Figure 4: example of unconstrained cell development for different variability. In (a), figure shows that the system is phasing because of a too weak standard deviation over the population. Figure (b) shows the phasing pattern attenuating itself thanks to a higher variability on the G1 phase. Increasing more the standard deviation induces a flattening of the curve and a constant evolution in each phase over time which matches with *in vivo* properties.

advantage of specific features of cell proliferation that allow strong simplification of the environment. Indeed, during exponential growth phase, cell proliferation is not inhibited by environmental signals, the environment being saturated in growth factors. This property allows the simplification of the chemical aspects of the environment, dispensing it with diffusion algorithm and chemical reactions.

The other inhibition factor undergone by the cells is the contact inhibition. It is not observed, in an exponential growth phase. This specificity allows us to dispense the environment and the simulation with physical consideration. The cells do not have shapes and they do not need to interact with each other. As our goal is to study the dynamics of the population and not its topological aspects, these simplifications are adapted to this first step.

In an exponential growth phase, the cell proliferation reveals that the ratio of cells in each phase (G1,S,G2,M) of the cell cycle remains constant over time. This property must be expressed in our model before testing the immersion of cells in a complex environment. To test this, an abstract model of cell behaviour based on the HCT116 cell (a colon cancer cell line often used by biologists for *in vitro* studies) lineage was designed. Experimentally, we have determined, by flow cytometry analysis, that in *in vitro* culture conditions, these cells spend 81% of their cycle in G1-phase, 10% in S-phase, 7% in G2-phase and 2% in Mitosis, for a global duration of the cell cycle of 18 hours. These measures are used to set up the  $T_{opt}$  value of the different activities.

These percentages also correspond to the distribution of cells in the different phases of the cell cycle. These param-

eters determine the initial distribution of the cells for the simulation. It should remain constant over time if the cell model is generic enough and if the designed population is heterogeneous enough.

Figure 4 shows exponential growth simulations executed with different values for the standard deviation  $\sigma_{max}$ . Those results are the average of 10 runs with the same parameters. It is important to specify that even though the random generator seed is not the same from one run to another the stability of the simulation results is not affected.

Curves (a) show the dynamics of the population with an homogeneous population of cells. We can observe that the dynamics of the population oscillates between each phase and that the initialisation pattern reproduces itself over time.

Curves (b) show a simulation where the variability of the *initialisation* action and of the *commitment* action have been increased. The initialization pattern is still present but we can observe that it is attenuating over time. This is essentially due to the fact that, after a cell division, all temporal parameters are reinitialise in daughter cells.

Curves (c) show the result of a 2-D culture with a high variability of *initialisation* and *commitment* action. The evolution of the population in each phase is constant over time. The heterogeneity of the population is high enough to maintain a constant rate in each phase.

In order to evaluate the heterogeneity of the population, the second experiment consists in taking only cells in mitosis from a population and to observe the desynchronisation of that population over time. Figure 5 shows, with the same parameters as in the previous experiment, the development

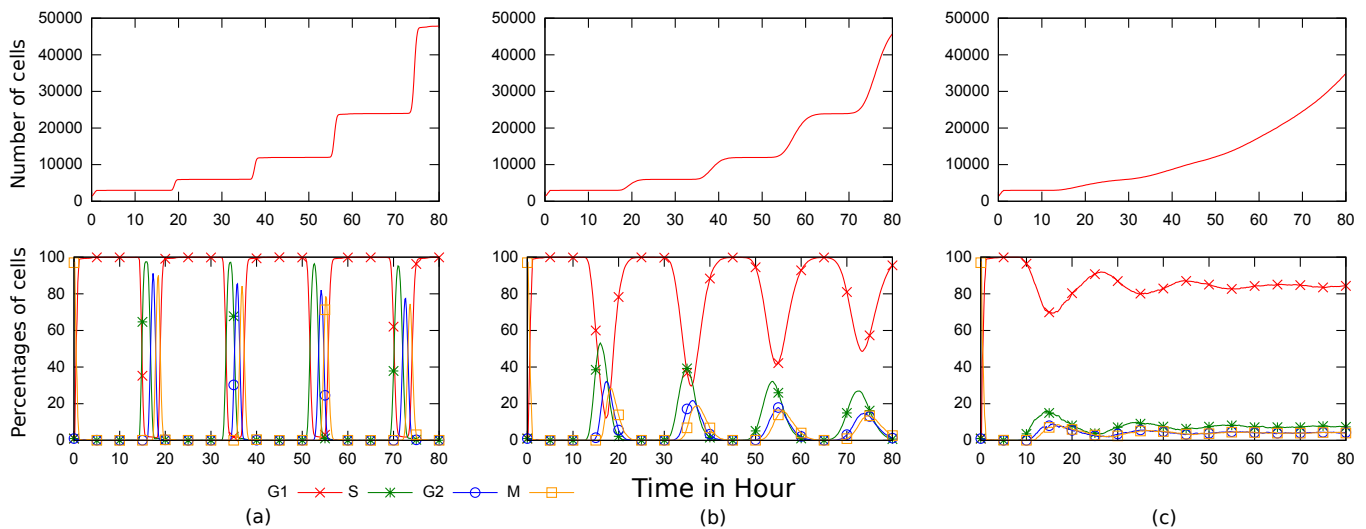

Figure 5: Example of population unsynchronisation, we can observe on the population growth curve the different steps before reaching a power law, if the simulation had lasted longer the dynamics of the population would have remained constant. (a) No unsynchronisation is observed because of homogeneous population. (b) and (c) The attenuation pattern is function of the degree of variability introduced in the simulation.

of a 2-D culture with all the initial population synchronised in the mitosis phase. The cells are not synchronised in a temporal manner, this means that they will not divide at the same time except in the first population which is homogeneous. As previously, the experiment (a) with fixed temporal value does not unsynchronise over time. The second experiment (b) shows that the population unsynchronises over time but that the phasing pattern needs more than 7 or 8 cycles to unsynchronise whereas in the third experiment (c) it loses synchrony by the end of the fourth cycle. More generally, if the cell population is heterogeneous enough, whatever the parameters of initialisation are, the dynamics of the population will balance itself until it observes a constant evolution over time.

## Conclusion

These preliminary results point out that the model can reproduce the dynamics of cell proliferation in an exponential growth phase. What becomes apparent is that the model - and more globally the simulations - is difficult to tune because of the high number of parameters. The main difficulty of tuning is related to undimensional parameters that cannot be defined with values measured with *in vivo* experiments. In the proposed model there are two kinds of parameter sets. The first one is the set of the known biological parameters. It is the set of the parameters that can easily be tuned thanks to biological knowledge or measurement. The other set contains some control parameters, which are difficult to tune because they define a global dynamics for the system. The influence of the different values is not predictable, therefore predicting the influence of the different combinations

becomes difficult.

We propose a strategy to validate the cell cycle models before it. The *in vitro* observation of cells exergues that the ratio of each cell phase during an exponential growth is constant. With this piece of information, the ratio of cells in each phase and the global duration of the cell cycle, the optimal duration for each activity can be deduced. The  $T_{opt}$  parameter is thus easily definable for each activity. The different  $T_{max}$  parameters could also be defined thanks to *in vitro* observation. As shown in the modelling section, we need to set up the standard deviation to build a heterogeneous population of cells. These values do not have a biological representation concerning a cell model and fitting them is difficult. The first step of the modelling process consists in tuning these parameters to obtain a simulation with a constant evolution of the ratio of cells in each phase.

To help the biologists in this process a dedicated tool is built for cell cycle modelling. This tool offers to the biologists a means of visualization for the duration of each activity, taking into account its different parameters. The modeller can then adjust his parameter values in function of his knowledge of the temporal behaviour of the cell cycle being designed.

Figure 3 shows the kind of output offered by this tool. In this case the output is average duration of a dedicated activity function of its  $T_{opt}$  value and its rate of success. The modeller should use this feedback to adjust the different parameters until the different values suit his purpose.

The second step of the modelling process is to reproduce the experiment of mitosis unsynchronisation to verify if the population is not too heterogeneous. The expected be-

haviour of a population of cells in this kind of simulation can be extracted from *in vitro* culture. In other words, the modeller is able to define the number of cycles needed to observe a constant evolution in each phase. If the heterogeneity of the population is too high the unsynchronisation will occur too early in the simulation and further experiments would be biased by this behaviour.

The sequential aspect and the properties of the model suggest that this modelling protocol could be automatised. In further work we could try to express the different probabilities of transition between the different phases (i.e G1,S,G2,M) and try to find the best set of standard deviation parameters for an expected simulation result i.e a constant evolution of the ratio of cells in each phase.

The simplified environment will shortly be extended to a 2-D continuous environment and, finally, to a 3-D continuous environment. This will allow to reach the final aim of simulating the spatial organisation of multicellular tumour spheroids. As an intermediate step, all the 2-D monolayer classical experiments done *in vitro* will be reproduced *in silico*. This step will evaluate the response and the influence of the physical model by comparison between the results of the simulation with the proposed simplify environment and *in vitro* experiments.

Precisely, this 2-D prototype will be validated by evaluating the convergence of *in vitro* experiments and *in silico* simulation with specific scenarii. For example, we will use the following validation experiments: cell cycle synchronisation through a lack of environmental factors (arrest in G0); cell cycle synchronisation using a procedure known as double thymidine block (arrest at G1/S); application of a compound targeting the assembly of the microtubules (arrest at mitosis); etc.

## Abstract

Gene expression is commonly modulated by a set of regulating gene products, which bind to a gene's *cis*-regulatory region. This region encodes an input-output function, referred to as signal-integration logic, that maps a specific combination of regulatory signals (inputs) to a particular gene expression state (output). The space of all possible signal-integration functions (genotypes) is vast and highly redundant: for the same set of inputs, many functions yield the same expression output (phenotype). Here, we exhaustively characterize signal-integration space within a computational model of genetic regulation. Our goal is to understand how the inherent redundancy of signal-integration space affects the relationship between robustness and evolvability in regulatory circuits. Among a number of results, we show that robust phenotypes are (i) evolvable, (ii) easily identified by random mutation, and (iii) mutationally biased toward other robust phenotypes. We then explore the implications of these results for mutation-based evolution by conducting an ensemble of random walks between randomly chosen source and target phenotypes. We demonstrate that the time required to identify the target phenotype is independent of the properties of the source phenotype.

## Introduction

Living organisms exhibit two seemingly paradoxical properties: They are robust to genetic change, yet highly evolvable (Wagner, 2005). These properties appear contradictory because the former requires that genetic alterations leave the phenotype intact, while the latter requires these alterations to be used for the exploration of new phenotypes. Despite this apparent contradiction, several empirical analyses of living systems, particularly at the molecular scale, have revealed that robustness often facilitates evolvability (Bloom et al., 2006; Ferrada and Wagner, 2008; Isalan et al., 2008). In the cytochrome P450 BM3 protein, for example, increased protein stability — defined as the tendency of a protein to adopt its native structure in the face of mutation — increases the probability that mutants can exploit new substrates (Bloom et al., 2006).

To clarify the relationship between robustness and evolvability, several theoretical models have been proposed (*e.g.*, Newman and Engelhardt (1998); Wagner (2008a); Draghi

et al. (2010)). A common feature of these models is the concept of a genotype network (a.k.a. neutral network). In such a network, each node represents a genotype and edges connect genotypes that share the same phenotype and can be interconverted via single mutational events. In the case of RNA, for example, nodes represent DNA sequences and two nodes are connected if their corresponding sequences confer the same secondary structure, yet differ by a single nucleotide (Schuster et al., 1994). Large genotype networks thus correspond to robust phenotypes, where most mutations are neutral and therefore leave the phenotype unchanged. Phenotypic robustness confers evolvability because a population can diffuse neutrally throughout the genotype network (Huynen et al., 1996) and build up genetic diversity, which allows access to novel phenotypes through non-neutral point mutations into adjacent genotype networks (Wagner, 2008a).

Genotype networks have been used to explore the relationship between robustness and evolvability in a variety of biological systems, ranging from the molecular (Schuster et al., 1994; Cowperthwaite et al., 2008; Ferrada and Wagner, 2008; Wagner, 2008b) to the cellular level (Aldana et al., 2007; Ciliberti et al., 2007a,b; Mihaljev and Drossel, 2009). In the latter case, the phenotype of interest is typically a gene expression pattern and its corresponding genotype is a gene regulatory network, which consists of a structured set of gene products that activate and inhibit one another's expression. Gene expression is controlled by a gene's *cis*-regulatory region (Fig. 1A), which can be thought to perform a computation (Fig. 1B), using the regulating gene products as inputs. The regulatory program that encodes this computation is referred to as signal-integration logic.

Previous studies of the robustness and evolvability of gene regulatory networks have focused on the specific case where genetic perturbations alter network structure by adding or deleting regulatory interactions (Aldana et al., 2007; Ciliberti et al., 2007a,b; Mihaljev and Drossel, 2009). In this case, two gene regulatory networks are connected in the genotype network if they confer the same gene expression pattern, yet differ in a single regulatory interaction. The correspond-

ing genotype network is therefore a “network of networks” (Ciliberti et al., 2007b). These analyses have revealed several general properties of gene regulatory networks. First, robustness is an evolvable trait (Ciliberti et al., 2007b; Mihaljev and Drossel, 2009). Second, phenotypes are made up of vast genotype networks that span throughout the space of all possible genotypes (Ciliberti et al., 2007a; Mihaljev and Drossel, 2009); and third, highly robust phenotypes are often highly evolvable (Aldana et al., 2007; Ciliberti et al., 2007a).

While these studies have helped to elucidate the relationship between robustness and evolvability in gene regulatory networks, they are limited by their assumption that genetic perturbations primarily affect network structure. It is well known that the presence or absence of regulatory interactions is not the only determining factor of gene expression patterns (Setty et al., 2003; Mayo et al., 2006; Kaplan et al., 2008; Hunziker et al., 2010). By altering the arrangement of promoters and transcription factor binding sites (Fig. 1A, shaded boxes) in a gene’s *cis*-regulatory region, the signal-integration logic of gene regulation can be dramatically influenced. For example, by simply rearranging the location of transcription start sites in the promoter region of a reporter gene in the galactose network of *Escherichia Coli*, it is possible to generate 12 out of the 16 possible Boolean outputs (Hunziker et al., 2010). Thus, it is not only the structure of regulatory interactions that affects robustness and evolvability, but also the logic of signal-integration used in the *cis*-regulatory region of each gene. When genetic perturbations correspond to changes in the signal-integration logic, two gene regulatory networks are connected in the genotype network if they are topologically identical and confer the same gene expression pattern, yet differ in a single element of their signal-integration logic. The extent to which genetic perturbations in the signal-integration logic of gene regulatory networks affect robustness and evolvability remains largely unexplored. Further, the ease with which a phenotype is accessed by blind mutation, and how this relates to robustness and evolvability in the signal-integration logic of gene regulation, has not been addressed.

Here, we investigate the relationship between robustness and evolvability in the signal-integration logic of model gene regulatory circuits. These small circuits are ideal for this investigation because their genotype networks are exhaustively enumerable, which allows for a full characterization of the relationship between robustness and evolvability. To understand how robustness and evolvability influence mutation-based evolution, we conduct an ensemble of random walks between randomly chosen source and target phenotypes. We discuss the implications of our results and present directions for future work.

Figure 1: (A) Schematic of genetic regulation, where gene products  $a$  and  $b$  serve as regulatory inputs, attaching to their respective binding sites (gray shaded boxes) in the *cis*-regulatory region of gene  $c$  to influence its expression. The input-output function encoded in this regulatory region is called signal-integration logic and can be modeled as (B) a discrete function that explicitly maps all of the  $2^z$  input-output combinations of a  $z$ -input function. Here,  $z = 2$ . (C) All interactions between gene products  $a$ ,  $b$ , and  $c$  can be represented as a Random Boolean Circuit (RBC) with  $N = 3$  nodes. Gene product  $c$  possesses the same regulatory inputs and signal-integration logic as in (A) to clearly depict how the RBC abstraction captures genetic regulation. (D) The signal-integration logic of every node in the RBC can be simultaneously represented with a single rule vector by concatenating the rightmost columns of each node’s look-up table. (E) The dynamics of the RBC begin with an initial state (e.g.,  $\langle 011 \rangle$ ) and eventually settle into an attractor (gray shaded region).

## Methods

### Random Boolean Circuits

We use Random Boolean Circuits (RBCs) to model genetic regulation (Kauffman, 1969). RBCs are composed of nodes and directed edges (Fig. 1C). Nodes represent gene products and edges represent regulatory interactions. Two nodes  $a$  and  $c$  are connected by a directed edge  $a \rightarrow c$  if the expression of gene  $c$  is regulated by gene product  $a$ . Node states are binary, reflecting the presence (1) or absence (0) of a gene product, and dynamic, such that the state of a node at time  $t + 1$  is dependent upon the states of its regulating nodes at time  $t$ . This dependence is captured by a look-up table associated with each node, which explicitly maps all possible combinations of regulatory input states to an output expression state. This look-up table is analogous to the

signal-integration logic encoded in *cis*-regulatory regions. The signal-integration logic of all of the nodes in the network can be simultaneously represented using a single *rule vector* (Fig. 1D).

The dynamics of RBCs occur in discrete time with synchronous updating of node states (Fig. 1E). The dynamics begin at a pre-specified initial state, which can be thought to represent regulatory factors upstream of the circuit (Ciliberti et al., 2007a; Martin and Wagner, 2009). The dynamics then unfold according to the circuit's structure and signal-integration logic. Since the system is both finite and deterministic, its dynamics eventually settle into an attractor (Kauffman, 1969), which represents the gene expression pattern, and is referred to as the phenotype. We refer to the combination of circuit structure, rule vector, and initial state as an *instance* of a RBC.

While simple, the Boolean abstraction has proven capable of precisely replicating specific properties of genetic regulation in natural systems. For example, variants of the model have emulated the expression patterns of the fruit fly *Drosophila melanogaster* (Albert and Othmer, 2003), the plant *Arabidopsis thaliana* (Espinosa-Soto et al., 2004), and the yeast *Saccharomyces pombe* (Davidich and Bornholdt, 2008). Due to their accuracy in capturing the dynamics of genetic regulation, and because the signal-integration logic of each gene is explicitly represented, RBCs are ideal synthetic systems for investigating the relationship between robustness and evolvability when genetic perturbations correspond to changes in signal-integration logic.

## Dynamical Regimes of RBCs

An important feature of RBCs is that they exhibit three dynamical regimes: ordered, critical, and chaotic (Kauffman, 1969). In the ordered regime, gene expression patterns are relatively insensitive to perturbations, while in the chaotic regime they are highly sensitive. The critical regime delineates these two extremes. For randomly constructed circuits, the transitions between regimes are controlled by two parameters: the average in-degree  $z$  and the probability  $\rho$  of gene expression (*i.e.*, the probability of observing a 1 in the rule vector). Letting  $S = 2\rho(1 - \rho)z$ , the RBC lies in the ordered regime when  $S < 1$ , the critical regime when  $S = 1$ , and the chaotic regime when  $S > 1$ . When there is an equal probability of observing a 0 or a 1 in the rule vector ( $\rho = 0.5$ ) the dynamical regime is determined solely by the average in-degree, with  $z < 2$  yielding the ordered regime,  $z = 2$  the critical regime, and  $z > 2$  the chaotic regime. In this study,  $\rho = 0.5$ .

## Genotype Networks

We refer to the signal-integration logic of a RBC, as represented by its rule vector (Fig. 1D), as the genotype. There are a total of  $2^L$  unique genotypes for a given combination of circuit structure and initial state, where  $L = N2^z$ . We refer

to this set of genotypes as the genotype space, or equivalently, as the signal-integration space. For the RBCs considered here, the size of the genotype space ranges from  $2^6$  for the ordered regime to  $2^{24}$  for the chaotic regime.

These genotypes map to a significantly smaller set of phenotypes. This high level of redundancy is a general feature of RBCs, and can be formalized using a genotype network, in which rule vectors are represented as nodes, and edges connect rule vectors that differ by a single bit, yet yield the same gene expression pattern (*i.e.*, phenotype). Thus, we define a neutral point mutation as a single change to an element of the genotype that does not lead to a change in phenotype. Such a mutation is analogous to a change in the position of a transcription factor binding site in the *cis*-regulatory region that leaves the gene expression pattern unchanged. Genotype networks are measured using an exhaustive breadth-first search, thus discovering all genotypes that yield the same phenotype and are accessible via neutral point mutations, starting from the original genotype of the RBC instance.

The quantity  $v_{ij}$  captures the number of unique non-neutral point mutations to genotypes in the genotype network of phenotype  $i$  that lead to genotypes in the genotype network of phenotype  $j$ . We call phenotypes  $i$  and  $j$  adjacent if  $v_{ij} > 0$ . By enumerating all of the phenotypes that are adjacent to phenotype  $i$ , and their corresponding genotype networks, we capture the mutational biases between adjacent phenotypes.

## Robustness, Evolvability, and Accessibility

Several definitions of robustness and evolvability have been proposed, at both the genotypic and phenotypic scales (Alldana et al., 2007; Wagner, 2008b; Mihaljev and Drossel, 2009; Draghi et al., 2010). Here, we focus on these properties at the level of the phenotype. We define robustness  $R_i$  as the proportion of signal-integration space occupied by the genotype network of phenotype  $i$ . This metric is independent of rule vector length  $L$ , and captures the fraction of all genotypes that yield the same phenotype and can be accessed via neutral point mutations.

We define evolvability using two metrics. The first  $E_{1,i}$  is simply the number of phenotypes that can be accessed through non-neutral point mutations from the genotype network of phenotype  $i$  (Wagner, 2008b). The second  $E_{2,i}$  captures the mutational biases that exist between the genotype networks of adjacent phenotypes (Cowperthwaite et al., 2008). Letting

$$f_{ij} = \frac{v_{ij}}{\sum_{k \neq i} v_{ik}} \quad (1)$$

denote the fraction of non-neutral point mutations to genotypes of phenotype  $i$  that result in genotypes of phenotype  $j$ , we define the evolvability  $E_{2,i}$  of phenotype  $i$  as

$$E_{2,i} = 1 - \sum_j f_{ij}^2. \quad (2)$$

Since  $\sum_j f_{ij}^2$  captures the probability that two randomly chosen non-neutral point mutations to genotypes of phenotype  $i$  result in genotypes with identical phenotypes, its complement  $E_{2,i}$  captures the probability that these same mutations result in genotypes with distinct phenotypes. This metric takes on high values when a phenotype is adjacent to many other phenotypes and its non-neutral point mutations are uniformly divided amongst these phenotypes. The metric takes on low values when a phenotype is adjacent to only a few other phenotypes and its non-neutral point mutations are biased toward a subset of these phenotypes.

In addition to measuring evolvability, which captures the uniformity of non-neutral mutations from phenotype  $i$  into adjacent phenotypes, we also consider accessibility

$$A_i = \sum_j f_{ji}, \quad (3)$$

which captures the propensity to mutate into phenotype  $i$  (Cowperthwaite et al., 2008). This metric takes on high values if the phenotypes adjacent to phenotype  $i$  are mutationally biased toward  $i$  and low values otherwise.

Lastly, we measure the robustness of all phenotypes that are adjacent to phenotype  $i$ , in proportion to the probability that these phenotypes are encountered through a randomly chosen, non-neutral point mutation from phenotype  $i$  (Cowperthwaite et al., 2008). We refer to this quantity as adjacent robustness,

$$B_i = \sum_j f_{ij} \times R_j. \quad (4)$$

This metric takes on high values when a phenotype is mutationally biased toward robust phenotypes and low values otherwise.

## Simulation Details and Data Analysis

For all RBC instances, the rule vector and initial state are generated at random with  $\rho = 0.5$ . The circuit structure is also generated at random, but subject to the constraint that each node has exactly  $z$  inputs. Self-loops are permitted, mimicking autoregulation. We separately consider RBCs in the ordered, critical, and chaotic regimes by setting  $z = 1, 2, 3$ , respectively. The initial state and circuit structure are held fixed for each RBC instance. To ensure that all of the genotype networks considered in this study are amenable to exhaustive enumeration, we restrict our attention to RBCs with  $N = 3$  nodes. While small, sensitivity analysis (Derrida and Pomeau, 1986) confirms that these RBCs exhibit the same dynamical regimes as larger networks, albeit with shorter attractors. To assess the strength and significance of the trends in our data, we employ Pearson's correlation coefficient.

## Results

### Characteristics of Genotype Networks

To characterize the genotype networks of signal-integration space in RBCs, we randomly generate 2500 RBC instances for each dynamical regime and exhaustively characterize the genotype networks of their corresponding phenotypes, and the genotype networks of all adjacent phenotypes.

The range of phenotypic robustness  $R$  varies with dynamical regime, with ordered RBCs spanning the smallest range ( $3.12 \times 10^{-2} \leq R \leq 1.25 \times 10^{-1}$ ), critical RBCs spanning an intermediate range ( $4.88 \times 10^{-4} \leq R \leq 1.25 \times 10^{-1}$ ), and chaotic RBCs spanning the largest range ( $1.19 \times 10^{-7} \leq R \leq 1.25 \times 10^{-1}$ ). The maximum value of phenotypic robustness is independent of dynamical regime, and corresponds to fixed-point attractors. Since these attractors comprise a single state, only  $N$  bits of the rule vector are accessed during the RBC's dynamics, leaving  $L - N$  bits unused. Thus, the corresponding genotype network is of size  $2^{L-N}$ , with phenotypic robustness  $R_{\max} = 2^{-N} = 1.25 \times 10^{-1}$ . The average phenotypic robustness decreases from the ordered ( $R = 9.44 \times 10^{-2}$ ) to the critical ( $R = 4.12 \times 10^{-2}$ ) to the chaotic ( $R = 3.02 \times 10^{-2}$ ) regime.

Evolvability  $E_1$  and phenotypic robustness  $R$  are positively correlated (Fig. 2A), and the strength of correlation increases from the ordered ( $r = 0.75, p \ll 0.01$ ) to the critical ( $r = 0.90, p \ll 0.01$ ) to the chaotic ( $r = 0.98, p \ll 0.01$ ) regime. This indicates that, in this system, no trade-off exists between robustness and the number of phenotypes accessible via non-neutral point mutations; the more robust the phenotype, the higher its evolvability. Average evolvability  $E_1$  increases faster than linearly with increasing  $z$ , indicating a rapid increase in the number of adjacent phenotypes as the dynamical regime shifts from ordered to chaotic (Fig. 2A, inset).

When mutational biases between adjacent phenotypes are taken into account using  $E_2$ , a slightly different relationship is observed between evolvability and phenotypic robustness (Fig. 2B). RBCs in the ordered regime exhibit a weak and insignificant correlation between  $E_2$  and  $R$  ( $r = 0.02, p = 0.41$ ). In contrast, RBCs in the critical and chaotic regimes exhibit weak, but significant correlations, with the strength of correlation increasing from the critical ( $r = 0.10, p \ll 0.01$ ) to the chaotic regime ( $r = 0.42, p \ll 0.01$ ). The average value of  $E_2$  increases approximately linearly as  $z$  increases (Fig. 2B, inset). Thus, the average probability that two randomly chosen, non-neutral point mutations lead to distinct phenotypes is only  $\approx 15\%$  higher in chaotic RBCs than in ordered RBCs, despite the four order-of-magnitude difference in the absolute number of adjacent phenotypes (Fig. 2A, inset).

Accessibility  $A$  and phenotypic robustness  $R$  are positively correlated (Fig. 2C), with the strength of correlation again increasing from the ordered ( $r = 0.88, p \ll 0.01$ )

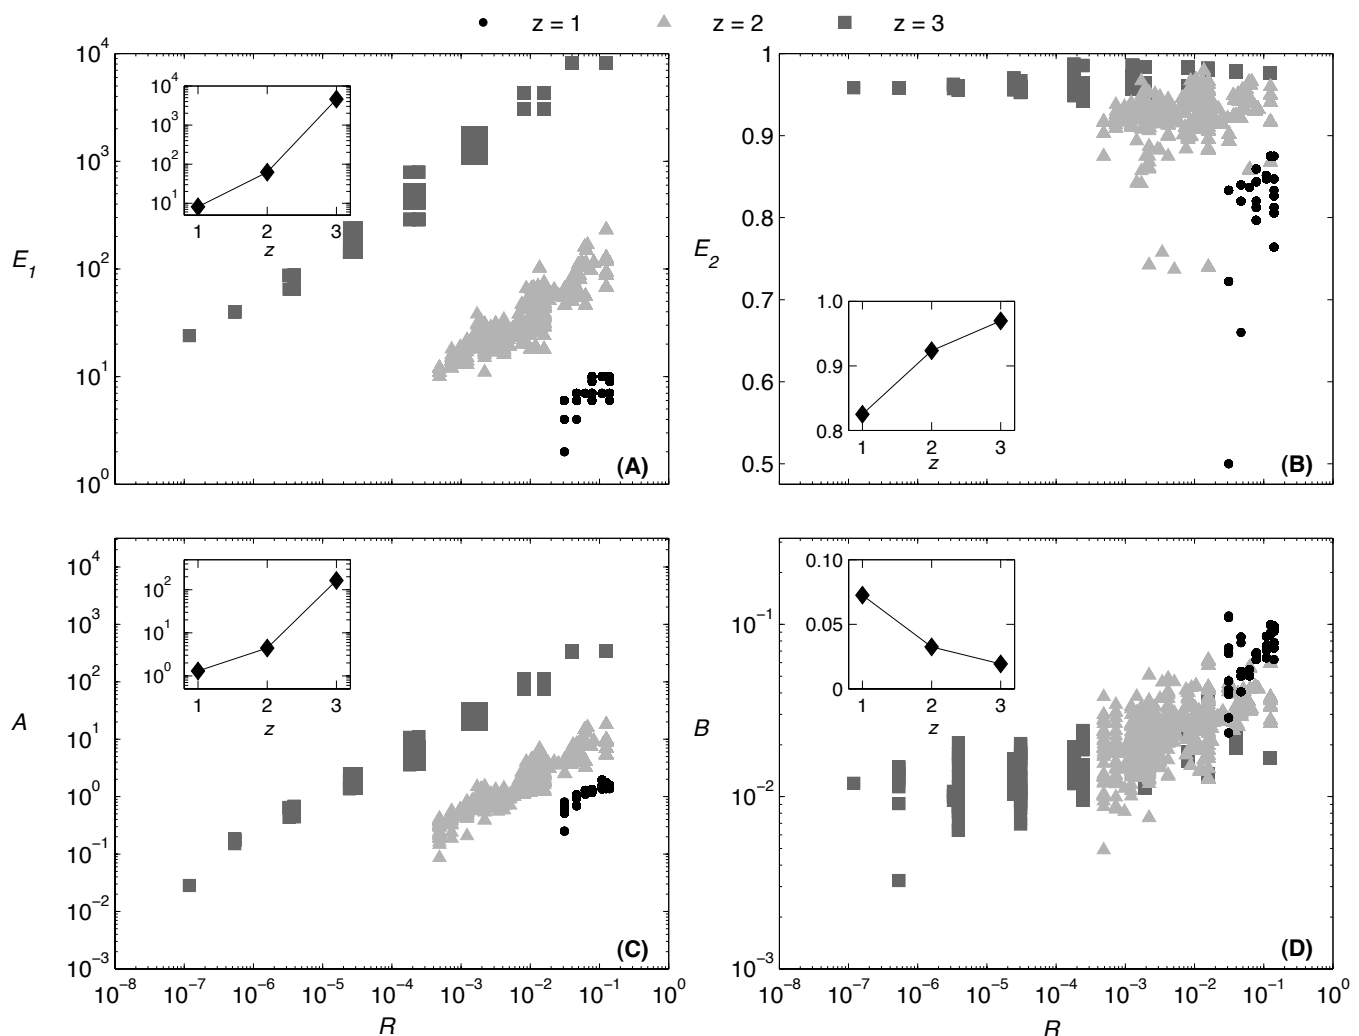

Figure 2: (A,B) Evolvability, (C) accessibility, and (D) adjacent robustness as a function of phenotypic robustness  $R$  for each of the three dynamical regimes: ordered ( $z = 1$ ), critical ( $z = 2$ ), and chaotic ( $z = 3$ ). Each data point represents one of 2500 RBC instances for each dynamical regime. The insets depict the corresponding averages, as a function of  $z$ . Lines are provided as a guide for the eye.

to the critical ( $r = 0.94, p \ll 0.01$ ) to the chaotic ( $r = 0.98, p \ll 0.01$ ) regimes. This implies that, for all three dynamical regimes, random point mutations are more likely to lead to robust phenotypes than to non-robust phenotypes. Average accessibility increases faster than linearly as  $z$  increases (Fig. 2C, inset), indicating a rapid increase in the relative ease with which phenotypes are found by random mutation as the dynamical regime shifts from ordered to chaotic.

Adjacent robustness  $B$  and phenotypic robustness  $R$  are positively correlated, with the strength of correlation decreasing from the ordered ( $r = 0.81, p \ll 0.01$ ) to the critical ( $r = 0.66, p \ll 0.01$ ) to the chaotic regimes ( $r = 0.35, p \ll 0.01$ ). This implies that non-neutral point mutations to genotypes within robust phenotypes often lead to

other robust phenotypes, but that the strength of this tendency weakens as RBCs approach the chaotic regime. The average adjacent robustness  $B$  decreases approximately linearly as  $z$  increases (Fig. 2D, inset), indicating that the expected robustness of a phenotype encountered via non-neutral point mutation decreases as the dynamical regime shifts from ordered to chaotic.

Taken together, these results suggest that a series of random point mutations will tend toward phenotypes of increased robustness (Fig. 2D) and correspondingly increased evolvability (Fig. 2A,B). Further, the ease with which such a blind evolutionary process identifies an arbitrary phenotype should increase with that phenotype's robustness (Fig. 2C) and as the dynamical regime shifts from ordered to critical to chaotic (Fig. 2C, inset).

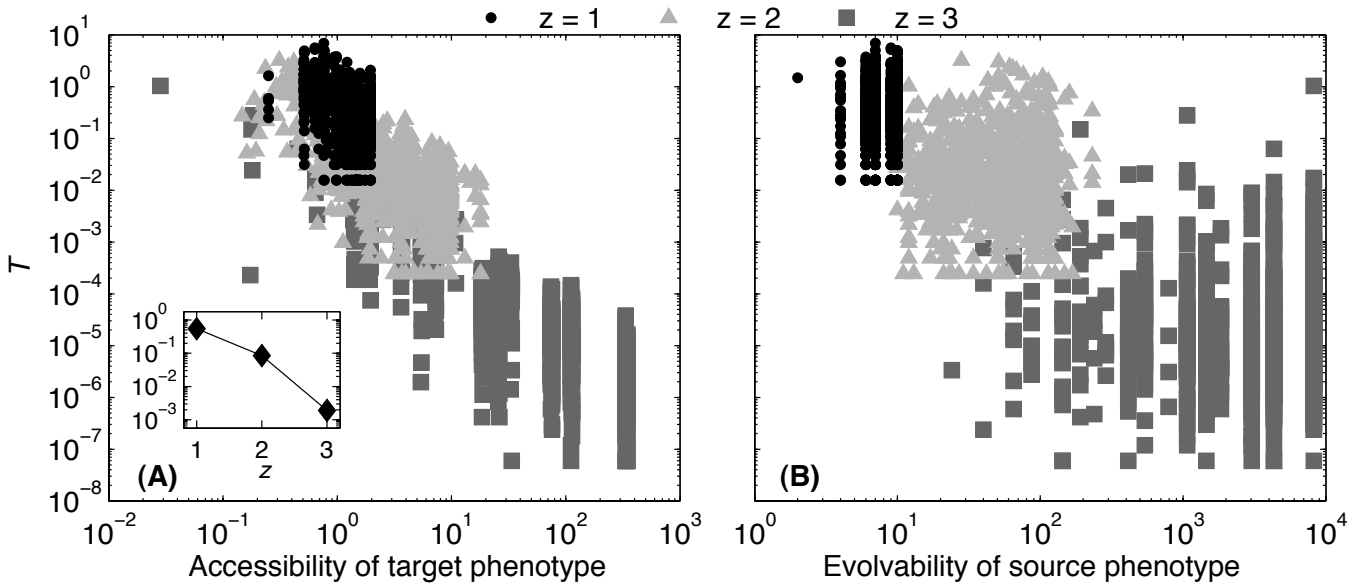

Figure 3: Waiting time of a random walk  $T = S/2^L$  as a function of (A) the target phenotype's accessibility  $A$  and (B) the source phenotype's evolvability  $E_1$ , for each of the three dynamical regimes: ordered ( $z = 1$ ), critical ( $z = 2$ ), and chaotic ( $z = 3$ ). The inset in (A) depicts the average waiting time  $T$  as a function of  $z$ . Lines are provided as a guide for the eye.

### Random Walks Through Signal-Integration Space

To investigate how robustness, evolvability, and accessibility influence blind, mutation-based evolution, we conduct an ensemble of random walks. For each dynamical regime, we randomly generate 1000 RBC instances and identify the phenotype of each instance as a source phenotype. For each instance, we then sample the genotype space at random until we discover a genotype that yields a different phenotype from the source phenotype, and we identify this as the target phenotype. For each pair of source and target phenotypes, we then perform a random walk, starting from the instance's genotype and ending when the random walk reaches any genotype in the target phenotype. Each step in the random walk corresponds to a single point mutation to the genotype. We record the number of steps  $S$  required to reach the target phenotype, which we normalize by the size of the signal-integration space  $2^L$ , and refer to as the waiting time  $T = S/2^L$ .

Waiting time  $T$  decreases faster than linearly as  $z$  increases (Fig. 3A, inset). For all three dynamical regimes, waiting time is strongly negatively correlated with the accessibility  $A$  of the target phenotype (Fig. 3A), and the strength of correlation increases from the ordered ( $r = -0.41, p \ll 0.01$ ) to the critical ( $r = -0.67, p \ll 0.01$ ) to the chaotic ( $r = -0.82, p \ll 0.01$ ) regime. In contrast, the correlation between waiting time  $T$  and the evolvability  $E_1$  of the source phenotype is weak and insignificant ( $z = 1 : r = -0.03, p = 0.38$ ;  $z = 2 : r = 0.01, p = 0.82$ ;  $z = 3 : r = -0.02, p = 0.56$ ) (Fig. 3B). Similarly weak and insignificant correlations were observed between wait-

ing time  $T$  and other characteristics of the source phenotype, such as  $E_2$ ,  $A$ , and  $B$ . These results indicate that the time required for a blind evolutionary search to identify a target phenotype is independent of the phenotypic properties of the starting point and solely dependent upon the phenotypic properties of the target.

### Discussion

This study has provided the first characterization of genotype networks in the signal-integration space of Random Boolean Circuits (RBCs), highlighting the relationship between robustness and the evolvability and accessibility of phenotypes. We found a positive correlation between robustness and evolvability, as measured by either the absolute number of adjacent phenotypes  $E_1$  (Fig. 2A) or by the probability that two non-neutral point mutations lead to distinct phenotypes  $E_2$  (Fig. 2B). Our results corroborate the observation made in previous studies that gene regulatory networks can simultaneously exhibit robustness and evolvability (Aldana et al., 2007; Ciliberti et al., 2007a,b). Further, our analyses extend these previous studies by providing an explicit description of this relationship and by considering genetic perturbations that alter the signal-integration logic encoded in *cis*-regulatory regions, instead of genetic perturbations that alter circuit structure.

We also found a positive correlation between robustness and accessibility (Fig. 2C), a measure that captures the relative ease with which a phenotype can be identified by mutation-based evolution. This result supports the intuitive notion that phenotypes comprising many genotypes are eas-

ier for evolution to identify than those comprising few genotypes. In addition, robust phenotypes are mutationally biased toward other robust phenotypes (Fig. 2D), indicating that the robustness of phenotypes encountered by blind mutation-based evolution should, on average, tend to increase.

To understand how phenotypic robustness, evolvability, and accessibility in signal-integration space influence mutation-based evolution, we considered an ensemble of random walks between pairs of source and target phenotypes. We found that the number of random mutations required to reach the target phenotype was entirely dependent upon its accessibility (Fig. 3A) and independent of any properties of the source phenotype (Fig. 3B). This suggests that a random walk through signal-integration space quickly loses any memory of its starting location. Consequently, extant evolvability metrics cannot be expected to predict the duration of a random walk between phenotypes.

The majority of our results are consistent with those made in RNA systems (Cowperthwaite et al., 2008; Wagner, 2008b). However, there is one difference worth emphasizing: the correlation between robustness and evolvability  $E_2$  is negative in RNA (Cowperthwaite et al., 2008). Since the relationship between robustness and adjacent robustness  $B$  is positive in RNA systems, Cowperthwaite et al. (2008) concluded that robust phenotypes act as “evolutionary traps.” That is, random mutation will tend toward phenotypes of higher robustness, which in turn are less evolvable, and therefore stagnate evolutionary search. Since we observed a positive correlation between (i) robustness and evolvability  $E_2$  and (ii) robustness and adjacent robustness  $B$ , we conclude that robust phenotypes in the signal-integration space of RBCs are not evolutionary traps, but instead facilitate the discovery of novel phenotypes. Such contrast between model systems highlights the fact that the relationships between robustness, evolvability, and accessibility are system dependent.

Evolvability increased monotonically as  $z$  increased (Fig. 2A,B, insets) and the maximum achievable robustness was independent of  $z$  ( $R_{\max} = 2^{-N}$ ). Taken together, these results indicate that robustness and evolvability can be simultaneously maximized in chaotic RBCs. This result contrasts with previous analysis (Aldana et al., 2007), which found robustness and evolvability to be simultaneously maximized in critical RBCs. This discrepancy can be understood by considering the two primary differences between the analyses. First, Aldana et al. (2007) focused on genetic perturbations that altered circuit structure (and consequently, in some cases, signal-integration logic) while we focused solely on genetic perturbations that altered signal-integration logic. Second, and of greater importance, the measures of robustness and evolvability considered by Aldana et al. (2007) were not based on genotype networks. Instead, robustness was defined as the ability of a single mu-

tated genotype to maintain the phenotypic landscape (*i.e.*, the set of all phenotypes observed across all possible initial states), and evolvability was defined as the capacity of the mutated genotype to expand the phenotypic landscape (*i.e.*, add new phenotypes to the set of existing phenotypes). Thus, Aldana et al. (2007) focused on robustness and evolvability at the level of the genotype rather than the phenotype (Wagner, 2008b). While these definitions are reasonable and insightful, our departure from their use precludes any direct comparison between the two studies. That said, our observation that chaotic RBCs simultaneously optimize robustness and evolvability must be interpreted with caution. For all dynamical regimes, robustness is maximal for fixed point attractors, and these occur with decreasing frequency as  $z$  increases. Thus, while it is only possible to simultaneously observe maximal robustness and maximal evolvability in chaotic RBCs, this case represents the exception rather than the rule.

Future work will seek to understand how evolution navigates signal-integration space. Is it possible for mutation and selection to identify the high-robustness, high-evolvability phenotypes of chaotic RBCs? If so, can they out-compete critical and ordered RBCs in static (Oikonomou and Cluzel, 2006) or dynamic (Greenbury et al., 2010) environments? How are these evolutionary outcomes affected by mutation rate (Wilke et al., 2001) or recombination (Martin and Wagner, 2009)? Future research will also focus on larger systems, moving from an analysis of circuits to entire networks. To accomplish this, Monte Carlo sampling methods will be required (Jörg et al., 2008), as the increased size of the signal-integration space will prohibit the exhaustive enumeration of genotype networks. In addition, future work will seek to understand both the influence of canalizing functions (Kauffman et al., 2004) and the probability of gene expression  $\rho$  on the size and structure of genotype networks. These directions, among others, will lead to a more thorough understanding of how the genetic flexibility of *cis*-regulatory regions influence evolutionary processes.

## Abstract

Institutional Robotics is a new approach to the coordination of distributed robotic systems, drawing inspiration from social sciences. It aims to provide a comprehensive strategy for specifying social interactions among robots in the form of institutions. In this paper, we present a formalism for institutions in the Institutional Robotics model. We apply this formalism to two case studies. The first is concerned with a swarm of simple robots which has to maintain wireless connectivity. The second focuses on role allocation in a robotic team aimed at improving coordination and performance in a transportation task.

## Introduction

Multi-robot systems are nowadays an important area of research within the broader field of robotics. Using multiple robots might enhance the overall system performance not only because of a faster task execution speed but also in terms of robustness to failures and flexibility in allocation of subtasks. It is also clear that a team of robots is capable of completing some tasks that are impossible for single robots, for instance, because of their physical limitations. However, in order to leverage these potential benefits, it is not enough to add robots to the team. Cooperative behavior has to be present, and therefore interactions among robots must be coordinated in some way.

Institutional Robotics (IR) (Silva and Lima (2007)) is a new approach to the coordination of distributed robotic systems, drawing some inspiration from social sciences, namely from Institutional Economics' concepts. It combines the notions of institution, coordination artifact, and environment, aiming to provide a comprehensive strategy for specifying social interactions (e.g., norms, roles, hierarchies) among robots. In order to do so, robots are situated not only in a physical but also in an institutional environment, where their interactions are guided by institutions. Through cooperative decision-making, these institutions can be modified by the robots, providing adaptation to a changing scenario. Coordination is achieved by this regulation of social interactions since the robots know not only how to be-

have in a given scenario but also what to expect from other robots and the environment.

One of the goals of our research is to formalize the concepts of IR from a computer science perspective, so as to create an ontology of the entities that will be part of the IR model, and to describe ways of interconnecting them (such as graphs and tuples describing the entities associated to each node), as well as algorithms to manage a robotic collective based on social science principles.

In this work, we focus on formalizing the central concept of IR - institutions. Institutions are coordination artifacts specifying social interactions of different types and encapsulating relevant behavioral rules (possibly designed based on problem-domain knowledge) that, once adopted, avoid the need for the behavior to be re-learned or re-acquired. Our goal is to formalize them using an abstract representation, that will allow us to design these coordination artifacts and execute them in robots (both in reality and simulation), so as to obtain behaviors capturing the social interactions of interest. In order to accomplish this objective we propose to use Petri Nets as an abstract representation for institutions. Our method will produce, from a set of institutions, a robot controller able to execute a desired task.

We apply this formalism to two case studies. The first is concerned with a swarm of simple robots which has to maintain wireless connectivity. The second focuses on role allocation in a robotic team aimed at improving coordination and performance in a transportation task.

In Section 2 we discuss related work and motivation for our formalization. This formalization is presented in Section 3 culminating with the definition of a controller based on our institutional approach. In Section 4 and 5 we apply this formalism to two different case studies.

## Related Work

Institutional economics is a fundamentally different approach from neo-classical theory, the current trend of economics and inspiration for market-based systems of task allocation in distributed robotics (Dias et al. (2006)).

In Hodgson (2000), the author refines a description of in-

stitutional economics outlining the following main features: institutions are the key element of any economy; the economy is an open and evolving system; and the notion of individuals as utility-maximizing agents is inadequate. The institutional approach is characterized also by the rejection of unbounded rationality. Agents are affected by the institutional environment they live in, but in no way does that environment fully determine their behavior. Every agent has individual goals and motivations that it wants to fulfill. Institutions are developed by these very same agents.

In Crawford and Ostrom (1995) and Ostrom (2005), the authors propose a formal “grammar” of institutions according to the New Institutional Economics (NIE) approach. NIE is a compromise between the institutional and neo-classical theories of economics. Therein, the authors study what are the elements that compose institutional statements. While at this point most of these elements are not ready to be applied to multi-robot systems, deontic operators are fundamental in our IR version in order to specify how institutions relate to one another.

IR (Silva and Lima (2007)) aims to provide a comprehensive strategy for specifying social interactions among robots, by combining the notions of institution, coordination artifact, and environment. According to the IR approach:

1. the coordination strategy is supported by a network of institutions;
2. institutions are coordination artifacts of different types (e.g., norms, roles, hierarchies);
3. robots are able to modify both their physical and their institutional environment;
4. robots need a high degree of autonomy, pursuing goals based on their “struggle for survival”.

From an institutional perspective, institutions are taken as the main tool of any sophisticated society, and individuals are both constructive within and constructed through institutional environments. In a first attempt at formalizing institutions in the IR model, Silva et al. (2008) define them as “cumulative sets of persistent artificial modifications made to the environment or to the internal mechanisms of a subset of agents, thought to be functional to the collective order”.

This definition is too abstract to be applied “as is” to distributed robotics experiments. Thus, we go back to the idea of institutions as coordination artifacts (Tummolini and Castelfranchi (2006)). Coordination artifacts (Omicini et al. (2004); Ricci et al. (2005)) are infrastructure abstractions in multi-agent systems meant to improve the synthesis and analysis of coordination activities. The main properties that describe coordination artifacts are: *specialization*, *encapsulation*, and *inspectability*. Specialization refers to the fact that coordination artifacts are specialized in automating coordination activities and can be represented with concurrency frameworks such as Petri Nets or process algebras.

Coordination artifacts encapsulate a coordination service, allowing the agents to abstract how it is implemented. Encapsulation is the key to achieve reuse of coordination. Inspectability refers to the property that an artifact should support some procedure to allow engineers or agents responsible for the system to check for errors in its specification.

Omicini et al. argue that coordination artifacts are exterior to the agents using them and perceived as individual entities, but can actually be distributed on several nodes of a multi-agent system. We propose that, when taking institutions as coordination artifacts, they can be part of the agent controller, working as norms or procedures the agent has to follow. Even with this assumption, we can still think of institutions being distributed in our multi-robot system, if we consider their representation to be replicated in each agent.

## Petri Nets and Institutions

Starting from the concept of institutions as coordination artifacts we model them using a formal representation, leading to a standard design and execution platform (in real robots, realistic simulations, and multi-agent systems). Considering the three main properties of coordination artifacts mentioned above, we propose to use Petri Nets as formal framework.

Our choice of Petri Nets is based mostly on the ability of this formalism to deal with distributed systems. State information is distributed among a set of places that capture key conditions that govern the operation of the system. Moreover, Petri Nets not only are able to deal with distributed systems but are also a suitable computational model for effective and efficient interaction management, a key aspect of coordination artifacts. Finally, Petri Nets also have a larger representational power than Finite State Automata (FSA), being able to represent, with finite structure, languages that are not representable by FSA (Cassandras and Lafortune (2008)).

The Petri Net Plans (PNP) language is a tool specifically directed to the design and execution of robotic plans using Petri Nets (Ziparo et al. (2010)). Therein, properties of safety and liveness of PNs are used to ensure that execution of robotic tasks in robots follows the designed plan. However, these properties can also be verified on simpler Petri Nets models without the need of using the PNP methodology, which can be restrictive on the types of tasks that can be designed.

A multi-layer methodology, introduced in Costelha and Lima (2010), enables organizing separately the interaction between multiple institutions and the behavior of the robot as a single individual (which we will hereafter call “individual behavior”). While this is achieved in a higher layer, the execution of each institution can be described in a lower layer and represented on the above layer by means of macro places. By using Costelha and Lima (2010) expansion algorithm we can obtain a full Petri Net that can be tested for our desired properties. Also, this will allow us to add more

institutions on-the-fly (during the robots execution) and still maintain these properties.

## Executable Petri Nets

We follow the definitions for Petri Nets and their dynamics (enabled transitions, state transition dynamics) in Cassandras and Lafortune (2008):

*Definition:* A *Petri Net* is a five-tuple  $(P, T, A, w, X)$  where:

- $P$  is the finite set of *places*;
- $T$  is the finite set of *transitions*;
- $A \subseteq (P \times T) \cup (T \times P)$  is the set of arcs from places to transitions and from transitions to places;
- $w : A \rightarrow \mathbb{N}^+$  is the *weight function* on the arcs;
- $X$  is a *marking* of the set of places  $P$ ,  $X = [x(p_1), \dots, x(p_n)] \in \mathbb{N}^n$  represents the *state* of the Petri Net.

Herein, we assume that all the weights of the arcs are 1. If  $x(p_i)$  in marking  $X$  is equal or larger than 1, we say that place  $p_i$  is marked. Each unit in  $x(p_i)$  is called a *token*, i.e., if  $x(p_i) = 1$  then  $p_i$  has one token. State transitions in Petri Nets occur by moving tokens through the net and changing the marking by doing so. The sets of input places  $I(t_j)$  and output places  $O(t_j)$  of a transition  $t_j$  are given by  $I(t_j) = \{p_i \in P : (p_i, t_j) \in A\}$  and  $O(t_j) = \{p_i \in P : (t_j, p_i) \in A\}$ . Petri Net dynamics are provided by the following state transition function:

*Definition:* The *state transition function*,  $f : \mathbb{N}^n \times T \rightarrow \mathbb{N}^n$ , of Petri Net  $(P, T, A, w, X)$  is defined for transition  $t_j$  if and only if

$$x(p_i) \geq w(p_i, t_j) \text{ for all } p_i \in I(t_j) \quad (1)$$

If  $f(X, t_j)$  is defined, then we set  $X' = f(X, t_j)$ , where

$$x'(p_i) = x(p_i) - w(p_i, t_j) + w(t_j, p_i), \quad i = 1, \dots, n \quad (2)$$

If transition  $t_j$  verifies condition (1) then we say it is *enabled*. When transition  $t_j$  is enabled, we say that it can *fire*, and thus trigger a state change on the net by moving tokens according to (2).

Our aim is to formalize institutions as Petri Nets both for design and execution of robotic controllers. This means that we need to take into account robot actions and sensor readings. We consider three sets of building blocks that will allow us to design our controllers.

The set  $Act$  contains all robot primitive actions (combinations of two or more primitive actions are not considered as primitive actions).

The set  $Cdt$  contains boolean conditions that can be verified by checking sensor readings.

Finally, the set  $Pac$  contains “parameter actions”, which are auxiliary actions not concerning actuators but that only modify variables needed for the actions in  $Act$ .

We are now able to define our own version of Petri Nets used for execution of our robotic controllers.

*Definition:* An *Executable Petri Net* (EPN) is a Petri Net  $(P, T, A, w, X)$  where:

- each place  $p_i \in P$  has an associated action  $a_i \in Act$ ;
- each transition  $t_i \in T$  has an associated condition  $c_i \in Cdt$  and an associated parameter action  $pa_i \in Pac$ .

The basic intuition behind this definition is that by associating actions with places we are able to define which actions are to be executed at each time step. This is done simply by checking if the corresponding place is marked. By associating transitions with conditions verified by sensor readings we trigger state changes in the Petri Net due to changes in the robots environment. The following algorithm is performed by the robots at each time step, allowing the robots to execute the behavior designed in an EPN.

---

### Algorithm 1 Execute Petri Net

---

```

1: repeat
2:   for all enabled transitions  $t_i \in T$  do
3:     if associated condition  $c_i$  is true then
4:       run associated parameter action  $pa_i$ 
5:       fire transition  $t_i$ 
6:     end if
7:   end for
8: until no transition has fired
9: for all marked places  $p_i \in P$  do
10:  run associated action  $a_i$ 
11: end for
```

---

The implementation code for actions and conditions present in the sets  $Act$ ,  $Cdt$  and  $Pac$  is not explicitly represented in the code that specifies an EPN. All robots share a common function table that implements all possible actions and conditions. These are then represented in the EPN by means of indices. This allows the EPNs to be generic, in a sense that although robots may have different implementations for the same action (e.g., heterogenous robots in terms of hardware), the same EPN could be used to achieve coordination in the same manner. Also, it enables the sharing of EPNs among robots without the sharing of the actual implementation of actions.

## Institutional Agent Controller

Our goal is to formalize institutions as coordination artifacts in a modular fashion. We intend to have each institution represented by an EPN that can be executed independently or together with other institutions. The *individual behavior* for

the robots is also represented by an EPN. While the institutions specify behaviors that have a *social nature*, i.e., they relate the robot to other robots in some way, the individual behavior specifies a set of basic behaviors that have exclusively an *individual nature*, i.e., they relate the robot with the surrounding environment. The composition of the individual behavior with a set of institutions will generate a robot controller.

We now present our formalized definition of institution:

*Definition:* An *Institution*  $I$  is a four-tuple  $(Inst, initial_I, final_I, d_I)$  where:

- $Inst$  is an EPN;
- $initial_I, final_I \in Cdt$  are initial and final conditions for the execution of  $Inst$ ;
- $d_I \in D$  is the associated deontic operator.

The EPN  $Inst$  specifies the desired behavior that should be performed by the robot. This behavior is not always being executed, its start and finish are dictated by conditions  $initial_I$  and  $final_I$ , which the robot verifies at each time step. Thus, we say that an institution  $I$  at each time step can be *active* or *idle*. Each institution also includes a deontic operator  $d_I$  which is used when combining it with the robot individual behavior and further institutions. Despite  $Inst$  being designed by hand, institutions can be kept simple (e.g., arc weights set to 1) and further behavioral complexity can be reached by composition, in a modular fashion.

A previous abstract definition of institution was presented in Silva et al. (2008). There, the authors define the institution as a tuple  $(ID, Rationale, Modifiers, Network, Institutional Building, History)$ , where each element of the tuple tries to capture the main constitutive elements of the social order dynamics. For our purpose of formalizing institutions using an abstract representation, allowing for a standard design and execution platform, this definition is not sufficient. However, the EPN  $Inst$  can be seen as part of *Rationale*, since it specifies the activity of the institution, and the deontic operator as part of *Network*, since it specifies how the institution relates to other institutions.

The composition of the individual behavior with a set of institutions is non-trivial since concurrent execution of some of the institutions might be impossible or at least inadequate to the task the robot is carrying out. An example of such institutional interplay is that an institution stating that you must drive on the right side of the road will be overruled by the institution of the road code of Great Britain, and thus should not be executed when in that territory. Crawford and Ostrom (1995) define a set of deontic operators,  $D = \{P, O, F\}$ , establishing permitted ( $P$ ), obliged ( $O$ ), and forbidden ( $F$ ) operations, to be applied to institutional statements in order to deal with this problem. In our formalization, these operators

affect whether institutions are active or idle at each time step. However, the conditions that govern when a specific institution is active might refer directly to the activity state of other institutions. For instance, the institution for driving on the right is forbidden (and thus should be idle) when the institution of the road code of Great Britain is active. This referencing of other institutions creates a problem for our intended modular approach to formalization. Therefore, we have chosen to use a more restrictive set of deontic operators in order to guarantee that institutions do not refer to any other specific institution but can still prevent the concurrent execution of undesired behaviors (individual behavior and other institutions in general).

*Definition:* The set  $D$  of deontic operators for IR institutions includes the following deontic operators:  $\{AllowAll, StopInd, StopInst, StopAll\}$ . Their corresponding definitions are as follows:

- *AllowAll* implies that the associated institution can be executed concurrently with the individual behavior and all the other institutions;
- *StopInd* implies that the associated institution cannot be executed concurrently with the individual behavior;
- *StopInst* implies that the associated institution cannot be executed concurrently with other institutions;
- *StopAll* implies that the associated institution cannot be executed concurrently with the individual behavior or other institutions.

Herein we define the individual behavior simply as an EPN  $Ind$ .

As previously mentioned, Petri Nets (and thus EPN) can be represented by macro places in a hierarchical fashion, using two distinct layers. We consider that individual behavior and institutions are part of a lower layer and are represented by one macro place in the higher layer, as shown in Fig. 1. On the left side (lower layer) the EPN  $Inst$  of institution  $I$  is displayed. On the right side (higher layer) the macro place  $m_I$  representing institution  $I$  is displayed. By adding arcs from each transition in  $Inst$  to  $m_I$  and from  $m_I$  to each transition (shown as a single bidirectional dotted arc), we guarantee that each transition will only be enabled if  $m_I$  is marked. When a transition in  $Inst$  fires,  $m_I$  will continue to be marked since it is an output place of the transition.

Thus, if a macro place is marked, the individual behavior or institution that it represents is active, otherwise it is idle. This allows us to compose our institutions in the higher layer where relationships among the institutions and the individual behavior should be specified, while keeping relationships between actions and conditions separated in the lower layer. Both layers can be then merged algorithmically

Figure 1: Hierarchical representation of an EPN in two layers. Dotted arcs represent two directional arcs, one from a transition to a place and one from a place to a transition. Left side: lower layer, EPN  $Inst$  with conditions and actions associated to transitions and places. Right side: higher layer, macro place  $m_i$  in red.

(Costelha and Lima (2010)) to obtain a full EPN that can be used as controller.

To understand how the composition of institutions is made, we consider a minimal setup with two institutions  $I_1$  and  $I_2$  and an individual behavior  $Ind$ . A representation of the higher layer of this setup before composition is presented in Fig. 2-(a). Places in red ( $m_{I_1}$ ,  $m_{I_2}$ ,  $m_{Ind}$ ) represent in the higher layer institutions ( $I_1$ ,  $I_2$ ) and the individual behavior ( $Ind$ ) implemented at the lower layer. Places  $idle_{I_1}$  and  $idle_{I_2}$  further represent the idea that institution  $I_i$  is active if place  $m_i$  is marked. Since only one place from the set  $m_i$  and  $idle_i$  can be marked at each time, we have that institution  $I_i$  is active if  $m_i$  is marked and idle if  $idle_i$  is marked. This allows us to regulate the activation and idling of institutions with their initial and final conditions as shown in the Fig. 2-(a). The individual behavior does not have an idle place since it has no initial or final conditions.

The composition of individual behavior and institutions is controlled by the deontic operators as presented in Fig. 2. As stated before, composition takes places only in the higher layer. We will see how different deontic operators for institution  $I_1$  control the composition while always maintaining the deontic operator of institution  $I_2$  as *AllowAll*. If the deontic operator of institution  $I_1$  is also *AllowAll* (Fig. 2-(a)), then no other relationship is necessary since all behaviors can be executed concurrently. If the deontic operator of  $I_1$  is *StopInst*, the structure in Fig. 2-(b) is added. Place  $idle_{Ind,I_1}$  represents the individual behavior being idle because of institution  $I_1$  being active. The added transitions have associated a special condition that is always true. This specifies that if institution  $I_1$  is activated, then the individual behavior is set to idle and vice-versa. If the deontic operator of  $I_1$  is *StopInst*, as in Fig. 2-(c), the same structure is added but now related to the macro places of the other institution and not the individual behavior. Our setup considers only two institutions but the structure would be added for

all institutions except  $I_1$ , if more institutions were present. This means that institution  $I_2$  can be idle if place  $idle_{I_2}$  is marked or if place  $idle_{I_2,I_1}$  is marked. On the latter case, institution  $I_2$  will resume being active when institution  $I_1$  becomes idle. If the deontic operator is *StopAll* then we consider a combination of the previous two cases, as show in Fig. 2-(d). These rules also apply for institution  $I_2$  if it has a different deontic operator than *AllowAll*.

We can now define our Institutional Agent Controller that will guide the performance of our robots:

*Definition: An Institutional Agent Controller (IAC) is an EPN resulting from the composition of an individual behavior  $Ind$  and a set of institutions  $\{I_1, \dots, I_n\}$  controlled by the deontic operators  $d_{I_1}, \dots, d_{I_n}$ .*

All macro places and control places ( $idle_i$ ) added during composition are associated with a void action. Considering these associations, our IAC is itself an EPN and can be executed by Algorithm 1. A minor change is needed to line 9 of the algorithm to make sure that not only the lower layer place is marked but also the higher layer macro place of the institution being executed. Time needed for the formalization includes the design time of the institutions and individual behavior and composition time. While the latter is performed algorithmically with negligible time, the former requires a certain amount of time and experience with design of behavior-based controllers (the same as with FSA).

The IAC for a desired task can be obtained prior to an experiment and transmitted to the robots. It is also possible for each robot to obtain the IAC from a given set of institutions at the start of the experiment. Thus, the method is fully scalable to any number of robots. Complexity of the IAC increases only with the number of institutions.

## Wireless Connected Swarm Case study

In this section we present a case study to illustrate how to apply our formalism of institutions in order to obtain an IAC that performs the desired task. Our aim is to be able to specify behaviors that have a social nature as institutions and behaviors that have an individual nature as individual behavior.

We have selected a case study previously investigated by Nembrini et al. (2002) and Winfield et al. (2008), where a decentralized control algorithm is able to maintain a certain degree of spatial compactness of a robotic swarm (with  $N$  robots) using exclusively, as information at the robot level, the current number of wireless connections to the neighbors. The communication is local and its bounded range a parameter of the robotic system. Let  $X$  be the number of connections perceived by a robot. In the default state, the robot simply moves forward. If at any time  $X$  falls below a threshold  $\alpha$  (where  $\alpha \in \{0, \dots, N - 1\}$ ), the robot assumes it is going in the wrong direction and turns back. Upon  $X$  returning to a value above  $\alpha$ , the robot performs a random turn and

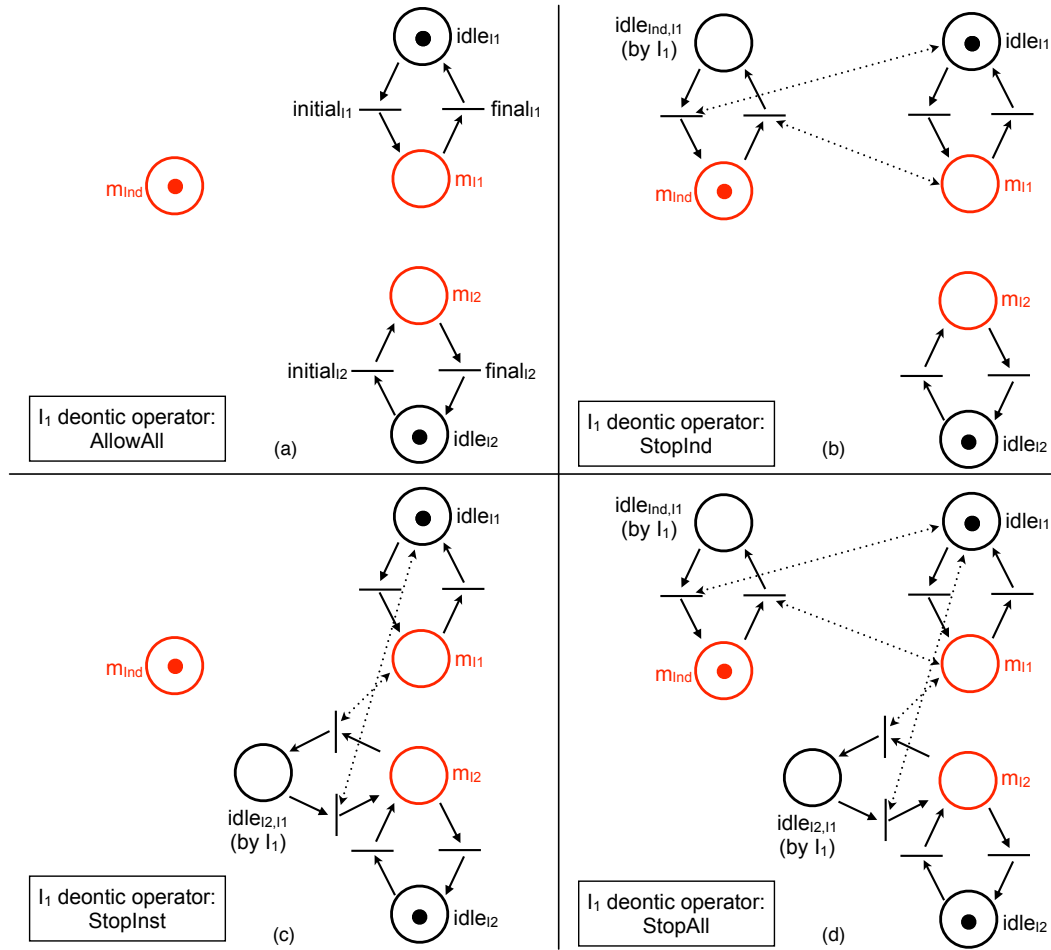

Figure 2: Composition scheme for two institutions  $I_1$ ,  $I_2$  and individual behavior  $Ind$ . Dotted arcs represent bidirectional arcs, as in Fig. 1. Places in red are macro places representing implementations of institutions and the individual behavior in the lower layer. These representations will be used throughout the paper. (a) composition rule with deontic operator *AllowAll*; (b) composition rule with deontic operator *StopInd*; (c) composition rule with deontic operator *StopInst*; (d) composition rule with deontic operator *StopAll*.

moves back to the default state. Robots always execute obstacle avoidance at the same time. This simple algorithm is quite fragile but allows the swarm to maintain its connectivity to a certain extent, with its spatial compactness being controlled by the communication range.

Our case study is similar to that of Nembrini et al. (2002) with the following differences: (i) no random turn is executed when the robots are connected again; (ii) our arena is bounded by a wall. Robots execute an individual behavior  $Ind$  and an institution  $I$ , both specified by EPNs with only two places shown in the left side (lower layer) of Fig. 3. Individual behavior  $Ind$  consists of a simple obstacle avoidance. Robots move forward until they find an obstacle (wall or other robot), perform a turn with random degree and return to moving forward. Institution  $I$  implements the social

rule, specifying that when a robot loses connections below  $\alpha$  it should turn back.

To consider the institution as defined in Section 3, we need initial and final conditions and a deontic operator. We say that initial condition  $initial_I$  is “number of connections is less than  $\alpha$ ” and the final condition  $final_I$  is “turn 180° procedure has ended”. The associated deontic operator is *StopInd* specifying that institution and individual behavior cannot be executed concurrently.

We now have all the elements needed to obtain the IAC that specifies our desired behavior. The composition of the individual behavior  $Ind$  and institution  $I$  on the left side (lower layer) of Fig. 3 is shown in the right side (higher layer) of Fig. 3. The final controller is the full EPN of Fig. 3 after the merging of the two layers. Lower layer actions and

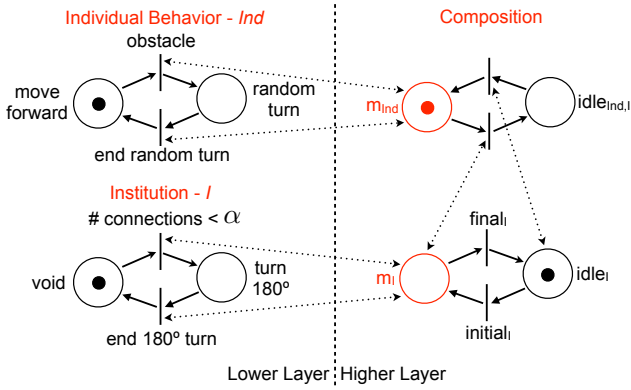

Figure 3: IAC for wireless connected swarm. Left side: lower layer EPNs for individual behavior *Ind* and institution *I*. Right side: EPN resulting from composition of individual behavior *Ind* and institution *I*.

conditions are implemented in the robot. Thus, to perform the task the robot needs only to execute Algorithm 1 taking the IAC as input. Actions associated with marked places are executed, much in the same manner as in a FSA actions associated with states would be executed.

### Corridor Case Study

A previous study concerning the institutional approach was presented in Pereira et al. (2010). Therein, institutional robotics concepts were taken into account when developing a controller for robots that had to coordinate their movement in order to traverse a narrow corridor while performing a simple transportation task. However, no formalization of the IR approach was proposed in that study. Again, our aim is to specify behaviors that have a social nature as institutions and summarize behaviors that have an individual nature as the robots' individual behavior. Our setup will consider two institutions and the individual behavior. As this case study is of higher complexity than the previous one, due to space limitations, we will not be able to describe the EPN implementations in its completeness. Therefore, we will focus only on the higher layer of the IAC.

The task consists of transporting a virtual payload in an arena with two rooms connected by a corridor. Navigation of the robots is done by performing a wall-following behavior. Transporting robots pick up the virtual payload in the left room. They must then navigate through the corridor and deploy the payload in the right room. This is the individual behavior *Ind* of the robots.

The corridor connecting the rooms is too narrow for two robots moving in opposite directions to pass one another. Thus, the robots must traverse the corridor in one direction at a time. Robots need to cooperate to avoid collisions and deadlocks in the corridor. In order to facilitate coordination,

we let a subset of the robots adopt the institutional role of “traffic regulators” to control the circulation of the remaining robots in the team. The overall traffic regulation implies robots serving as regulators and robots accepting to give priority to others in case the regulators will ask them to do so. We will therefore need two institutions, one to manage the allocation and execution of the role of regulator, and one to receive information about priority from the regulators.

If the need of traffic regulating robots arises due to a physical conflict between two robots in the corridor, these very same robots assume the role as traffic regulators. The two traffic regulators place themselves at the opposite ends of the corridor so that each regulator can control the flow of transporting robots entering the corridor from one of the rooms. The goal of the regulators is to ensure that robots only move through the corridor in one direction at a time. The regulating robots are synchronized so that only one of them will let transporting robots enter the corridor from their respective rooms at any given time. The regulation is performed by sending stop and go messages to the transporting robots.

This is clearly a behavior that has a social nature. We consider that this behavior corresponds to an institution  $I_R$  that manages the role of traffic regulator. Its initial condition  $initial_R$  is the detection of a conflict in the corridor and its final condition  $final_R$  is the end of regulation (time limit). Since we do not want this behavior to be executed concurrently with any other behavior, the deontic operator of institution  $I_R$  will be *StopAll*.

If a transporting robot receives a message to stop, it will stop in order to give priority to the robots traversing the corridor from the opposite direction. It will also begin to relay the stop message so other transporting robots behind it will stop too. As a result, the transporting robots will form a queue. When a robot in the queue receives a message to proceed, it forwards the message to any robots that may be behind it. After receiving and relaying the message the robot has priority and will traverse the corridor.

This is again a behavior that has a social nature. The behavior corresponds to an institution  $I_M$  that manages the reception and relay of messages. Its initial condition  $initial_M$  is the reception of a stop message and its final condition  $final_M$  is the reception of a go message. We do not want this behavior to be executed concurrently with the individual behavior, so its deontic operator will be *StopInd*.

In Fig. 4 we show the result of the composition of our two institutions and individual behavior. The IAC for this case study will be the result of merging this EPN with those on the lower layer.

### Conclusion and Future Work

In this work we introduced an extension to the Petri Net formalism, Executable Petri Nets. These EPN have associated actions and conditions that allow them to be executed in robots through an algorithm presented in the paper. We de-

Figure 4: Higher layer EPN for corridor study. Place  $m_{Ind}$  represents the individual behavior  $Ind$ . Place  $m_{IR}$  represents institution  $I_R$ . Place  $m_{IM}$  represents institution  $I_M$ .

defined institutions and an individual behavior for robots in a distributed robotic system making use of this new extension. In our approach, institutions are modular behaviors that can be specified through an EPN and executed in a robot. Using a composition scheme controlled by dedicated deontic operators of a set of institutions we are able to obtain an Institutional Agent Controller (IAC) in the form of an EPN that combines several institutions and an individual behavior.

We applied this formalism to a simple case study where robots have to maintain wireless connections with their neighbors. We also applied the formalism to a more complex case study dealing with institutional concepts, in this case, the institutional role.

In the future we wish to study how our formalism of institutions with EPN allows us to study logical properties of the controller, such as safeness and liveness. We are also interested in studying stochastic properties of the controller, such as the steady state distribution of a given EPN or throughput of transitions. To enable this study we need to further refine our formalism of institutions to allow for stochastically timed transitions. We will also study the possibility of using the IAC as a starting point for the application of a multi-level modeling methodology. Learning of institutions and corresponding EPN will also be studied.

# Coordination Games on Small-Worlds: Artificial Agents Vs. Experiments

Enea Pestelacci<sup>1</sup>, Marco Tomassini<sup>1</sup>, and Alberto Antonioni<sup>1</sup>

<sup>1</sup>Information Systems Department, HEC, University of Lausanne, Switzerland  
alberto.antonioni@unil.ch

## Abstract

Effective coordination is a key social ingredient and social structure may be approximated by networks of contacts. Using Stag Hunt games, which provide socially efficient and inefficient equilibria, we compare our simulation results using artificial players and evolutionary game theory with laboratory experimental work with human subjects on small-world type networks and with theoretical results. The conclusion is that the apparently encouraging results obtained in the few human experiments in which the local interaction structure seems to promote efficient equilibria, is neither supported by simulation results nor by theoretical ones.

## Introduction

Many types of conflicting interactions between agents in biology and society can be usefully described with the tools of Game Theory (Vega-Redondo, 2003). The Prisoner's Dilemma and the Hawk-Dove games are well known metaphor for representing the tension that appears in society when individual objectives are in conflict with socially desirable outcomes, and most of the vast research literature has focused on conflicting situations in order to uncover the mechanisms that could lead to cooperation instead of socially harmful interactions. However, in many important situations in society agents are not required to use aggressive strategies. In fact, many frequent social and economic activities simply require individuals to coordinate their actions on a common goal since in many cases the best course of action is to conform to the standard behavior. For example, if one is used to drive on the right side of the road and travels to a country where the norm is reversed, it pays off to follow the local norm. Games that express this extremely common kind of interactions are called *coordination games*.

Coordination games are apparently simple but they confront the players with multiple Nash equilibria (NE) and thus with the problem of how to choose among them. Evolutionary game theory (EGT) offers a dynamical view which is based on concepts of positively selecting fitter variants in the population, i.e. strategies that score best are more likely to survive and provides a justification for the appearance of stable states of the dynamics that represent solutions of the

game (Vega-Redondo, 2003).

For mathematical convenience, standard EGT is based on infinite mixing populations where pairs of individuals are drawn uniformly at random at each step and play the game. Correlations are absent by definition and the population has an homogeneous structure. However, everyday observation tells us that in animal and human societies, individuals usually tend to interact more often with some specified subset of partners; for instance, teenagers tend to adopt the fashions of their close friends group; closely connected groups usually follow the same religion, and so on. In short, social interaction is mediated by networks, in which vertices identify people, firms etc., and edges identify some kind of relation between the concerned vertices such as friendship, collaboration, economic exchange and so on. Thus, locality of interaction plays an important role. Recently, in the wake of a surge of activity in network research in many fields (Newman, 2003), the dynamical behavior of games on networks that are more likely to represent actual social interactions than regular grids has been investigated (see (Szabó and Fáth, 2007; Roca et al., 2009) for comprehensive recent reviews). These studies have been conducted on games of conflict such as the Prisoner's dilemma or the Hawk-Dove in most cases and have shown that there are network structures, such as scale-free and actual social networks that may favor the emergence of cooperation with respect to the fully mixing populations used in the theory (Santos et al., 2006; Luthi et al., 2008; Roca et al., 2009). Recently, some work has been done following this approach for games of the coordination type too to try to unravel the effect of structure on the population behavior, e.g. (Roca et al., 2009; Tomassini and Pestelacci, 2010).

Several analytically rigorous results are available for coordination games in well-mixed populations (Kandori et al., 1993), as well as populations with a simple local interaction structure such as rings and grids (Ellison, 1993; Morris, 2000). These results are very useful; however, while game theory has normative value, its prescriptions are not always reflected in the way people act when confronted with these situations. This has been made manifest by a host of results

of experiments with people (Camerer, 2003). Coordination games are no exception and also confront the theory with many puzzles. For coordination games on small-worlds and regular networks the recent laboratory experiments carried out in (Cassar, 2007) and in (My et al., 1999; Keser et al., 1998) are particularly relevant.

It has been argued that multi-agent learning simulations have the potential for greatly improving our knowledge of the game-theoretical interactions in artificial societies (Shoham et al., 2007). We also believe that numerical simulations, with their possibility of modeling many different situations, may shed light on the factors, both endogenous such as strategy update policy and exogenous, such as population structure, that have an influence on the game outcome. In this way, this can be a valuable tool to experiment in both the theoretical and experimental sides and to build a bridge between the two.

The paper is organized as follows. In the next section we present a brief introduction to the subject of coordination games. Then we describe the dynamical model, as well as the main results obtained in previous work. The following sections deal with the main theme of the present study, namely, the relationship between recent experimental results and our simulations. Finally, we present our conclusions.

## Coordination Games

General two-person, two strategies coordination games have the normal form of Table 1. With  $a > d$  and  $b > c$ ,  $(\alpha, \alpha)$  and  $(\beta, \beta)$  are both Nash equilibria. Now, if we assume that  $a > b$  and  $(a - d) \leq (b - c)$  then  $(\beta, \beta)$  is the risk-dominant equilibrium, while  $(\alpha, \alpha)$  is the Pareto-dominant one (Harsanyi and Selten, 1988). This simply means that players get a higher payoff by coordinating on  $(\alpha, \alpha)$  but they risk less by using strategy  $\beta$  instead. There is also a third equilibrium in mixed strategies but it is evolutionarily unstable. A well known example of games of this

	$\alpha$	$\beta$
$\alpha$	$a, a$	$c, d$
$\beta$	$d, c$	$b, b$

Table 1: A general two-person, two strategies coordination game.

type are the so-called Stag-Hunt games (Skyrms, 2004). This class of games has been extensively studied analytically in an evolutionary setting (Kandori et al., 1993; Ellison, 1993) and by numerical simulation on several model network types (Skyrms, 2004; Luthi et al., 2008; Roca et al., 2009).

## Evolutionary Games on Networks

The network of agents will be represented by an undirected graph  $G(V, E)$ , where the set of vertices  $V$  represents the

agents, while the set of edges (or links)  $E$  represents their symmetric interactions. The population size  $N$  is the cardinality of  $V$ . A neighbor of an agent  $i$  is any other agent  $j$  at distance one from  $i$ . The set of neighbors of  $i$  is called  $V_i$  and its cardinality is the degree  $k_i$  of vertex  $i \in V$ . The average degree of the network is called  $\bar{k}$ .

## Strategy Revision Rules

Since we shall adopt an evolutionary approach, we must define the decision rules by which individuals will update their strategy during time. Let  $\sigma_i \in \{\alpha, \beta\}$  be the current strategy of player  $i$  and let us call  $M$  the payoff matrix of the game, see Table 1. The quantity

$$\Pi_i(t) = \sum_{j \in V_i} \sigma_i(t) M \sigma_j^T(t)$$

is the accumulated payoff collected by agent  $i$  at time step  $t$  and  $\sigma_i(t)$  is a vector giving the strategy profile at time  $t$ .

Here we shall describe two among the most commonly used strategy revision rules. These rules, although they are extremely simple, also make sense when human players are concerned, at least at a very low level of knowledge and information processing capabilities. The first rule is to switch to the strategy of the neighbor that has scored best in the last time step. This *imitation of the best* policy can be described in the following way: the strategy  $\sigma_i(t)$  of individual  $i$  at time step  $t$  will be

$$\sigma_i(t) = \sigma_j(t-1),$$

where

$$j \in \{V_i \cup i\} \text{ s.t. } \Pi_j = \max\{\Pi_k(t-1)\}, \forall k \in \{V_i \cup i\}.$$

That is, individual  $i$  will adopt the strategy of the player with the highest payoff among its neighbors including itself. If there is a tie, the winner individual is chosen uniformly at random, but otherwise the rule is deterministic.

At a slightly higher sophistication level, a well known adaptive learning rule is *myopic best-response* (Young, 1998), also called best-reply, which embodies a primitive form of bounded rationality and for which rigorous results are known. In the local version of this model, time is discrete i.e.  $t = 0, 1, 2, \dots$  and, at each time step, an agent has the opportunity of revising her current strategy with probability  $p$ . She does so by considering the current actions of her neighbors and switching to the action that would maximize her payoff if the neighbors would stick to their current choices. In other words,  $\hat{\sigma}_i$  is a best response for player  $i$  if  $\Pi_i(\hat{\sigma}_i(t)) > \Pi_i(\sigma_i(t)), \forall \sigma_i$ . In case of a tie, agent  $i$  keeps its current strategy.

The model is thus completely local and an agent only needs to know her own current strategy, the game payoff matrix, who are her neighbors, and their current strategies. This

rule is called myopic because the agents only care about immediate payoff, they cannot see far into the future. In order to introduce some stochasticity, an agent can make a mistake with some small probability  $q$ . These small random effects are meant to capture various sources of uncertainty such as deliberate and involuntary decision errors. Deliberate errors might play the role of experimentation, and involuntary ones might be linked with insufficient familiarity with the game, for example. This dynamic will be called best-response with noise.

The simulation represents a dynamical system in which time  $t$  is discrete, i.e.  $t = 0, 1, \dots$ . Let us call  $\Sigma(t) = (\sigma_1(t), \dots, \sigma_N(t))$  the strategy profile at time  $t$ . For the imitation of the best and best response rules the evolution of  $\Sigma(t)$  is deterministic. In the best response with noise case the resulting process is stochastic. It can be described by a Markov chain (Kandori et al., 1993) since the probability of strategy profile  $\Sigma(t) = (\sigma_1(t), \dots, \sigma_N(t))$  at time step  $t + 1$  only depends on the previous time step:

$$Pr(\Sigma(t+1) | \Sigma(t), \Sigma(t-1), \dots) = Pr(\Sigma(t+1) | \Sigma(t)).$$

It is clear that more refined forms of learning, such as reinforcement learning could be used to represent the agents' decisions (Camerer, 2003). However, these more sophisticated approach do not have yet a firm theoretical basis and could not be compared with baseline dynamical models. This is the reason why, in the interest of simplicity, we stick with very simple basic protocol revision rules here.

## Summary of Previous Simulation and Theoretical Results

This section summarizes previous numerical results on Stag Hunt games. Several populations topologies have been studied, including regular lattices (Skyrms, 2004; Roca et al., 2009), random graphs (Roca et al., 2009; Luthi et al., 2008), scale-free graphs (Luthi et al., 2008; Roca et al., 2009), model and actual social networks (Luthi et al., 2008) using several strategy update rules such as replicator dynamics, imitation of the best, and best response dynamics. In the average, for initially equidistributed strategies, at the steady state the population is monomorphic, with all individuals playing  $\alpha$  or  $\beta$ . For all network types, the more efficient  $\alpha$  strategy is enhanced with respect to what would happen in a mixing population. This is true for all update rules except best reply, for which the topology does not seem to play an important role (Roca et al., 2009). Social networks also favor the Pareto-efficient outcome in the average but the steady state population is often dimorphic, i.e. there is a mix of the two strategies. The reason why there can be mixed states in social networks has been attributed (Tomassini and Pestelacci, 2010) to the presence of *communities*. In fact, social networks can usually be partitioned into recognizable clusters (Newman, 2003); within these clusters strategies

may become dominant as in the pure coordination case just by chance. In other words, as soon as a strategy dominates in a given cluster, it is difficult to eradicate it from outside since other communities, being weakly connected, have little influence.

We now briefly comment on the relationship between the results of numerical simulations and well known theoretical results on Stag-Hunt games (for a recent review see (Weidenholzer, 2010)). These theoretical models are based on ergodic stochastic processes in very large well mixed populations and state that, when using best-response dynamics in random two-person encounters, and in the presence of a little amount of noise, both for well mixed populations as well as for populations structured as rings, the risk-dominant strategy should take over the population in the long run (Kandori et al., 1993; Ellison, 1993). But coordination seems to be sensitive to the exact type of revision protocol and dynamic. For example, Robson and Vega-Redondo (Robson and Vega-Redondo, 1996) found that the Pareto-dominant equilibrium is selected if players are immediately randomly rematched after each encounter.

Simulations results on networked populations indirectly confirm the above, i.e., at the steady state there is always either a single strategy, but not necessarily the risk-dominant one. However, owing to network reciprocity effects related to clustering, a mix of both strategies is also possible. In summary, it can be said that network effects tend to reinforce cooperation on the Pareto-dominant case, which is a socially appreciable effect. However, these results must be taken with a grain of salt. Numerically studies deal with finite, network-structured populations during a limited amount of time, while theoretical results have been established for large well mixed populations in the very long run. Thus, numerical results and theoretical predictions based on different assumptions do not necessarily agree with each other.

## Discussion of Some Experimental Results on Coordination Games

In this section we comment on some experimental results on coordination games in the light of the conclusions that have been reached by numerical simulation and also with respect to theoretical results. There have been many experiments in the field and we cannot be exhaustive; however, the main conclusions are the following. When the analog of a (finite and generally small) well mixed population of players have been used, the general result is that polymorphic final states are rare, the initial state of play i.e. the strategy played at the first period is a good predictor of convergence, and the risk-dominant equilibrium is often reached in the laboratory, i.e. coordination failures emerge, although in some cases, especially in finitely repeated games and by varying the payoff structure, coordination on the Pareto-efficient equilibrium can also be achieved (Cooper et al., 1992; Bat-

talio et al., 2001). It has also been observed that the number of rounds, the size of the group, and the fact of playing repeatedly with the same player may influence the result, i.e. small groups, higher number of rounds, and repeated interactions have been shown to favor the Pareto-efficient outcome (Huyck et al., 1993, 1990). This lends support to the idea that human agents play the games using some imperfect decision rules that, nonetheless, may be similar to some variant of myopic best response, perhaps with a longer memory of past encounters instead of just one step behind. No doubt, human decision-making is a lot more complex, but simple learning rules should somehow evolve during these experiments.

A more interesting situation from the point of view of the present work is the one in which some more specific population structure has been recreated in the laboratory setting. We are aware of three experiments of this type, the work of (Cassar, 2007), and the studies of (My et al., 1999) and of (Keser et al., 1998).

Keser et al. used a ring structure where each player has a neighbor on either side and a well mixed structure for comparison. Their conclusions were that in the ring the preferred equilibrium is the risk-dominant one, while the payoff-dominant equilibrium was the more frequent result in the globally communicating population. This is in qualitative agreement with the theoretical predictions of (Ellison, 1993) for the ring and (Robson and Vega-Redondo, 1996) for the mixing case.

My et al. performed a comparative experimental study of Stag Hunt games with three different payoff matrices on mixing and structured populations. The population with local structure was composed by a circle of eight people where each player only interacts with her immediate right and left neighbors. They find that the first period modal choice of strategy, which is the payoff dominant one, plays a major role in the final outcome. In the global population case, the steady state generally lies in the same basin of attraction as the initial state. This result, which is commonly observed in many laboratory experiments, does not agree with the theoretical results of (Kandori et al., 1993) which predict that all the probability at stochastic equilibrium be placed on the risk-dominant state. However, we have to bear in mind that the latter have been established for stochastic processes in the very long run taking place in large populations and neither of these conditions can be satisfied in a laboratory setting.

For the ring structure, the convergence to the risk-dominant outcome is more frequent than in the well mixed case, especially when the payoff matrix values are such that the Pareto-superior basin shrinks. However, still often times the system converges to the Pareto-dominant state, which disagrees with the theoretical predictions of (Ellison, 1993) based on noisy best reply dynamics. By examining the detailed history of play, the experimenters have found that, while in the

global population subjects on average play myopic best response, in the ring with local structure a kind of imitation rule fits the data better than best reply. This is in qualitative agreement with the very extensive numerical studies of (Roca et al., 2009), where the simple strategy of imitating the individual having the best payoff in the neighborhood is the one that best promotes cooperation in the Stag Hunt played on several classes of networks.

## The experimental Study of Cassar and its Numerical Simulation

The study of Cassar (Cassar, 2007) is the most interesting one from the standpoint of the present paper as it investigates network structures that are more realistic than the ring and the two-dimensional lattice, although the ring is also used in the experiments for comparison. One particular Stag Hunt payoff matrix is used in (Cassar, 2007) with the following payoff values (see Table 1):  $a = 5$ ,  $b = 1$ ,  $c = -1$ ,  $d = 4$ . With this choice the frequency  $\alpha$  of stag players at the (unstable) mixed equilibrium would be  $2/3$ , since at this point the expected value playing strategy  $\alpha$ ,  $E[\alpha]$ , is equal to the expected value  $E[\beta]$ , which implies  $5p - (1-p) = 4p + 1 - p$ , i.e.  $p = 2/3$ , where  $p$  is the probability with which  $\alpha$  is played in the mixed strategy or, equivalently, the  $\alpha$  fraction in the population. This leads to a basin of attraction for the payoff-dominant strategy  $\alpha$  that is half the size of the corresponding basin for the risk-dominant strategy.

Figure 1: Final average ratio of  $\alpha$ -players as a function of their initial ratio in small-world networks of size  $N = 18$  and  $\bar{k} = 4$ . With noise (dashed curve) the system converges almost always to the risk-dominant steady state. Without noise (continuous curve) the payoff-dominant steady state is often reached when the initial ratio is in the corresponding basin of attraction. The dotted line marks the theoretical Nash equilibria and their basins of attraction. The small squares represent the results of Cassar's experiments.

Figure 2: Final ratio of  $\alpha$ -players as a function of their initial ratio. (a): Watts–Strogatz small-world networks scaling;  $\bar{k} = 4$ . (b): Other network topologies with size  $N = 1000$  and  $\bar{k} = 6$ . The horizontal scale starts at  $\alpha = 0.4$ . Results are averages over 50 runs for each network class using myopic best response as a strategy update rule.

Summarizing Cassar’s experimental settings, groups of 18 subjects were used, virtually connected with a local network according to three types of graph topology: ring, random, and Watts–Strogatz small world (Watts and Strogatz, 1998). Watts–Strogatz graphs are constructed starting from a regular lattice of low degree and rewiring each link in turn with some small probability to a node chosen uniformly at random. Thanks to the formation of shortcuts between distant parts of the ring the clustering coefficient remains high, while the path lengths are dramatically shortened. Although the resulting graphs are poor representations of actual social networks, some statistical quantities are qualitatively correctly reproduced (Watts and Strogatz, 1998; Newman, 2003).

The degree of each node  $k$  was exactly 4 for the ring, while it was  $k = 4$  on the average for random and small-world networks. Of course, a single realization of the ring was used, while three different realizations of each of the other two topologies were generated.

Cassar’s results can be summarized as follows. In all three networks the Pareto-dominant equilibrium was the preferred result, with a significant advantage for the small-world networks in terms of coordination on the efficient outcome. Likewise, the ring was more favorable than the random graph. The frequency of choice of the Pareto-dominant outcome on the small-world graphs is unusually high, about 95%. Thus, the qualitative conclusion is that rings, and especially small-world networks, are favorable topological structures for coordination on the socially efficient outcome. This is in contrast with theoretical results on rings using noisy best response dynamics (Ellison, 1993) while there are no theoretical results on Watts–Strogatz small worlds to compare with. However, from the extensive numerical work

of (Roca et al., 2009) it appears that several different graph structures do favor the payoff-dominant equilibrium in the population for the Stag Hunt for most of the strategy update rules tried, but not for best reply dynamics. In light of the above, Cassar’s results seem to us less compelling than they would appear at first sight.

To obtain more insight into the matter, we decided to simulate the game behavior on an ensemble of computer-generated networks of the same size  $N = 18$  as those used by Cassar with best response dynamics. We are aware of the limitations of the comparison: artificial agents are not the same thing as rational or semi-rational humans in the laboratory and time scales are vastly different since only a limited number of runs can be effectively tested in experiments. Nevertheless, we think that the exercise is worthwhile and can shed some light into the question. One important thing to note is that in (Cassar, 2007) the first period move in most cases is the payoff-dominant one, which might be due to psychological reasons in human subjects and is frequently observed in experiments (see also (Battalio et al., 2001; My et al., 1999)). In order to explore the whole spectrum thus avoiding such initial bias in the simulations, we have studied several different initial proportions between 0 and 1. Small-world instances were generated anew for each run and each computed point is the average of 50 runs. We have used a fully asynchronous update scheme in which a randomly selected agent is chosen for update with replacement at each discrete time step. To detect steady states of the dynamics we first let the system evolve for a transient period of  $5000 \times N \simeq 5 \times 10^6$  time steps. After a quasi-equilibrium state is reached past the transient, averages are calculated during  $500 \times N$  additional time steps. A steady state has always been reached in all simulations performed within the

prescribed amount of time, for most of them well before the limit.

As an update rule we used both myopic best reply as well as best reply with a small amount of mutation  $q = 0.02$ . Figure 1 reports the average results of 50 runs for each case. As prescribed by theory (Kandori et al., 1993; Ellison, 1993) and confirmed by simulations, the noisy dynamics leads essentially to risk-dominant outcomes. On the other hand, with deterministic best response dynamics, the results are that, in general, the system reaches at steady state the basin corresponding to its initial strategy proportion, with a slight advantage for the risk-dominant equilibrium, also in qualitative agreement with the expected theoretical results. Focusing more specifically on the average initial conditions that arose in Cassar's experiment, i.e. with a proportion of  $\alpha$  of about 0.7, one sees that at this point the amount of cooperation found in the simulations is much lower, about 0.30 instead of full or almost full cooperation found in the few laboratory experiments shown as small squares. Again, note that the above results are for automata playing mechanically a deterministic myopic best response. Instead, Cassar's results have been obtained with human players; nevertheless, the difference is striking.

Cassar tried to relate her results to some statistical topological features of the networks. Her main suggestion was that the higher the clustering coefficient<sup>1</sup>, the higher the probability of players choosing the Pareto-superior strategy. Unfortunately, given the small size  $N = 18$  of such networks and only three network realizations each for random and Watts–Strogatz, all sampled quantities such as the degree distribution function  $p(k)$  and mean clustering coefficient  $\bar{C}$  are too noisy to be statistically significant. For example, for a random graph, the clustering coefficient  $C$  asymptotically tends to 0 as  $N \rightarrow \infty$ . However, for small  $N$  clustering remains high in random graphs, which is actually the case for the values reported by Cassar. Thus, it is difficult to relate  $\bar{C}$  with the game dynamics for such small networks. With those caveats in mind, in order to get an idea as to the effect on the dynamics of scaling-up the network, we report in Fig. 2 (a) the results on graphs of size  $N = 100$  and  $N = 1000$ , together with those for  $N = 18$ . It is apparent that, apart from smoothing the finite-size fluctuations, scaling-up the graph has only the effect of shifting the inset of cooperation on the payoff-dominant outcome a bit further to the right. In Fig. 2 (b) we report the fraction of population coordinating on the payoff-dominant strategy  $\alpha$  as a function of the initial proportion of  $\alpha$ -strategists in various network types of size  $N = 1000$  for the payoff values used in Cassar

(2007). It can be seen that the clustering coefficient does not seem to play an important role on the population behavior. In fact, rings and Watts–Strogatz small-world graphs which both have high clustering values lead to the lowest amount of payoff dominance. On the other hand, both model and real social networks, which also have high clustering, show more coordination on the payoff-dominant strategy for  $\alpha$  below the theoretical 0.66 value, as well as slightly diminished value in the region above this value. The explanation for this behavior is related to the community structure that these networks possess (Tomassini and Pestelacci, 2010). In fact, very often at steady state the population is polymorphic, with a minority of clusters in which  $\alpha$  dominates below 0.66 and a minority of clusters of agents playing  $\beta$  above this limit. Table 2 illustrates the above by giving the mean clustering coefficient  $\bar{C}$  and the modularity  $Q^2$  of the irregular network types for  $N = 1000$ . The modularity values have been computed with Newman's and Girvan's divisive algorithm based on betweenness Newman and Girvan (2004).

In conclusion, these numerical experiments confirm that the key factor to promote cooperation in networks of agents playing coordination games according to best response when risk-dominance should theoretically prevail, is the network community structure, not the clustering coefficient. Conversely, this same community structure makes it possible for a fraction of  $\beta$ -strategists to survive in clusters when payoff-dominance should prevail.

Figure 3: Final average fraction of  $\alpha$ -players as a function of their initial fraction in the population in small-world networks of size  $N = 18$ ,  $N = 100$ , and  $N = 1000$  with  $\bar{k} = 4$ . Agent strategy update rule is by imitation of the best.

<sup>1</sup>The clustering coefficient  $C_i$  of a node  $i$  is defined as  $C_i = 2E_i/k_i(k_i - 1)$ , where  $E_i$  is the number of edges in the neighborhood of  $i$ . Thus  $C_i$  characterizes the extent to which nodes adjacent to node  $i$  are connected to each other. The clustering coefficient of the graph is simply the average over all nodes:  $C = \frac{1}{N} \sum_{i=1}^N C_i$  (Newman, 2003).

<sup>2</sup>According to Newman (Newman, 2006), where quantitative definitions are given, modularity is proportional to the number of edges falling within clusters minus the expected number in an equivalent network with edges placed at random.

	Ring	Small-World	Random	Scale-Free	Model Social	Real Social
$\bar{C}$	0.6	0.44	0.006	0.03	0.57	0.69
$Q$	-	-	0.31	0.30	0.66	0.69

Table 2: Average clustering coefficient  $\bar{C}$  and modularity  $Q$  for various network types of size  $N = 1000$  and  $\bar{k} = 6$ . The values are averages over 20 independent graph realizations. A - sign means that  $Q$  is not meaningful.

Since multi-agent simulations are cheap, while laboratory experiments demand a lot of time and resources, we have also simulated the same system assuming that the agents play unconditional imitation of the best in their neighborhood, instead of playing best response. Imitation of the best is a primitive strategy for humans, but it could be used in the absence of more refined reasoning tools, as in the experiment of (My et al., 1999). After all, such imitative behavior is very common in the stock market. The results for different initial shares of  $\alpha$  and for three network sizes are shown in Fig. 3, and should be compared with Figs. 1 and 2 (a). The notable feature is that the fraction of population playing  $\alpha$  is strongly enhanced with respect to the simulations using best reply as a strategy update rule. This is in agreement with the numerical findings of (Roca et al., 2009) where it is shown that unconditional imitation of the best gives rise to the highest amount of efficient coordination on all network types tested. Indeed, Cassar’s experimental observations would be much closer to the results using imitation of the best than to those updating with best reply, as can be seen by comparing Figs. 1 and 3. However, in Cassar’s experiment, neighbors’ payoffs were not made known to the players and thus they could not employ a decision rule based on payoff differences. Indeed, Cassar’s analysis of the subjects’ behaviors favored rules based on myopic best reply and inertia, which means that after having chosen a strategy, a player may keep it for some time.

Clearly, a delicate point is the actual decision rule, or rules, humans do use during these experiments. While the simulated protocol revision rules used in simulations are extremely simple and homogeneous in the agents population, this is probably not the case with human players. Certainly, some amount of more sophisticated learning is at work which is not fully represented in the basic rules, as explained in Camerer’s book (Camerer, 2003), for example. For this reason, we think that it is extremely useful to validate statistical learning models arising from the experiments. These could then in turn guide and pave the way for better and more realistic strategy revision rules.

## Summary and Conclusions

In this work we have studied general coordination games on complex networks by numerical simulation and we have compared the results with those of the few experimental studies that have been performed on structured populations.

For general coordination games of the Stag Hunt type there is a tension between payoff-dominance and risk-dominance and thus it is of interest to know whether there exist population topology conditions that might favor the socially efficient, Pareto-superior outcome. We have simulated a particular, yet representative, coordination game on several classes of complex networks in order to compare the results with the laboratory experiments of Cassar (Cassar, 2007). This experiment with human beings is, to our knowledge, the only one to date which employs complex network structures resembling, at least from some statistical point of view, real social networks. Our results suggest that Cassar’s claims on the role of Watts–Strogatz small-world networks, and especially their clustering coefficient, on the predominance of payoff-dominant outcomes are inconclusive and are essentially due to favorable average initial conditions. These, in turn, seem to be a bias that is almost always present in such experiments and which may well be due to human psychological propensities, something that cannot be reproduced by the artificial agents used in the simulations but which can be easily simulated by generating the corresponding initial conditions. The numerical work also show that an important source of promotion of the efficient outcome is due to the community structure present in some networks for reasonable-sized networks, i.e. with a size of at least one hundred nodes. This, however, cannot be directly related to the experimental studies as the size of the populations used in the latter have been too small till now for any meaningful partition into clusters. In conclusion, we suggest that further laboratory work on a larger scale, such as those reported in Grujic et al. (2010) should be performed to elucidate the role that complex networks of contacts may have on the emergence of efficient coordination patterns when human agents are considered. In conclusion, we think that, although numerical multi-agent simulations cannot be directly compared with heterogeneous and possibly complex human decision rules, they are a useful guide for planning and interpreting laboratory experiments and social dynamics in general.

Living organisms perform and control complex behaviors by using webs of chemical reactions organized in precise networks. Understanding how life-like behaviors emerge from such complex chemical systems is a challenge for artificial life scientists. An approach is to implement minimal *in vitro* systems, possessing the characteristic dynamic properties of living systems. In a bottom-up perspective, the ultimate purpose is to lead to the description of minimal functional cells. Taking example on the modularity of biosystems Kitano (2002), complex artificial networks can be obtained by the assembly of elementary building blocks Qian and Winfree (2011). In that scope, we developed an experimental framework of dynamic DNA-based modules, that can be assembled to generate large networks with non-trivial dynamic.

This study focuses on the description of a minimal cell as a computing unit. With respect to their environment, simple organisms like bacteria must perform a number of basic computing operations: detection of chemical gradients (chemotaxis), prediction of night and days alternation (circadian rhythms) or remembering of past decisions. In molecular terms, these behaviors correspond to various information processing abilities, like adaptation, oscillations, or bistable switching. They are performed within the cell by networks of intercoupled biochemical reactions, one prominent example being the gene regulatory networks.

Our work consisted in building experimental chemical webs that can implement such dynamic functions. We developed a modular DNA toolbox based on a simple biochemical machinery, enabling the construction of arbitrary chemical networks, and their easy *in vitro* implementation (Montagne et al., 2011). A theoretical work was performed in a continuous feedback loop with the experimental implementation. Simulations of the chemical networks are used for their design, their optimization and their study. Based on the knowledge of the thermodynamic and kinetic parameters of individual reactions, numerical integrations of the corresponding ODE sets enable the assembly of novel networks for predicting their behavior, and to adapt the network topologies for obtaining the target behavior.

Figure 1: A DNA toolbox. An activation module (A) can be designed for synthesizing a specific oligonucleotide (Inh) when a signal oligonucleotide ( $\alpha$ ) is present. An inhibition module (B) can be built from the synthesis of an oligonucleotide (Inh) that can specifically interact with a module in order to block its activity. These modules can be assembled in a chemical oscillator (C) that was experimentally designed with a predictable behavior (D).

This system is based on the replication of DNA strands by enzymatic reactions (see Fig. 1). Template DNAs are designed for producing specific message strands, when activated by specific signal strands. Autocatalytic networks are obtained when the signal strand is identical to the message strand. An inhibitor strand can be designed for each template. Full networks can be obtained by assembling these modules, generating positive and negative feedbacks. The dynamics of the system is guaranteed by the presence of an excess of activated nucleotide monomers, and the continuous destruction of the oligomers, for sustaining reaction fluxes.

This toolbox can be used to build non-trivial behaviors. As a proof of concept, we recently reported the de novo construction of a biochemical oscillator, by assembling an autocatalytic unit with a negative feedback loop (Montagne et al., 2011). The dynamic behavior (stability, period, amplitude) of this experimental system can be quantitatively predicted and modulated. We'll discuss how the same toolbox can be used to construct other life-like functions, like bistable or gradient responsive switches, but also logical gates or boolean networks. In the future, compartmentalization of these amorphous systems in vesicles or droplets may provide a good platform for the design of autonomous protocells.

## Abstract

This paper presents a mechanism of programs self-healing in an environment of agents looking for food. The failure system is defined based on initial failures that each agent (termite) has on their programs. By using language games concepts and the Q-learning algorithm, termites diagnose failures on their programs. Termites also have enough information to determine if their programs are failing based on a simple voting system that is the result of language games of diagnosis. The proposed self-healing mechanism was tested on virtual worlds with 100 and 200 termites and a different failure per termite. The results show that the proposed approach is capable, from local interactions, of building a set of very specific diagnosis questions, allowing the system to diagnose more than one type of failure at the same time, while the accounted number of diagnosis questions for instructions with low failure probability is reduced. By using the voting system and storing a ranking of possible missing code lines, mutations are induced on the code and the system is capable of recovering the programs.

## Introduction

Self-healing is based on the ability to detect software and hardware components that are failing. Systems must detect failures on components and then replace, eliminate or repair them without disrupting the system operation (Nami and Bertels, 2007).

Self-healing involves: the design and verification of an autonomic system which has some of the complexity of a real system in order to locate functions and services offered by an autonomic element in an efficient manner (Kephart and Chess, 2003), to make an abstraction of behaviors to obtain emergent properties and global behaviors from local actions (Kephart and Chess, 2003; Biccocchi and Zambonelli, 2007; De Wolf and Holvoet, 2003), to reallocate resources (Arora et al., 2006) and to locate faults as fast as possible (Gao et al., 2004).

An important part of the problem is to develop a virtual organization in an area where certain items may have certain types of failures and to reduce the risk of large losses by getting a reconfiguration that ensures the continuity of the

system and the potential generation of learning about corrective actions (Nami and Sharifi, 2007; Gao et al., 2004).

Some works try to find the cause of failures on distributed transaction environments with good times of response (Gao et al., 2004). One of them is about failure detection on heterogeneous environments as a NP-hard problem. Its approach is based on a dependency matrix of transactions versus resources and consider only binary dependencies i.e. a 0/1 matrix. Another work deals with the concept of self-regeneration introduced as a survival mechanism of systems that reduces the role of human experts. This work is focused on security and shows as an application the project CSISM, which implements multi-layer reasoning with fast reaction rules designed to take effective defensive actions within 250 ms after the initiation of the attack (Atighetchi and Pal, 2009).

Self-healing has been proposed for operating systems and distributed network environments (Rott, 2007). Rott decomposed this process in four main components: Monitoring, Adaptation, Interpretation and Resolution. By adopting the behavior of human administrators, also defined an optimal self-healing process in a computer environment into three stages: prevention, first aid and immunization. Rott considered as an example the ability to restore a service from an XML policy, which was implemented in Solaris 10. Some research demonstrated that it is possible to build self-healing operating systems through simple and effective techniques such as code reloading, component isolation and automatic restarts (David and Campbell, 2007).

A code injection mechanism for Java to introduce self-healing in object-oriented applications also has been proposed (Fuad et al., 2006). The model includes sensors that capture the state of the variables before calling the functions and encapsulating the exceptions. When any runtime failure occurs, the failure is notified and the system tries to reconstruct the unsuccessful method, so that it could be restarted at the point where the failure occurred. Otherwise, the system notifies the system administrator and some actions are executed like log generation. Fuad remarked that the code must be analyzed and the autonomic functionality should be

inserted in such a manner that it is separated from the service functionality of the legacy system. Also, a framework based on Java annotations was presented. This framework creates and builds applications with self-healing using a simple language of annotations (Breitgand et al., 2007).

Self-healing over networks was performed by injecting different types of faults to a network during training using cost-sensitive fault remediation (Littman et al., 2004). In cost-sensitive fault remediation, a decision maker is responsible for repairing a system when it breaks down. To narrow down the source of the fault, the decision maker can perform a test action, at some cost, and repair the fault if a repair action can be carried out.

A framework to specify, validate and generate autonomic systems, called Autonomic System Specification Language (ASSL) presented concrete results to specify a self-healing behavior model for NASA swarm-based exploration missions. The system send messages from a worker similar to heartbeats, or messages with a diagnosis (Vassev and Hinchey, 2009; Vassev and Paquet, 2007). A mechanism of self-healing for resource allocation using Ant Colony Optimization is also presented (Zhou et al., 2008). The obtained results are scalable to different kind of problems.

NASA has an initiative to carry out explorations in asteroid belts in a project called ANTS (Autonomic Nano Technology Swarm), based on autonomic computing (Truszkowski et al., 2004). The system has specialized workers to obtain information about asteroids, a central agent that gives a global goal and some messengers that send signals between the agents and the spatial station. NASA prototypes offer autonomic properties and these are defined in the architecture design that implements a wide level of autonomous and intelligent agents. These prototypes manage concepts, like specialization, in which an agent is designed to carry out a specific work and can redefine its task, it can also adapt itself to the environment and learn from its work or be easily replaced for other, if it has high-level failures. A concept mission is currently being planned to be launched between the years 2020 and 2030 as functional prototypes (Truszkowski et al., 2006).

In order to work self-healing from a generic perspective, taking some of the previous works as that of space exploration (ANTS) and the challenge of reproducing a system that captures part of the complexity of the real world, a virtual world in which termites that can carry out a task in a given environment is created. The termites simulator is an environment that includes the interaction among multiple elements, providing a more general solution instead of defining self-healing over operating systems or software, providing a motivation and a possible future extension not only for an application for self-healing in software but also for being extended to a hardware one.

Swarms have self-organization that makes them interesting. Considering that from self-organization it can be ob-

tained self-administration like an emergent property (Bicocchi and Zambonelli, 2007), not only it is possible to obtain self-administration but also self-healing. In this paper self-healing is studied from a perspective of artificial life that is based on the emergency and self-organization ideas, with many elements that interact with others through local rules and a synthetic approach would be adopted in which behaviors are understood throughout the construction of the same ones, using computer simulations (Langton, 1989).

Agents are called "termites" because they have social organization (only the worker termites are modeled). Feeding of termites is carried out for trophallaxis, it means that food is stored in their stomach and it is transferred among members of a community through mouth-to-mouth or anus-to-mouth feeding (Wikipedia, 2011). In this case also the pheromones define a communication mechanism.

In this paper, a simulator of a termite's swarm, a failure system, and a self-healing mechanism are introduced. Termites were modeled as agents with a virtual machine that execute instructions about motion and diagnosis. An Ant Colony System algorithm (ACS) was used to locate two points of food in the space. A failure was defined as a bad copy of a base program of a termite. Agents also diagnose others using language games and Q-learning.

Language games involves local interactions between two agents (a speaker and a hearer), in an environment with other agents, objects and situations. Some games allow the speaker to make the hearer perform an action (Steels and Vogt, 1997). The language game of diagnosis in this paper consists of one question of diagnosis about the programs of the termites; if the hearer termite does not have the code line that the speaker is expecting, the speaker rewards the diagnosis question. After recognizing the error, a voting parameter about failures is updated on each hearer termite, using a vector called belief vector of failures per each termite.

This paper is organized in the following way: first, the agents and the binary programs of the termites are described. The second part deals with the failure system, the diagnosis mechanism and the self-healing algorithm. Finally, the experiments with 100 and 200 termites are performed, with 10, 30, 50 and 70 percent of the sick termites at the beginning. Results are organized in terms of sick termites and termites that were healed.

## The Termites System

### Agents and ACS

Agents are termites that look for food, carry it, take it to the nest and continue searching for more food using Ant Colony System (Dorigo and Gambardella, 1997). The world is a toroidal space initialized with a pheromone value of zero for the termite nest and all termites start from this position with the simulation. Two points of food were defined with a pheromone value of one and the other world positions have a pheromone value of 0.5. Termites are represented as white

squares if they are looking for food and blue squares if they are carrying food and have eight possible movements: none, down, left, right, up, upleft, upright, downright and downleft (Fig 1).

Figure 1: The Termites World

Termites start making random movements when looking for food and when they finally reach the food its color changes from white to blue and the pheromone production starts. Pheromone values in vicinity of termite and the search status (seeking, carrying) are the input of algorithm to select an action (Fig 2). If termite is looking for food, the first direction with the less amount of pheromone is chosen and if the termite is carrying food, the termite chooses the first direction with more pheromone. Then the termite moves in this direction, and the pheromone of termites and world pheromone are updated (Eq 1 and 2).

$$tph = (tph + 0.01 * (0.5 - tph)) \quad (1)$$

$$wph(x, y) = wph(x, y) + 0.01 * (tph - wph(x, y)) \quad (2)$$

Where:

- $tph$  is the pheromone of the termite.
- $wph(x, y)$  is the pheromone of world in the new location of the termite (x,y).

If the termite reaches its nest, its pheromone value is updated to 0, if the termite reaches a food point the pheromone of the termite gets a value of 1.

## The Termites Programs

Each agent has a simple program, which is executed line by line, that encapsulates the Ant Colony System algorithm and the mechanism of diagnosis based on language games. Each program is a vector of binary values that represent the sensations and actions to be performed by the termite. The base program of termites is exposed in Table .  $sSeek$  is a sensor that indicates if the termites are looking for food,  $sCarry$  indicates if the termites are carrying the food and  $sNeigh$  indicates if termites have only one neighbor. Neighbor and

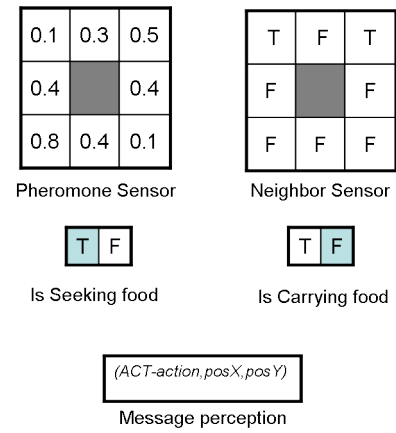

Figure 2: The Termites Sensors

pheromone sensors are defined in the Moore neighborhood  $r = 1$  with center in the termite location (Fig 2).  $acSeek$  and  $acCarry$  are simple instructions that execute the Ant Colony System algorithm and  $acDiag$  starts a diagnosis. The first instruction of the base program (Table ), is generated based on the rule: "if the termite is looking for food and the termite does not have one neighbor, then the termite has to look for food".

sSeek	sCarry	sNeigh	acSeek	acCarry	acDiag
1	0	0	1	0	0
0	1	1	0	0	1
0	1	1	0	1	0
0	1	0	0	1	0
1	0	1	0	0	1
1	0	1	1	0	0

Table 1: Base program for a termite

Each termite has an interpreter for its program. The interpreter takes each line of code and compares it with the perception of each sensor. If the line of code matches the perceptions, then the action indicated in the code line is performed. If more than one action is specified, the interpreter returns the action with the greatest priority. Priority is defined in the following order:  $acSeek > acCarry > acDiag$ .

## Failures definition

Program failures are simulated as bad coding from the beginning. Each termite has a variation of the program that the "queen" has (the base program). The programs are copied with a failure probability, it means not all termites will have programs with failures. For example, a failure probability of 0.1 means that approximately the 10% of the population have a failure.

A failure is a change in a random bit of the code per ter-

mite, so each termite has a different failure and it makes that the termites act in unexpected ways (Fig 3).

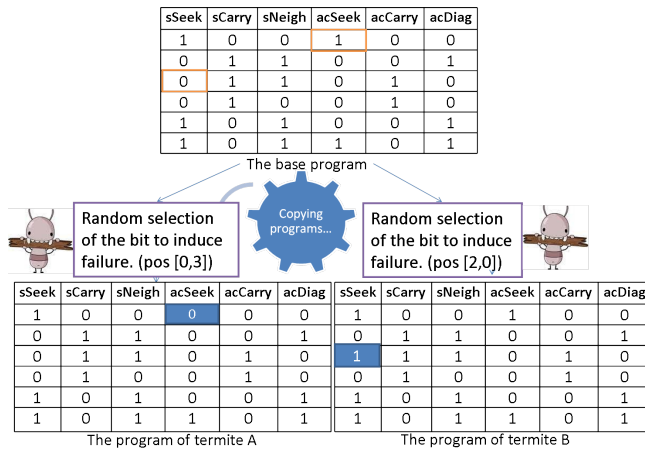

Figure 3: Failure selection for two termites

## Diagnosis Mechanism

### Diagnosis based on Language Games

A Language game is a sequence of local interactions between two agents (a speaker and a hearer) located in a specific environment (Steels, 2001). Some language games allow agents to identify objects in the environment using linguistic means and others allow the speaker to obtain actions from the hearer (Steels and Vogt, 1997). Some of language games were taken to design the mechanism of diagnosis for the programs.

A termite can send messages to a world location, if there is a termite in this place and the termites are neighbors. A diagnosis is started if a termite receives a message in its current position. This termite has to remain at this location, to clean the message from the world location and to reply the message. The diagnosis is encapsulated in the `acDiag` instruction in the termites program and was modified following the process below (Diagnose instructions are defined on Table 2):

- **Making contact:** Two agents are physically close (they are neighbors) and make contact with each another. One assumes the role of speaker and the other is the hearer.
- **Start Diagnosis:** The speaker chooses one line from its program (using Q-learning) and sends the codeline to the hearer location using the `RUNINSTR` instruction.
- **Action:** The hearer reviews its program, in this case compares its code with the line of code given by the speaker, and reports whether its program has this instruction or not (`INSTRRES` instruction). If the hearer does not have this line, the code line and a vote are added to a vector of possible code lines.

Instruction(syntax)	Definition
<code>RUNINSTR</code> ( <i>RUNINSTR-codeline, x, y</i> )	Indicates to the hearer a code line of the program from the speaker <i>code-line</i> and the position of the speaker ( <i>x, y</i> )
<code>INSTRRES</code> ( <i>INSTRRES-result, x, y</i> )	Indicates to the speaker if the hearer has the codeline or not and the current position of the hearer ( <i>x, y</i> )

Table 2: Diagnose instructions

- **Feedback:** If the hearer has this instruction, the diagnosis ends in failure (it does not discover a possible failure), the question of diagnosis about this line is punished using Q-learning. Otherwise, the hearer receives a positive vote for this code line, and the diagnose question is rewarded using Q-learning.

Q-learning (Watkins, 1989), is used to optimize the questions of diagnosis. There are questions of diagnosis about each code line per agent and weights associated with each code line which are stored in a vector of diagnosis questions.

If an error is detected (the hearer does not have the speaker's line), the question of diagnosis about this line of code receives a reward and otherwise the question receives a punishment. The goal of the agents in Q-learning is to maximize their total reward (Alpaydin, 2004). Questions of diagnosis with the greatest value are selected; if there is more than one question with the same greatest value, we choose the first one in the diagnosis vector.

The following equation is the reward when a failure is diagnosed:

$$d[c] = d[c] + \eta * (r + \gamma * \text{Max}_i(d[i]) - d[c]) \quad (3)$$

If a failure is not found, the following punishment for the question of diagnosis is given:

$$d[c] = d[c] - \eta * (r + \gamma * \text{Max}_i(d[i]) - d[c]) \quad (4)$$

Where:

- $d$  is the vector of weights about diagnosis questions.
- $c$  is the selected codeline for the diagnosis.
- $\eta$  is the learning rate ( $0 < \alpha < 1$ ).
- $r$  is the reward for taking the action.
- $\gamma$  is the discount factor for the maximum of the weights.

## Voting system

Each termite has a vector called belief vector of failures which stores the feedback of the diagnosis based on language games (a vote is added if the hearer does not have the code line that the speaker indicated). In this case, a value of 1 is added for this line of code if it belongs to the vector, otherwise the code line is added to this vector with a vote equal to 1. Table , shows four votes for the code line 100100, and three votes for the line 101011.

codeline	votes
100100	4
101011	3
101100	2
100101	1
110001	1

Table 3: belief vector of failures for a termite

## Self-healing

Self-healing is defined using some concepts of evolutionary algorithms. Evolutionary algorithms (EA) are optimization techniques based on the principles of natural evolution (Holland, 1992). First, a threshold was defined for the code lines in the belief vector of failures. If a code line of the belief vector of failures reaches this threshold (five votes in this case), it is introduced in a random position of the termite program, instead of adding another line. It could be considered like an operator of an EA. When this operator is applied, the introduced code line and its votes are removed from the belief about failures vector of this termite and the termite will disable the diagnosis instruction (Termite is sick so it cannot diagnose others), which is useful for avoiding failure propagation (Fig 4).

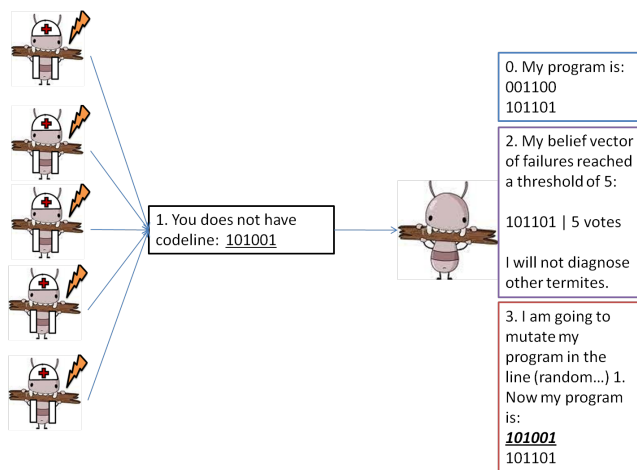

Figure 4: Self-healing process

## Dynamic of the process

Each termite gets their programs from the queen (base program). The base program is copied to all the termites and some termites of the population get bad copies of their programs (see failures definition section to get details). Some termites will be healthy and others will be sick and will act in unexpected ways. After that, the termites load and execute their programs. Thanks to the program, the termites know that they must look for food, carry food or make diagnostics.

Sick termites can diagnose healthy termites, so if a healthy termite receives bad diagnosis from sick termites (reach the threshold of the belief vector of failures), a code line of the healthy termite would be replaced and the healthy termite can get sick (see Self-healing section to get details) and disable its diagnosis instruction. In the same way a sick termite that is diagnosed by healthy termites, change their code, disable their diagnose instruction to avoid failure propagation and can be healed. With the time, the self-healing mechanism of programs avoid failure propagation and to induce changes in the lines of code of the sick termites decreasing disease.

## Experiments and Results

A virtual world was defined and each agent and food point were given a size of 1x1. For the Q-learning equations (Eqs 3 and 4) the following parameters were set:  $\eta = 0.01$ ,  $\gamma = 0.06$ , and a  $r = 1$ . Each question of diagnosis has an initial weight of  $1/\text{codelines}$ . There was a population of 100 and 200 termites with 0.1, 0.5 and 0.7 as the probability of failure (pf) in the program for the population at startup (see the faiures definition section for details). Code to validate if a program has been healed was introduced, but the agents have no knowledge about it.

Each experiment was performed 30 times, with 100000 iterations (movements per termite) per experiment. Data in Tables 4 and 5 presents the mean and the standard deviation of the experiments in terms of:

- PF = probability of Failure
- TS = Termites Sick at the Beginning are the termites that get sick by bad copy of their programs.
- TSBD = Termites Sick by Bad Diagnosis are the termites that get infected by bad diagnosis.
- TH = Termites Healed are termites which changed their code and got a code with the same instructions of the base program.
- TSDS = Termites Sick During Simulation are all the termites that got sick during the simulation (TS+TSBD).
- TSAS = Termites Sick After Simulation (TSDS - TH).

PF	TS	TSBD	TH	TSAS
0.1	9.76 ± 2.31	7.13 ± 4.59	16.4 ± 5.92	0.5 ± 0.68
0.3	30.2 ± 4.32	18.6 ± 5.44	42.43 ± 5.70	6.4 ± 4.07
0.5	49.6 ± 7.43	24.23 ± 6.60	47.06 ± 7.89	26.7 ± 6.14
0.7	68.5 ± 10.02	20.1 ± 5.89	20.2 ± 11.34	68.4 ± 13.92

Table 4: Experiments with 100 termites.

PF = probability of Failure, TS = Termites Sick at the Beginning, TSBD = Termites Sick by Bad Diagnosis, TH = Termites Healed, TSAS = Termites Sick After Simulation

PF	TS	TSBD	TH	TSAS
0.1	20.26 ± 4.64	9.63 ± 5.54	29.26 ± 7.89	0.63 ± 1.12
0.3	57.30 ± 7.42	27.53 ± 9.37	72.53 ± 8.67	12.30 ± 8.73
0.5	97.87 ± 15.24	53.43 ± 9.86	97.70 ± 15.59	53.60 ± 24.23
0.7	134.97 ± 9.52	32.27 ± 8.03	48.17 ± 13.52	119.07 ± 23.72

Table 5: Experiments with 200 termites.

PF = probability of Failure, TS = Termites Sick at the Beginning, TSBD = Termites Sick by Bad Diagnosis, TH = Termites Healed, TSAS = Termites Sick After Simulation

To determine if the algorithm is efficient, a t-test for related samples was performed with the following hypothesis. Results are organized in terms of total sick termites that got sick during the simulation (TSDS) and termites sick at the end of the simulation (TSAS):

- $H_o$  : the mean of the termites that got sick during the simulation TSDS ( $TSDS = TS + TSBD$ ) is equal to the mean of sick termites at the end of the simulation TSAS ( $TSAS = TSDS - TH$ ).
- $H_a$  : the mean of the total of termites sick > the mean of the termites sick at the end of the simulations ( $TSDS > TSAS$ ).

A value of  $\alpha = .05$  is selected for the tests (this value is the most used in social sciences), this means that five times out of a hundred a statistically significant difference between the means is found even if there was none.

For experiments with 100 termites, the means showed a difference between the termites sick during the simulation and the termites sick at the end of the simulation. The difference between the means is 15.467, the value of  $t$  is 14.096 for experiments with 0.1 as the failure probability. In the experiments with 100 and 0.3 of failure probability the difference between the means is 42.433, the value of  $t$  is 40.750. With 100 and 0.5 of failure probability the difference between the means is 47.067, the value of  $t$  is 32.651. For 0.7 we have a difference between means of 20.233 and a  $t$  value of 9.773. For 100 termites and  $pf = 0.1$ , Table 7 presents a sig value greater than .05 but the Paired Samples Test of table 8 reveal a statistically reliable difference between the means. The null hypothesis is rejected in all cases, so the

Pf		Mean	Std. Deviation.	Std. Error mean
0.1	TSDS	16.167	5.977	1.091
	TSAS	.70	.952	.174
0.3	TSDS	48.833	7.368	1.345
	TSAS	6.40	3.490	.637
0.5	TSDS	73.833	10.952	1.999
	TSAS	26.77	15.542	2.838
0.7	TSDS	88.633	7.513	1.372
	TSAS	68.40	13.922	2.542

Table 6: Paired Samples Statistics (100 termites, N = 30)

Pf	Correlation	Sig
0.1	.045	.812
0.3	.660	.000
0.5	.879	.000
0.7	.582	.001

Table 7: Paired Samples Correlations between TSDS and TSAS (100 termites, N = 30)

algorithm is efficient for the 100 termites and  $pf$  (0.1, 0.3, 0.5, 0.7) (Tables 6 and 8).

For experiments with 200 termites, the means also showed a difference between the total sick termites and the termites sick at the end of the simulation. For  $pf = 0.1$  the difference between the means is 29.266, the value of  $t$  is 20.314. In the experiments with  $pf = 0.3$  the difference between the means is 75.533, the value of  $t$  is 45.848. With  $pf = 0.5$  of failure probability the difference between the means is 97.700, the value of  $t$  is 34.325. For  $pf = 0.7$  we have a difference between means of 48.167 and a  $t$  value of 19.518. The null hypothesis is rejected in all cases, so the algorithm also is efficient for 200 termites and  $pf$  (0.1, 0.3, 0.5, 0.7) (Tables 9, 10 and ).

Pf		mean	Std. Deviation.	Std. Error mean
0.1	TSDS	29.9	8.442	1.541

sented. The system diagnoses and heals failures in an efficient way even with a 70% of the sick population. We observed that each termite is able to identify its own failures given the diagnosis of others.

Local interactions in the mechanism of diagnosis allow

the system to be specialized in the detection of more than a failure at the same time even if the failure is different per termite. By running the simulation, it was observed that some sick termites caused bad diagnosis, which induced failures in other termites. However, the rule that states that a termite cannot diagnose other if a failure is detected (votes threshold = five), makes that after some iterations, the termites stop propagating the failure and the population continues evolving their code until programs are recovered and the number of programs that were bad is reduced. In all cases the healing mutations stop after several iterations (Tables 4 and 5).

In all the experiments performed, the mean of the termites sick during the simulation (TSDS) is greater than the mean of the termites sick at the end of the simulation (TSAS) (Tables 6 and 9), so the null hypothesis ( $H_o$  : the mean of the

termites that got sick during the simulation is equal to the mean of sick termites at the end of the simulation) is rejected given the statistical analysis. With the time, the self-healing mechanism avoids failure propagation and induces changes in the lines of code of the sick termites obtaining less sick termites that the termites sick during the simulation. In this way, self-healing is an emergent property that arises from local interactions between termites (diagnosis based on language games).

As future work we are going to include some improvements like allowing the termite to locate the code line of the failure and perform diagnosis to others even if a failure is detected.

## Abstract

Multilevel selection and the evolution of cooperation are fundamental to the formation of higher-level organisation and the evolution of biocomplexity, but such notions are controversial and poorly understood in natural populations. The theoretic principles of group selection are well developed in idealised models where a population is neatly divided into multiple semi-isolated sub-populations. But since such models can be explained by individual selection given the localised frequency-dependent effects involved, some argue that the group selection concepts offered are, even in the idealised case, redundant and that in natural conditions where groups are not well-defined that a group selection framework is entirely inapplicable. This does not necessarily mean, however, that a natural population is not subject to some interesting localised frequency-dependent effects – but how could we formally quantify this under realistic conditions? Here we focus on the presence of a Simpson's Paradox where, although the local proportion of cooperators decreases at all locations, the global proportion of cooperators increases. We illustrate this principle in a simple individual-based model of bacterial biofilm growth and discuss various complicating factors in moving from theory to practice of measuring group selection.

## Group selection in theory and practice

Some argue that the theoretic principles of group selection are well developed and crucial for understanding evolution in natural populations (Wilson and Wilson, 2007; Okasha, 2006). Indeed, many artificial life models seeking to explain the evolution of cooperation make either explicit or implicit reference to group-level selection (e.g., Scogings and Hawick 2008; Goldsby et al. 2009; Wu and Banzhaf 2009). The group selection position, however, suffers from at least two serious problems. The first is whether the phenomena involved, though undisputed, formally require group selection concepts. The second is whether the idealised conditions they assume are applicable in natural populations. We briefly overview the standard model of multilevel selection and discuss these limitations. Our aim is to devise a practical theoretical approach to assess whether something interesting is happening in a natural population with respect to the scale of selection. As a practical exemplar, we have in

mind the possibility of group selection occurring within natural bacterial biofilms. Biofilms are formed when bacteria attach to a surface and develop into dense aggregations, and they are in fact the most common mode of bacterial growth (compared to well-mixed planktonic populations). Bacteria living in biofilms are known to engage in many cooperative interactions, including the sharing of various 'public goods' such as extra-cellular enzymes. Biofilms also exhibit collective properties, such as anti-biotic resistance, that are significantly different from those of free-living bacteria (Ghanoun and O'Toole, 2004). Accordingly, they have potential to serve as an ideal model empirical system for studying the transition to multicellularity (Penn et al., 2008). However to do so, we need to be able to connect idealised models of multilevel selection (for example, where groups are discrete and non-overlapping) with real-world biological systems (where the "groups" may simply be local neighbourhoods with no discrete boundary). In this paper, we discuss the theoretic and practical issues involved in studying multilevel selection in biofilms and other natural populations. We illustrate our discussion with a simple individual-based model of bacterial growth, in which growth rate depends upon the local concentration of a 'public good' that is costly to produce. As such, this system might be expected to fit standard theory on the evolution of cooperation. However in our individual-based model, as in many real-world cases, the groups are not discrete and so it is not immediately obvious how, if at all, a multilevel selection framework can be useful. How, for example, can we measure the relative strengths of within- and between-group selection if the groups do not have discrete boundaries?

Despite this practical difficulty, theoretical and philosophical work suggests that multiple scales of selection should still be present in such systems (Wilson, 1980; Sober and Wilson, 1998; Nowak and May, 1992). Here, we illustrate the use of Simpson's Paradox (Simpson, 1951; Sober and Wilson, 1998) as a quantifiable indicator of a group-level selection effect. Crucially, we illustrate that this need not rely on a priori knowledge of the exact group structure, or even on the presence of discrete group boundaries. A Simp-

son's paradox occurs when, although the proportion of cooperators *decreases* in every locality, the global proportion of cooperators nevertheless *increases*. This can be measured in situ and does not require comparison with a well-mixed population, nor that we know the exact evolutionary game (fitness function) that individuals are engaged in. Then, by measuring the magnitude of the discrepancy between local and global proportions of cooperators over a range of local scales, we can identify the effective selective scale in a natural population. We also illustrate several further complicating factors that arise in moving from idealised theoretic models to more realistic biological scenarios.

### The idealised model of multilevel selection and its limitations

The idealised model of multilevel selection involves a population of individuals that is divided into discrete (equal-sized) sub-populations or demes (Wilson, 1980; Sober and Wilson, 1998), Fig. 1.

Figure 1: Growth of cooperators (green) & selfish individuals (red) living in groups. Individuals in each group (only two are depicted) are drawn randomly from a global population (left) such that the proportions of types (cooperators and defectors) varies slightly between groups. Groups with more cooperators grow more than groups with fewer cooperators and therefore contribute more individuals (specifically cooperators) to the global cell-count. Hence, the global proportion of cooperators increases (right).

Note this model assumes that localised fitness interactions are contained within neatly circumscribed groups. To sustain cooperation at high levels the population must be subject to multiple episodes of 'aggregation and dispersal', alternating between phases with a single 'migrant pool' (the global population or a representative sample thereof), and phases with multiple localised interaction groups. Without a group mixing stage, selfish behaviour would eventually go to fixation within each group founded by one or more selfish individuals (assuming Prisoner's Dilemma cooperative interactions; Powers et al. (2008); Powers (2010)).

**Is this really group selection?** It has been widely argued that this classic model shows nothing more than individual

selection given localised frequency-dependent effects (Maynard Smith, 1976; Nunney, 1985; Sterelny, 1996; Grafen, 1984), and hence does not involve group selection at all. That is, rather than saying *groups* with more cooperative individuals are fitter than *groups* with fewer cooperative individuals, we could equally say that *individuals* in groups with more cooperators are fitter than *individuals* in groups with fewer cooperators. In fact, our position is that if we could not explain the outcome of such models in terms of (context dependent) individual selection the result would be 'mystical' - that is, we would not have an evolutionary explanation at all. The behaviour of such models is fully explainable, as it must be, in terms of modified selective pressures on individuals given the group-living assumed. Nonetheless, it is at least interesting to note that the increase in levels of cooperation are consistent with the differential productivity of groups, i.e., more cooperative groups are fitter in terms of the genetic contribution they make to future generations, as well as consistent with the differential productivity of individuals, i.e. individuals in more cooperative groups are fitter in terms of the genetic contribution they make to future generations (Dugatkin and Reeve, 1994; Kerr and Godfrey-Smith, 2002). Indeed, this has to be the case because in this (very common) kind of multilevel selection model, group fitness is by definition the mean individual fitness of the group members (Damuth and Heisler, 1988; Okasha, 2006). However, even this pluralist position seems to be on shaky ground when the groups are not neatly defined. For example, how can we empirically measure group phenotypes (e.g., level of cooperation within the group) if we cannot identify discrete groups? In this case, a group based account will lose accuracy whereas the individual selection perspective remains undeniably precise (Godfrey-Smith, 2006).

**Is the standard model relevant to natural populations?** The standard model describes neatly partitioned sub-populations where the benefits of cooperative acts are distributed equally to members within each group, but not with members of other groups (Wilson, 1980; Godfrey-Smith, 2006). Such idealised conditions are likely to be rare in natural populations. Of course, the effect does not immediately vanish when groups are less neat. But in such cases, localised frequency-dependent selection seems a perfectly adequate explanation (Maynard Smith, 1976), and there seems to be little value in arguing for a 'group selection' account. Moreover, even if we wanted to retain a group selection framework, it is not clear how we could measure and quantify the differential productivity of groups in realistic scenarios where groups are somewhat ill defined (Godfrey-Smith, 2006).

These considerations should not lead one to conclude, however, that there is nothing of consequence presented in the idealised models (Okasha, 2006) nor that nothing interesting can happen in natural populations. But it is a bit tricky

to say what it is exactly, and more tricky to know how to measure it in a natural population. Certainly, if we were to assess the level of cooperation in a natural population, and then (assuming this were practically possible) assess it again in an artificially well-mixed version of the same experiment, we might see a difference in the two levels. This would at least tell us that localised frequency-dependent effects were significant in this system. But frankly, it does not sound all that interesting – it is rather obvious that selective pressures will be different in well-mixed populations if locally dispersed resources or public goods are involved. Simply examining the global frequency of cooperation tells us nothing about the mechanism behind its evolution, e.g., is cooperation a simple mutualism or is it individually-costly?

Moreover, although a comparison of well-mixed versus spatial or viscous populations is possible in synthetic simulations, the practicalities of say, mechanically mixing a biofilm or adding surfactants to break-up the extra-cellular matrix that holds cells together would not merely alter spatial relationships, but potentially affect many important environmental factors that could confound the result. We are left, therefore, with a significant gap between the theoretic idealisations of group selection and methodology that would be useful in practical situations (West et al., 2008).

An alternative is to look for a Simpson's paradox in situ. A Simpson's paradox clearly emphasises the crucial mechanics of multilevel selection (Sober and Wilson, 1998), see below, and it can be measured in situ so that it does not require disruption of the natural population structure.

### Group selection and Simpson's paradox

Simpson's paradox is a statistical phenomenon that arises when correlations or trends within sub-groups of a data set fail to represent the overall correlation when all the data is assessed together (Simpson, 1951; Sober and Wilson, 1998). Table 1 shows a very simple hypothetical example based on a group selection scenario. It shows the numbers of cooperators and selfish individuals in two groups, A and B, at two time points,  $t = 1$  and  $t = 2$ . Note that both groups show a *decrease* in the proportion of cooperators in this time interval, yet overall, from the same data, there is nonetheless an *increase* in the total proportion of cooperators.

It may be useful to clarify that at a given point in time, the average within-group proportion of cooperators can be different from the global proportion of cooperators. This is simply because the average within-group proportion weights all groups equally, whereas the global proportion is implicitly the same summation but with each group contribution 'weighted' in proportion to its size. In the example, at  $t = 1$  the groups are equal sized and the average within-group proportion and the global proportion are therefore the same. But in the second time point, the groups are different sizes and the average within-group proportion  $((31\% + 62\%)/2 = 46.5\%)$  is not equal to the global pro-

portion (51%).

In this example then, the growth trend paradox (i.e., cooperation decreases within groups but increases globally) is caused by the fact that one group grows much more than the other. Specifically, the B group, with twice the initial proportion of cooperators, is assumed to grow at about twice the rate as the A group in this example. So, although selfish individuals always grow faster than the cooperators in any given environment, some cooperators grow faster than some selfish individuals (specifically, when cooperators are in an environment of many other cooperators). Accordingly, because highly cooperative groups grow more, cooperators can increase in total proportion even though they decrease in proportion within each group.

### Using Simpson's paradox to indicate group selection

Simpson's paradox as a basis for group selection is well understood. However, it is generally not used as a direct indicator of group selection. Instead, the norm is simply to assess the global level of cooperation and see if it increases. But in practical experiments this is insufficient to conclude that group selection is responsible for such an increase. When the exact form of the evolutionary game that individuals are engaged in is unknown, due to numerous modes of interaction and multiple 'public goods' for example, or competition for multiple resources, it can be difficult to genuinely ascertain whether the 'cooperator' is really cooperating and whether the 'selfish' type is really selfish. That is, should we be surprised that the global level of cooperation increases, or is it a simple case of mutualism? The obvious control is to compare with a well-mixed population or to increase the diffusion rate in a spatial model, but aside from the practical difficulties of this in natural populations (even bacterial ones), this cannot maintain the 'all other things being equal' condition necessary to determine that only the localisation of interactions is producing the difference in results. Instead, by looking for a divergence between the average within-group and global proportions of types, we can both verify that the types are behaving as expected (that in any given environment the selfish individuals have the advantage) and identify a group selection effect if there is one. Thus Simpson's Paradox provides an in situ measurement of group selection in the sense that we do not need to disrupt groups to provide a control, and can therefore assess the effect that groups are having merely by observing how the frequencies of types change in the natural population.

To measure Simpson's Paradox in scenarios that have poorly defined groups requires an additional small step. For this we propose the following practical methodology for a spatially distributed population. Rather than attempt to define boundaries around one group and distinguish it from another, we can simply divide the physical space into equal-sized local regions and measure both the average local pro-

	$t = 1$			$t = 2$		
	Coop	Selfish	%Coop	Coop	Selfish	%Coop
A	2	4	<b>33%</b>	4	9	31%
B	4	2	<b>66%</b>	16	10	62%
Total	6	6	50%	20	19	<b>51%</b>

Table 1: Numbers of cooperative and selfish individuals in two hypothetical groups, illustrating Simpson’s paradox. Bold highlighting indicates the time point where the proportion of cooperators is highest. Note that within both group A and group B the proportion of cooperators decreases over this period, but overall, the proportion of cooperators increases.

portion of cooperators within all regions, and the global proportion of cooperators. If the selfish individuals are indeed selfish individuals then the average local proportion of cooperators must be always declining. But if, at the same time, the global proportion of cooperators is increasing then there is significant group selection activity.

Note that if every region exhibited approximately the same amount of total cell growth, then a paradox could not occur; but if some local regions are growing much faster than others (because local frequency-dependent fitness effects are sufficiently strong) a Simpson’s Paradox may be observed. In principle, it does not matter whether the space is divided into contiguous tiles (as we employ below), or whether regions are selected at random with random centres. But it does matter that regions are not selected in any manner that is biased by cell density, for that would amount to taking a weighted average. Taking a weighted average would necessarily make the local average the same as the global, and so would result in the local group dynamics disappearing from the analysis. This is the “averaging fallacy” described by Sober and Wilson (1998), which causes the appearance of group selection to vanish. For example, measuring the proportion of cooperators in the vicinity of each and every cell or within its radius of influence will bias measurements of local proportions in such a manner that dense areas contribute more to the average in exact proportion to how dense they are – in this case, the average local proportion cannot be different from the global proportion.

In the remainder of this paper we develop a simple individual-based model of bacterial growth, such as would apply to a locally-dispersing ‘public good’, to illustrate the use of this methodology and as a basis for discussion of several additional complicating factors that are important in its application. Of particular interest is the possibility of measuring the local proportions at several different spatial scales to determine the effective scale of selection.

## An individual-based model

### Bacterial Biofilms

In developing the following model we have bacterial biofilms in mind. Social evolution in bacterial systems is currently receiving considerable attention both as a model system of social evolution and because of the practical im-

plications of biofilms (Crespi, 2001; Griffin et al., 2004; Burmolle et al., 2006). Biofilms show a physical structure especially suited for localised fitness interactions via the formation of semi-isolated micro-colony structures (Hall-Stoodley et al., 2004). However, the following model is general – not dependent on any of the particulars that pertain to specific bacterial strains or types of fitness interaction. The vital assumptions are that there are two types of individual, that the presence of one of these types (but not the other) is beneficial to other individuals within a certain spatial radius, and that this type bears a cost for providing this benefit. For example, one type may be a wild-type strain of *Pseudomonas Aurigenosa*, that releases into the environment an enzyme useful for binding iron (Griffin et al., 2004). This enzyme can be understood as a ‘public good’ because it can be used by others within the diffusion radius of the molecule. The other type may be a selfish mutant strain that does not produce the public good and is therefore not burdened by its production, but can, like any other individual, benefit from the public good produced by cooperators.

### Model definition

The state of the model at any point in time is defined by a population of individuals each of which has a type (cooperate/selfish), an age, a location in continuous 2D space and a ‘reproductive potential’. Reproductive potential can be thought of as the resources the individual has accumulated over time. There is no explicit modelling of the public good, diffusion constants, extra-cellular matrix, or such like – and in the default model, cells do not move. At every point in time, the fitness potential of each cell is incremented by a fitness benefit,  $W$ . This is a function of both the individual’s own type, and of the number of cooperators in the local vicinity. Specifically, the fitness benefit of an individual is:

$$W = m + Pb - c, \quad (1)$$

where  $m = 1.5$  is a constant representing the intrinsic growth rate,  $P$  is the proportion of cooperators within a given radius,  $r_1 = 15$ , of the individual (including itself),  $b = 4$  is a constant representing the fitness benefit received from cooperators, and  $c = 0$  for selfish individuals and  $c = 1.8$  for cooperators is the cost of being a cooperator (i.e., the cost of producing the public good). This fitness

function is standard in evolutionary models of altruism (Wilson, 1980), and amounts to an  $n$ -player public goods game / Prisoner's Dilemma (Fletcher and Zwick, 2007).

The model proceeds by updating each individual, in each time step, according to Algorithm 1.

---

**Algorithm 1** Individual update algorithm.

---

1. The age is incremented by 1.
  2. If the age is 5 the cell dies.
  3. Otherwise, the fitness benefit is calculated (as above) and added to the individual's current reproductive potential.
  4. Whilst the reproductive potential  $> 4$ ,
    - (a) Reproduce, placing descendant cell in a new location according to a placement algorithm (see text). An offspring is an exact genetic clone of its parent.
    - (b) Decrement reproductive potential by 4.
- 

The model is initialised with equal numbers of cooperators and selfish individuals distributed uniformly at random. Each initial cell (and new cell from reproduction) is initialised with reproductive potential=0, and age=0. The placement algorithm may take account of competition for space (and possibly fail to produce an offspring if space does not allow) but by default it simply places an individual in a random location within a radius,  $r_2 = 5$ . Thus, an offspring is placed close to its parent.

Measuring the global proportion of cooperators is trivial. To measure the average local proportion of cooperators, the space is divided into contiguous square regions of size,  $r_3 = 15$  (note that the area of each square local region,  $(r_3)^2 = 225$ , in which local proportions are measured, is the same order of magnitude as the circular area over which a cooperator may affect other individuals,  $\pi(r_1)^2 = 707$ . See Fig. 5.).

In an advanced version of the model, cells are motile and move toward cooperators. This represents attraction towards concentration of the public good, for example. At each time step, a vector is calculated which is a distance-discounted sum of vectors to all other local regions, weighted by the number of cooperators in that region. The regions used are the same as those used for calculating the average local proportion of types. Each cell then moves a random distance  $d$  in the direction of this vector;  $d$  is uniformly distributed in the range 0 to  $15r_4$ , where  $r_4$  is a constant controlling the amount of movement.

### Model illustrations

We initialised each simulation with 150 cooperators and 150 selfish individuals, distributed randomly across a square grid of size  $250 * 250$ . Each simulation was repeated 50 times,

and the mean of both the average local and global proportions of cooperators recorded.

Figure 2 shows that although the initial distribution of bacterial cells is random, the cells grow into spatial clusters due to non-motility and the fact that offspring are placed close to their parents (as per *Model definition*).

Figure 2: Illustration of biofilm growth in the model. Green cells are cooperators, red are selfish cheats.

From standard social evolution theory, we would not expect cooperation to increase or be stable in the absence of localised interactions (Wilson, 1980). Thus, in such cases we should not see a Simpson's Paradox, since without localised interactions there should be no difference in the growth-rates of different localities, *ceteris paribus*. We verified that this was the case in our model by making the radius of social interactions,  $r_1$ , equal to the size of the whole grid. Thus, each individual would experience the global proportion of cooperation for the purposes of determining their fitness. This corresponds to complete mixing of the public good, but not of the individuals themselves. Thus, we still measured the local proportion of cooperation across squares of size  $r_3 = 15$ . As Figure 3a shows, the global frequency of cooperation steadily declines in this case, and there is no observation of a Simpson's Paradox. This is because although there are still spatial groups in the system, membership of these groups does not affect fitness when the public good is global, and hence they are meaningless to evolution. This serves as an illustration of the fact that the groups we can readily observe in a system (e.g., the clusters in our model) may not be the same scale as the groups that matter for the evolution of cooperation (in the case of well-mixed public goods, the 'group' is the whole population).

On the other hand, in Figure 3b we set the radius of the public good to  $r_1 = 15$ . This represents localised interactions, and so we might expect cooperation to evolve. Moreover, we set the window size over which we measure local proportions of cooperators to be of this same scale ( $r_3 = 15$ ). In this case cooperation evolves, and we observe a difference between average local and global proportions of cooperation, and hence a Simpson's Paradox. It should

be noted that Simpson's Paradox is present even when the global proportion of cooperators is falling, so long as the average local proportion of cooperators is falling at a faster rate (e.g., generations 1-6 in Figure 3b). In this case there is a non-zero between-group component of selection, but this is weaker than within-group selection.

Figure 3b also illustrates that the paradox cannot be sustained indefinitely. This is because selfish individuals are fitter than cooperators sharing the same public good (same  $P$  value but  $c = 0$  in Equation 1). Thus, they must necessarily increase in frequency within each locality. As this happens,

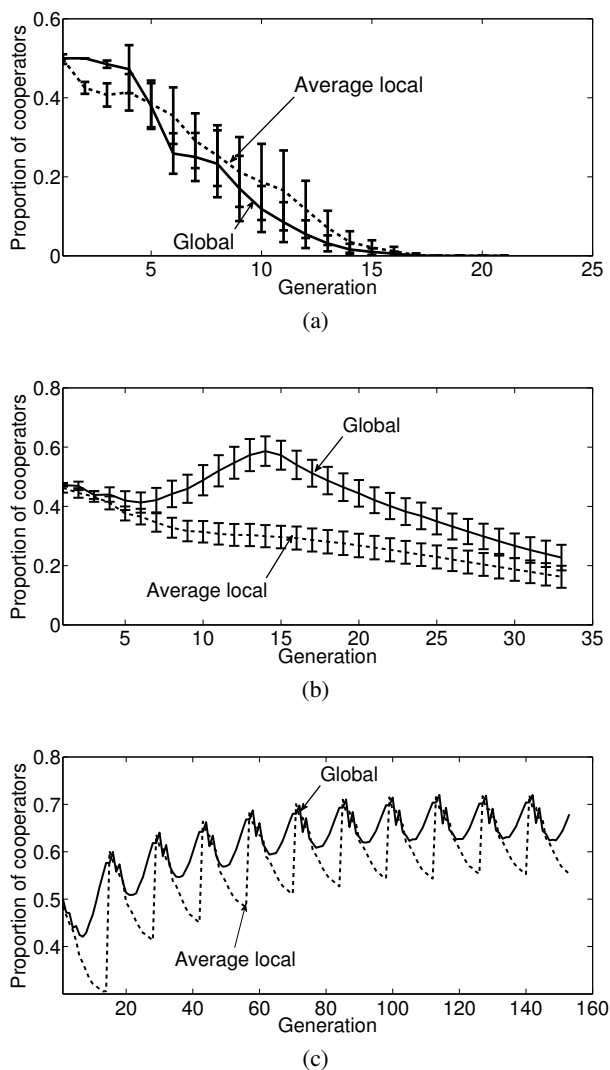

Figure 3: A) When the average of interaction,  $r_1$  covers the entire space, cooperation does not evolve and Simpson's Paradox is not observed. B) When  $r_1 = 15$  cooperation evolves, and there is a difference between local and global proportions. C) Multiple aggregation and dispersal cycles with  $r = 15$ .

the differential growth of different localities decreases, and hence the paradox reduces. In Figure 3b, the paradox peaks at 14 generations, after which the global frequency of cooperation starts to fall back down. This seemingly inevitable decrease in cooperation as the generations go by need not occur, however, if individuals are periodically mixed and redistributed in space (Sober and Wilson, 1998). Essentially this is because such a redistribution of individuals reestablishes variance in the proportion of cooperators (and hence in the amount of the public good) between groups, and so once again allows for differential group productivity to have an effect and create a paradox. This is illustrated in Figure 3c, where dispersal from clusters and global mixing occurs every 14 generations. These dispersal events explain the see-saw shape of the average local curve: at each dispersal event, the average local proportion is returned to the global proportion of cooperators. Dispersal is known to occur in natural biofilms (Ghannoum and O'Toole, 2004) (although simultaneous and complete mixing is a simplifying assumption of our model), and the single-celled bottleneck in the development of multicellular organisms provides a similar redistribution of genetic variance (Maynard Smith and Szathmáry, 1995; Michod, 1999). Thus, some degree of dispersal is likely to be important in maintaining cooperation in natural populations (West et al., 2002), and may actually be an evolutionary adaptation at least partly for this purpose (Maynard Smith and Szathmáry, 1995; Michod, 1999).

Figure 4 shows the effect of cell motility on the observation of Simpson's Paradox. Again, from standard theory we would expect increasing motility to reduce global levels of cooperation. We see that increasing motility decreases Simpson's Paradox. This is because it increases the heterogeneity of localities, making their  $P$  values more similar and hence the differential in group productivity lower.

Figure 4: Effect of increasing cell motility on the observation of Simpson's Paradox. Error bars show standard deviation.

Figure 5 shows how the peak observation of a Simpson's Paradox changes depending on the scale at which local proportions of cooperators are measured. Observation of the paradox will peak when this scale corresponds to the actual scale of social interactions in the system, e.g., to the radius

in which the public good is shared. The peak in Figure 5 is where the measured locality size corresponds, approximately, to  $r_1$ , the actual scale of interaction. Measuring Simpson's Paradox using different local scales could thus be used to determine the actual scale of social interactions in a real-world system, where this may well not be known *a priori*.

Figure 5: Effect of the magnitude of the locality size measured on the observation of Simpson's Paradox (difference between local average and global proportion of cooperators). The observed paradox is strongest when the measured locality size corresponds to the actual scale of social interaction; measurements were taken after the number of generations that yielded the peak difference between global and local frequencies, for each window size. Error bars show standard deviation. The length of the error bars increases with the window size because a larger window size corresponds to fewer localities and hence fewer samples to average over.

## Discussion

We have presented a methodology for measuring the effect of group-level selection in natural populations. Real-world populations may often not be formed of clearly observable groups with discrete boundaries, which makes the application of standard multilevel selection theory non-trivial. In particular, theoretical techniques for measuring the strength of group selection, such as the Price Equation or contextual analysis, rely on being able to measure properties of discrete groups (Godfrey-Smith, 2006). Thus, their application to systems such as bacterial biofilms remains problematic.

Here, we have suggested observation of Simpson's Paradox as a way to quantify the effect of group-level selection in a natural population. It is now widely appreciated that Simpson's Paradox, the difference between average local and global frequencies of cooperation, will be present whenever individually-costly cooperative behaviours evolve (Sober and Wilson, 1998). Moreover, its presence indicates multiple scales of selection in a system (Sober and Wilson, 1998). However, discussions of Simpson's Paradox have so far remained in the theoretical domain. In particular, illustrations of it have, to our knowledge, only been conducted in models with discrete group boundaries. By contrast, we

have shown that Simpson's Paradox can be readily measured in populations where individuals are continuously distributed throughout space. Thus, the exact group structure does not have to be known *a priori* for this technique to be applied. We have illustrated the measurement of Simpson's Paradox in such a case with an individual-based model of public goods production in bacterial biofilms.

Significantly, measurement of Simpson's Paradox can be used to determine the effective group structure in a natural population. Specifically, the difference between average local and global proportions of cooperation will peak when the size of localities measured is of the same scale as that over which the public good is shared. That is, when the measurement window size matches the scale of fitness-affecting social interactions. Wilson (1980) terms the scale over which social interactions occur "trait groups". He stresses that the groups which matter to natural selection are subsets of individuals in which fitness-affecting interactions occur, and that these subsets may not correspond to the apparent groups that are most readily observable in a population. For example, although discrete clusters may be observable in a biofilm, these may not correspond to the radius over which a public good diffuses. Varying the window size over which the change in local proportions of cooperators is measured, and looking for the peak difference with the global proportion, can identify the effective trait groups in the population. Searching for the trait groups in this way can be done by image analysis at the end of the experiment – the experiment does not have to be re-run in order to measure Simpson's Paradox on different scales. Regarding biofilms, one may also measure local proportions using regions that specifically enclose micro-colonies to see if micro-colony structure is a stronger selective unit than arbitrary local regions. That is, our methodology can be used to determine whether the micro-colonies correspond to trait groups, or whether the trait groups are in fact smaller or larger.

In future work, it would be interesting to investigate whether the Price Equation can be meaningfully applied to the appropriate window size. In particular, our methodology identifies non-arbitrary groups. Thus, once we have identified the effective trait group size, we could calculate the covariance between group character (local proportion of cooperators), and group productivity. Likewise, we could calculate the covariance between individual character (cooperator or not) and individual fitness (number of cell divisions). Our methodology also fits within a kin selection framework (Hamilton, 1964), as used by Griffin et al. (2004) to study bacterial social evolution, for example. Finding the trait groups corresponds to finding the scale at which genetic relatedness should be measured in a natural population.

## Abstract

A main challenge in Evolutionary Algorithms (EAs) is determining a termination condition ensuring stabilization close to the optimum in real-world applications. Although for known test functions distribution-based quantities are good candidates (as far as suitable parameters are used), in real-world problems an open question still remains unsolved. How can we estimate an upper-bound for the termination condition value ensuring a given accuracy for the (unknown) EA solution?

We claim that the termination problem would be fully solved if we defined a quantity (depending only on the EA output) behaving like the solution accuracy. The open question would be, then, satisfactorily answered if we had a model relating both quantities, since accuracy could be predicted from the alternative quantity. We present a statistical inference framework addressing two topics: checking the correlation between the two quantities and defining a regression model for predicting (at a given confidence level) accuracy values from the EA output.

## Introduction

Evolutionary Algorithms (EAs) are a class of stochastic optimization methods that simulate the process of natural evolution. EAs maintain a population of possible solutions that evolve according to rules of selection and other operators, such as recombination and mutation. Several evolutionary methodologies have been proposed for solving real world optimization problems: genetic algorithms (Holland, 1975), evolutionary strategies (Schwefel, 1995) and differential evolution (Storn and Price, 1997) among others. By their ability to optimize non-analytic multi-modal functions, EAs have been successfully applied to a wide range of real life problems, such as parameter estimation (Ravikumar and Panigrahi, 2010), pattern and text recognition (Rizki et al., 2002) and image processing (Cagnoni et al., 2008).

As any iterative technique, EA requires a stop criterion. Unlike optimization methods adapting a single initial value (which rely on real analysis theory), by their stochastic nature, there is not a solid mathematical theory ensuring con-

vergence of evolutionary methodologies in general (Safe et al., 2004; Bäck et al., 1997).

The simplest (and most extended (Safe et al., 2004; Price et al., 2005; Tagetiren and Suganthan, 2006)) stopping criterion consists in reaching a number of iterations or function evaluations. This stopping criterion is not useful by itself (the number of iterations that guarantee convergence significantly varies across problems (Safe et al., 2004)), though it can be necessary when used in addition with alternative criteria to ensure that the algorithm stops (Zielinski and Laur, 2008).

Existing approaches defining general alternative termination conditions address two issues. First, the definition of a quantity reflecting the amount of change between consecutive iterations and, second, the condition that such quantity should fulfill. The quantities reported in the literature (Zielinski and Laur, 2008; Safe et al., 2004) measure either the rate of change in the objective function (improvement-based) or the distribution of the evolving population (distribution-based). Concerning the termination condition, two different conditions are considered. The first condition terminates EA if the measure of the amount of change is below a given threshold. The second one terminates EA in the case that such measure is below a threshold for a number of generations. Improvement-based criteria may lead to early termination (possibly far from the optimum) due to the stochastic nature of EA (Zielinski and Laur, 2008). Meanwhile, distribution-based quantities compare to the accuracy of the solution (distance to the optimum) in terms of number of function executions, as far as suitable parameters (threshold and number of generations) for the termination condition are set (Zielinski and Laur, 2008).

A main limitation for application to real-world problems is that the parameters of the termination condition strongly depend on the function shape of the objective function (Zielinski and Laur, 2008). Another concern is that current approaches constrain to statistically comparing the number of iterations reached by the termination condition to the number of iterations required to achieved a given distance to the optimum (Zielinski and Laur, 2008). Although ex-

periments report promising results, the statistical tools used so far can not answer two main (still open) questions. How can we define a termination condition? Given a confidence level, how can we estimate an upper-bound for the number of iterations required to ensure convergence?

We propose posing the termination problem in statistical inference terms. From the perspective of statistical inference, the termination problem consists in designing a measure (depending only on the EA output) that correlates to the accuracy of the solution, so that they can be swapped. This paper introduces a general inference model for predicting the accuracy of the EA solution from the EA current state. We show that a linear regression model in logarithmic scale accurately relates accuracy and distribution-based quantities. We use the inference model to compare several types of distribution-based quantities reported in the literature (Zielinski and Laur, 2008). Our experiments indicate that the maximum distance to the best individual is the best choice in terms of computational efficiency and capability of predicting EA accuracy.

## Inference Model

All measures are taken in the domain of definition of the objective function, that is in the parameter space of the population being evolved. The distance to the (known) function minimum is our gold-standard reference convergence criterion, given that is directly associated to the algorithm accuracy. This criterion can only be computed if the optimum of the test function is known and, thus, is useless in real-world problems. We compute it as the maximum distance to the function minimum of a certain percentage  $p$  of the individuals (Zielinski and Laur, 2008) and denote it by *RefCrit*. Regarding the alternative quantities, which we will denote by *AltCrit* in general, we have considered the following distribution-based quantities (Zielinski and Laur, 2008):

1. **Maximum Distance (MxD).** It is given by the maximum distance of the population to the best individual.
2. **Population Variability (Std).** It is the maximum of the standard deviations (computed using the population individuals) of each dimension of the search space (in our case, the number of dimensions is limited to two).

Both quantities can be computed using all individuals or considering only a percentage  $p$  of the individuals. The latter is computationally faster and will be indicated by the suffix **Quick**.

Our final goal is to control (predict) the values taken by *RefCrit* from the values taken by the alternative measure *AltCrit*. In inference statistics, this is achieved by relating both quantities using a regression model. From now on and when appropriate,  $x$  stands for *AltCrit* (explicative variable) and  $y$  for *RefCrit* (response variable).

## Regression Model

Given a sampling of two random variables ( $x$  and  $y$ ), the linear regression of  $y$  (response variable) over  $x$  (explicative variable) is formulated as:

$$y_i = \beta_0 + \beta_1 x_i + \varepsilon_i \quad (1)$$

where  $x_i, y_i$  are the sampling of  $x$  and  $y$  and  $\varepsilon_i$  a random error satisfying:

### Model Assumptions

1. Linearity:  $E(\varepsilon_i) = 0$
2. Homocedasticity:  $VAR(\varepsilon_i) = \sigma^2, \forall i$
3. Uncorrelation:  $COV(\varepsilon_i \varepsilon_j) = 0, \forall i, j$
4. Gaussianity:  $\varepsilon_i \sim N(0, \sigma^2)$ , for  $N(0, \sigma^2)$  a normal distribution.

The parameters of the regression model (1) are the regression coefficients  $\beta = (\beta_0, \beta_1)$  and the error variance  $\sigma^2$ . The regression coefficients describe the way the two variables relate, while the variance indicates the accuracy of the model and, thus, measures to what extent  $x$  can predict  $y$ .

Given that, in our case, the inference is over *RefCrit*, our model is:

$$RefCrit_i = \beta_0 + \beta_1 AltCrit_i + \varepsilon_i \quad (2)$$

for *RefCrit<sub>i</sub>*, *AltCrit<sub>i</sub>* the values of *RefCrit* and *AltCrit* obtained at the  $i$ -th iteration.

For a sample of length  $N$  (in our case  $N$  is the number of iterations), the regression coefficients,  $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1)$ , are computed by Least Squares Estimation (LSE) as:

$$\hat{\beta} = (X^T X)^{-1} X^T Y \quad (3)$$

for  $X = \begin{pmatrix} 1 & x_1 \\ \vdots & \vdots \\ 1 & x_N \end{pmatrix}$ ,  $Y = (y_1, \dots, y_N)$  and  $^T$  denoting the transpose of a matrix. The differences between the estimated responses,  $\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i$ , and the observed responses  $y_i$ :

$$e_i = y_i - \hat{y}_i$$

are called residuals. Their square sum provides an estimation of the error variance:

$$S_R = \hat{\sigma}^2 = \frac{\sum e_i^2}{N - 2} \quad (4)$$

The four model conditions endow desirable properties to the LSE of the regression coefficients (Ashish, 1990). By the Gauss-Markov theorem under the first three assumptions, the LSE are best linear unbiased estimators and assure that predictions made by least squares fitted equations are

## Residual model diagnostics for normal scale

## Residual model diagnostics for logarithmic scale

Figure 1: Residual diagnosis plots for Rastrigin function

good. By adding the fourth assumption (error gaussianity), the LSE has minimum variance among all unbiased estimators (not just linear) and allows the use of parametric tests, such as the Student's t-test for testing hypothesis on parameter values. The central limit theorem (asymptotically) guarantees this last property for large samples. Therefore, given that we have as many samples as EA iterations, in our case, the gaussianity is not a critical issue.

The standardized residuals:

$$en_i = (e_i - \mu(e_i)) / \text{std}(e_i)$$

, for  $\mu$  the average and  $\text{std}$  the standard deviation, are used to verify the model assumptions. The plot of  $en_i$  over  $\hat{y}_i$  is called the versus fit plot and reflects linearity (in the measure that it is centered at zero) and homocedasticity (uniform deviation from zero). The plot of  $en$  vs the sorted explicative variable is called the versus order plot and serves to detect any correlation pattern. Finally, the histogram of the standardized residuals reflects Gaussianity (Newbold et al., 2007).

Figure 1 shows the residuals diagnosis plots for Rastrigin function. From left to right, we plot the versus fit plot, the versus order plot and the histogram for the standardized residuals  $en$ . The plots at normal scale in the first row show that linearity (versus fit plot is centered at zero) and uncorrelation (versus order plot presents no pattern) are fully satisfied. Meanwhile, we observe a clear heteroscedasticity in the versus fit plot which presents an increasing deviation from zero.

This heteroscedasticity is due to a decrease in the population sparseness at advance stages of EA and also affects the Gaussianity assumption, as shown in the histogram of the first row. A monotonous increase in  $\sigma^2$  is usually solved by taking logarithms in both variables (Arnold, 1997). The residuals plots for the regression model in logarithmic scale (second row in fig. 1) indicate a good homocedasticity and Gaussianity for the standardized residuals.

From now on, the values of  $RefCrit$  and  $AltCrit$  will be assumed to be in logarithmic scale for the inference model:

$$\log(RefCrit_i) = \beta_0 + \beta_1 \log(AltCrit_i) + \varepsilon_i \quad (5)$$

We note that, by taking exponentials, the regression model in the original scale is polynomial with multiplicative errors:

$$RefCrit_i = e^{\beta_0} AltCrit_i^{\beta_1} e^{\varepsilon_i} \quad (6)$$

**Model verification** Previous to any kind of inference, it is mandatory to verify that the estimated parameters make sense. That is, whether it really exists a linear relation between  $x$  and  $y$ . By the Gauss-Markov theorem, such linear relation can be statistically checked using the following T-test (Newbold et al., 2007)

$$H_0 : \beta_1 = 0 \quad H_1 : \beta_1 \neq 0$$

where a  $p$ -value close to zero (below  $\alpha$ ) ensures the validity of the linear model with a confidence  $(1 - \alpha)100\%$ .

## Prediction Model

In order to predict the values of *RefCrit* from the values achieved by *AltCrit*, we use the regression prediction intervals (Newbold et al., 2007):

$$PI(x_0) = [L_{PI}(x_0), U_{PI}(x_0)]$$

since, for each  $x = x_0$ , they provide ranges for  $y$  at a given confidence level  $1 - \alpha$ . That is, given  $x_0$ , the values of the response  $y$  are within  $L_{PI}(x_0) \leq y \leq U_{PI}(x_0)$  in  $(1 - \alpha)100\%$  of the cases.

Given  $x_0 = AltCrit_0$ , the confidence interval at a confidence level  $(1-\alpha)$  predicting *RefCrit* is given by:

$$\begin{aligned} PI(x_0) &= [L_{PI}(x_0), U_{PI}(x_0)] = \\ &= [\hat{y}_0 - t_{\alpha/2} S_R \sqrt{1 + h_0}, \hat{y}_0 + t_{\alpha/2} S_R \sqrt{1 + h_0}] \quad (7) \end{aligned}$$

for  $t_{\alpha/2}$  the value of a T-Student distribution with  $N - 2$  degrees of freedom having a cumulative probability equal to  $\alpha/2$  and:

$$\begin{aligned} \hat{y}_0 &= b_0 + b_1 x \\ h_0 &= (1 \quad x_0)(X^T X)^{-1} \begin{pmatrix} 1 \\ x_0 \end{pmatrix} = a_0 + a_1 x_0 + a_2 x_0^2 \end{aligned}$$

Where  $(a_0, a_1, a_2)$  stand for the coefficients of the quadratic polynomial resulting from the previous algebraic expression.

The exponential of *PI* already provides (with confidence  $1 - \alpha$ ) an upper bound for the accuracy of EA solution given EA current state. In order to obtain the upper bound for *AltCrit* ensuring a given accuracy  $U_{PI}(x_0)$ , it suffices to find the value  $x_0$  that solves:

$$\hat{y}_0 + t_{\alpha/2} S_R \sqrt{1 + h_0} = U_{PI}(x_0) \quad (8)$$

Using the expressions for  $\hat{y}_0$  and  $h_0$  in (8) and solving for  $x_0$ , we obtain:

$$x_0 = \frac{2b_0b_1 - t_{\alpha/2}^2 S_R^2 a_1 - 2b_1 U_{PI}(x_0) + \sqrt{D}}{2(t_{\alpha/2}^2 S_R^2 a_2 - b_1^2)} \quad (9)$$

where the discriminant is given by:

$$\begin{aligned} D &= (t_{\alpha/2}^2 S_R^2 a_1 - 2b_0b_1 + 2b_1 U_{PI}(x_0))^2 - \\ &- 4(t_{\alpha/2}^2 S_R^2 a_2 - b_1^2)(t_{\alpha/2}^2 S_R^2 (a_0 + 1) - \\ &- b_0^2 + 2U_{PI}(x_0)b_0 - U_{PI}(x_0)^2) \end{aligned}$$

By taking exponentials from (9) we get the upper bound for *AltCrit*.

## Experimental Settings

In this study we have compared the predictive capability of the following distribution-based measures given at the beginning of the previous Section: **MxD**, **MxDQuick** and

**StdQuick**. We have used  $p = 30\%$  of the population for computing **Quick** scores. We have considered six well-known test functions (Digalakis and Margaritis, 2002) having a minimum value of zero:

1. Esphere:

$$f_1(x) = \sum_{i=1}^n x_i^2$$

2. Rosenbrock:

$$f_2(x) = \sum_{i=1}^{n-1} [100(x_{i+1} - x_i^2)^2 + (x_i - 1)^2]$$

3. Rastrigin:

$$f_3(x) = \sum_{i=1}^n [x_i^2 - 10 \cos(2\pi x_i + 10)]$$

4. Ackley:

$$f_5(x) = 20 + e - 20e^{-0.2\sqrt{\frac{1}{n}\sum_{i=1}^n x_i^2}} - e^{\frac{1}{2}\sum_{i=1}^n \cos(2\pi x_i)}$$

5. GoldstenPrice:

$$\begin{aligned} f_6(x) &= (1 + (x_1 + x_2 + 1)^2) \cdot \\ &\cdot (19 - 14x_1 + 3x_1^2 - 14x_2 + 6x_1x_2 + 3x_2^2) \cdot \\ &\cdot (30 + (2x_1 - 3x_2)^2) \cdot \\ &\cdot (18 - 32x_1 + 12x_1^2 + 48x_2 - 36x_1x_2 + 27x_2^2) \end{aligned}$$

6. Easom:

$$\begin{aligned} f_7(x) &= -\cos x_1 \cdot \cos x_2 \cdot \\ &\cdot \exp(-((x_1 - \pi)^2 + (x_2 - \pi)^2)) \end{aligned}$$

We have used a Differential Evolution (DE) technique for the minimization task. Differential evolution is a real parameter encoding evolutionary algorithm for global optimization over continuous spaces (Storn and Price, 1997; Das and Konar, 2005). In this paper, we use the 3-parameter DE1 scheme (Storn and Price, 1997) for solving DE. For a real search space of dimension  $D$ , the population is randomly initialized with  $ND$  vectors (for  $ND$  the first algorithm parameter). Each vector  $v$  in the population is evolved by mutation and recombination operators. Given a mutation rate  $F \in [0, 2]$  (second parameter of the algorithm), the mutation operator produces a new vector  $vm$  by adding a vector difference of two randomly chosen population vectors  $v1$  and  $v2$  to another randomly chosen vector  $v3$ :

$$vm = v1 + F(v2 - v3)$$

Figure 2: Scattered plots for Rastrigin test function and 10 different runs of DE in logarithmic scale.

For the recombination step, a new vector  $vf$  is created from the mutation vector by means of a combination rate  $CR$  (third parameter of the algorithm) as follows:

$$vf_i = \begin{cases} vm_i & \text{if } r_i < CR \text{ or } i = k \\ v_i & \text{otherwise} \end{cases}$$

for  $vf_i$  the  $i$ -th component of  $vf$  and  $r_i \in [0, 1]$  a random number and  $k$  a random number uniformly distributed in  $[1, D]$ . Finally a selection operator is applied. The vector  $vf$  and the initial vector  $v$  are compared and the vector that better fits the objective function is selected and remains in the next population. This process is iteratively repeated until a stopping criterion is reached. Following the literature (Das and Konar, 2005), we have chosen the following values for DE parameters:  $D=2$ ,  $ND=20$ ,  $F=0.9$ ,  $CR=0.5$ . For each test function, we have executed 100 runs of the algorithm during 10.000 iterations each one.

For each test function and alternative quantity, two different experiments have been carried out:

1. **Model Assessment.** The suitability and accuracy of the linear model in logarithmic scale has been assessed by the T-test on the regression coefficients, as well as, the analysis of the residuals variance ( $S_R$ ).
2. **Model Prediction.** In order to assess the prediction capabilities of each model two different experiments have been addressed. On one hand, we have explored the relation between  $RefCrit$  and  $AltCrit$  by analyzing the confidence intervals of the regression coefficients. On the other hand, we have compared the prediction intervals across the three distribution-based quantities.

## Experiments and Results

### Model Assessment

Figure 2 shows scattered plots associated to the regression model for the Rastrigin test function. The  $y$  axis represents

$RefCrit$  values and the  $x$  axis each of the alternative quantities (from left to right **MxD**, **MxDQuick** and **StdQuick**). Each plot shows 10 different runs marked with distinct colors and markers. For all alternative quantities, we observe a uniform behavior across DE executions, which present the same linear pattern with a small variation.

Table 1 reports the estimation of the model parameters (the regression coefficients  $\hat{\beta}_0$ ,  $\hat{\beta}_1$  and the residual variance  $S_R$ ) and the p-value of the model verification T-test. We report values for each test function (rows) and alternative quantity (columns). For all cases, there is a clear linear relation between accuracy and the alternative quantities (with p close to the working precision). Besides the goodness-of-fit is excellent, given that  $S_R$  is extremely small compared to the variable ranges (see fig. 2).

Concerning the relation between the two variables, it is worth noticing two aspects. Firstly, we observe that the estimated slope  $\hat{\beta}_1$  is close to 1 for all cases. This implies that the relation in logarithmic scale is a translation of the identity and the regression model in the original scale is also linear. Secondly, the constant coefficients  $\hat{\beta}_0$  are sorted as follows:

$$\hat{\beta}_0(\text{MxD}) \leq \hat{\beta}_0(\text{MxDQuick}) \leq 0 \leq \hat{\beta}_0(\text{StdQuick})$$

The above commented points indicate that there might be the following tendency:

$$\text{StdQuick} \leq RefCrit \leq \text{MxDQuick} \leq \text{MxD}$$

This already suggests that the value of maximum distances itself might guarantee an upper bound for the EA accuracy. In order to really confirm such hypothesis, we should analyze the prediction intervals.

### Model Prediction

Figure 3 shows the prediction intervals for the 6 test functions. Each plot shows the prediction interval for all alternative quantities, as well as the identity line (solid line)

	MxD				MxDQuick				StdQuick			
	$p$	$b_1$	$b_0$	$S_R$	$p$	$b_1$	$b_0$	$S_R$	$p$	$b_1$	$b_0$	$S_R$

Table 1: Model fitting scores

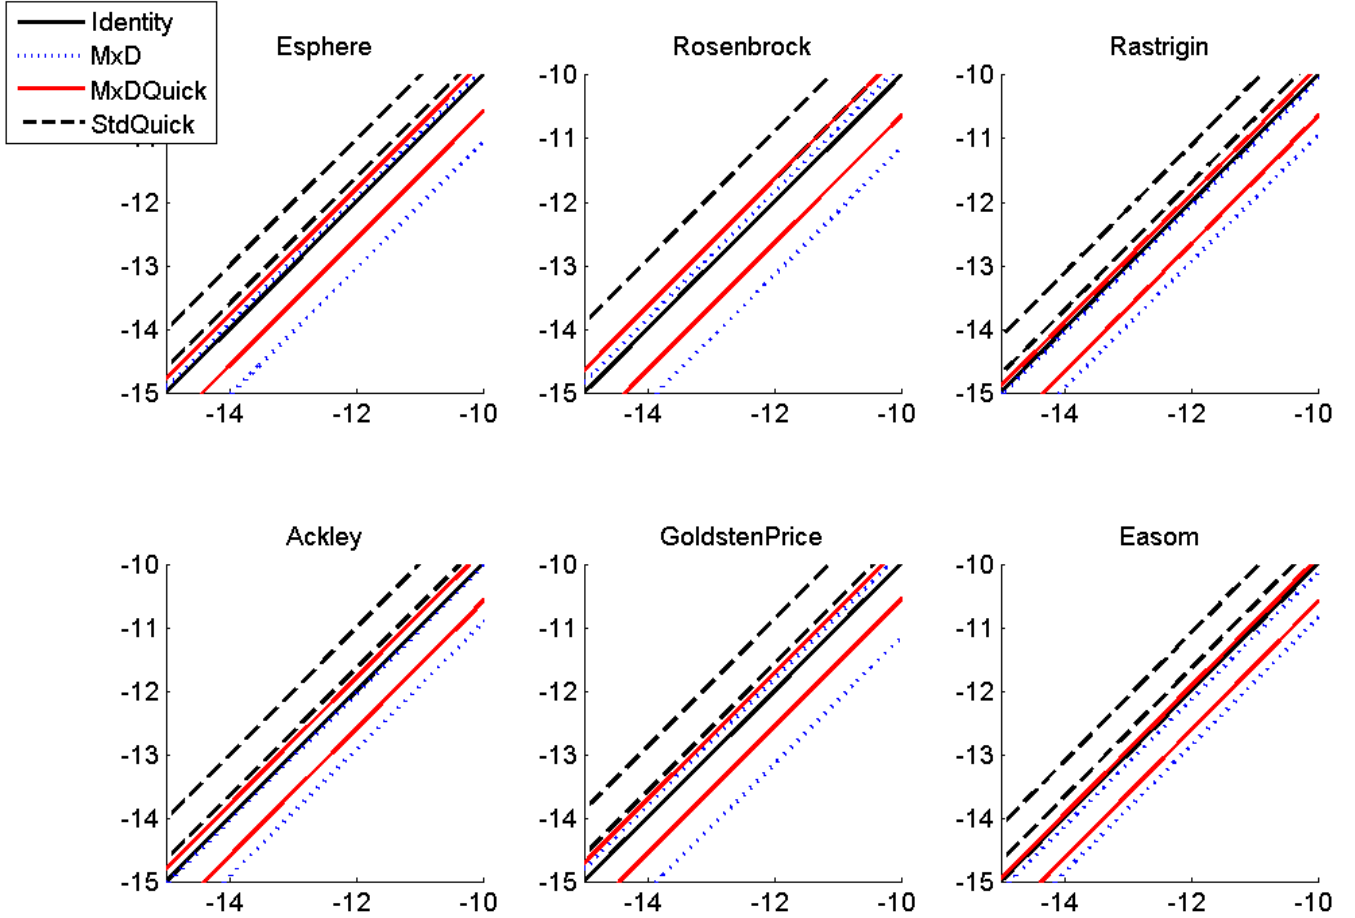

Figure 3: Prediction intervals

for a better visual comparison between *AltCrit* prediction and *RefCrit* values. The alternative quantity can substitute *RefCrit* in the measure that the identity line is within the range given by the prediction interval. This is the case for quantities based on maximum distances. In the case of **StdQuick** the predicted values are above the reference identity line. This implies that **StdQuick** and *RefCrit* can not be directly swapped and, thus, we need the upper bound given in (9) for predicting *RefCrit* values.

Table 2 reports the upper bounds for each alternative quantity ensuring a given accuracy for *RefCrit*. For each test function (rows), we report values for two accuracies  $10^{-6}$  and  $10^{-9}$ . As suggested by the plots in fig. 3, for Rastrigin, Ackley and Easom test functions, the upper bound for **MxD** is almost equal to the accuracies  $10^{-6}$  and  $10^{-9}$ . This is also the case for Easom test function and **MxDQuick**. For the remaining cases, **MxD** and **MxDQuick** upper bounds are a little lower (though still comparable). We would like

		<b>MxD</b>	<b>MxDQuick</b>	<b>StdQuick</b>
<b>Esfere</b>	$10^{-6}$	$8.3 \cdot 10^{-7}$	$7.5 \cdot 10^{-7}$	$3.5 \cdot 10^{-7}$
	$10^{-9}$	$8.3 \cdot 10^{-10}$	$7.5 \cdot 10^{-10}$	$3.5 \cdot 10^{-10}$
<b>Rosenbrock</b>	$10^{-6}$	$7.5 \cdot 10^{-7}$	$6.4 \cdot 10^{-7}$	$3.1 \cdot 10^{-7}$
	$10^{-9}$	$7.6 \cdot 10^{-10}$	$6.5 \cdot 10^{-10}$	$3.2 \cdot 10^{-10}$
<b>Rastrigin</b>	$10^{-6}$	$9.8 \cdot 10^{-7}$	$8.4 \cdot 10^{-7}$	$4.0 \cdot 10^{-7}$
	$10^{-9}$	$9.5 \cdot 10^{-10}$	$8.7 \cdot 10^{-10}$	$4.2 \cdot 10^{-10}$
<b>Ackley</b>	$10^{-6}$	$9.7 \cdot 10^{-7}$	$7.6 \cdot 10^{-7}$	$3.5 \cdot 10^{-7}$
	$10^{-9}$	$9.7 \cdot 10^{-10}$	$7.8 \cdot 10^{-10}$	$3.6 \cdot 10^{-10}$
<b>GoldstenPrice</b>	$10^{-6}$	$7.3 \cdot 10^{-7}$	$7.0 \cdot 10^{-7}$	$3.0 \cdot 10^{-7}$
	$10^{-9}$	$7.2 \cdot 10^{-10}$	$7.0 \cdot 10^{-10}$	$3.1 \cdot 10^{-10}$
<b>Easom</b>	$10^{-6}$	$1.0 \cdot 10^{-6}$	$8.9 \cdot 10^{-7}$	$3.9 \cdot 10^{-7}$
	$10^{-9}$	$1.1 \cdot 10^{-9}$	$9.6 \cdot 10^{-10}$	$4.2 \cdot 10^{-10}$

Table 2: Upper-bound ensuring a given accuracy of EA

to note that this does not contradict the swapability of the two quantities. The upper bound condition requires that  $RefCrit$  equals  $U_{PI}$ . This is a stronger condition than the swapability one, which just requires  $RefCrit \leq U_{PI}$ . Concerning **StdQuick**, its upper bounds are clearly lower (a 40% at most) than the two accuracies. This confirms that **StdQuick** and  $RefCrit$  are not directly swapable.

## Conclusions and Future work

In real-world problems (which have unknown optimums) it is mandatory to design a termination condition for EA ensuring stabilization close to the unknown optimum. As far as we know, this is the first work addressing EA termination condition in terms of statistical inference. In this context, we have explored to what extent a reference quantity (not available in real-world problems) measuring EA accuracy ( $RefCrit$ ) can be substituted by an alternative quantity ( $AltCrit$ ) computed from EA population.

According to our experiments on several known test functions, there is a strong (almost ideal) linear relation between distribution-based quantities (**MxD**, **MxDQuick** and **StdQuick**) and the distance to the optimum. This allows analyzing the prediction capabilities of each distribution-based quantity by means of the regression prediction intervals. From our analysis, we conclude that quantities based on maximum distances (**MxD**, **MxDQuick**) have the highest concordance to EA accuracy and, thus, can substitute it as termination condition. Given that **MxDQuick** is computationally faster than **MxD**, it is the best candidate for terminating EA in real-world problems.

We consider that there are some issues that should be further developed. The test functions used are a small set of benchmarking data sets (we cover two out of the five categories described in (Hansen et al., 2010)) and only 2-D problems have been solved. However, the functions used include three properties (multimodality, global structure and scalability) reported in a recent study (Mersmann et al., 2010)

to have a high influence in the performance of EA's. In order to fully test the applicability to real-world problems, we will enlarge the test set to include groups of functions with specific key features (Hansen et al., 2010) affected by noise and stochastic variability. Regarding size, although it definitely influences convergence rate (more iterations of EA are required (Hansen et al., 2010)), this is independent of the relationship between  $RefCrit$  and  $AltCrit$ . Thus, size is not a limitation for the prediction model, which links convergence rate with population stability.

In this study we have restricted to DE algorithm. We are currently extending our analysis to other EA methods in order to cover existing EA paradigms: genetic algorithms (Goldberg and Richardson, 1987), evolutionary strategies (Beyer and Schwefel, 2002), particle Swarm optimization (Barrera and Coello, 2009), among others. Nevertheless, we do not expect any significant changes in our conclusions since DE already presents the main features of EA (Ronkkoenen, 2009).

In our experimental setting test functions have been studied separately. We consider that the influence of the test function should be taken into account, so that the inference can be done independently of the function features. This will be studied by using generalized regression models including random effects (Lee et al., 2006) modelling the impact of the test function group.

Finally, it is worth noting that in numerical analysis, a termination condition for an iterative scheme only makes sense in the case that the algorithm converges (that is, it reaches a steady point). The convergence rate of an iterative minimizing method depends on some properties of the target function (whether there is a minimum or not) and the method itself (its capability to find the minimum). In complex real-world problems, there is no guarantee that such conditions will be satisfied. Therefore, in practice, a termination condition in terms of a number of iterations or function evaluations is required in order to guarantee that the algorithm

stops. We note that this is not a specific limitation of our methodology, but a general feature of real-world applications, which might present a poor convergence rate.

# Local Information Maximisation creates Emergent Flocking Behaviour

Christoph Salge<sup>1</sup> and Daniel Polani<sup>1</sup>

<sup>1</sup>University of Hertfordshire, Hatfield, UK  
c.salge@herts.ac.uk

## Abstract

The three boids rules of alignment, separation and cohesion, introduced by Reynolds to recreate flocking behaviour have become a well known standard to create swarm behaviour. In this paper we want to demonstrate how similar flocking behaviour can be created by a local, agent based model, following a principle of information maximisation. The basis for our model is an extension of Vergassola's *infotaxis* model, where agents determine their actions based on the highest expected reduction of entropy. We adapted this approach to a grid world-based search task, and extended the agents abilities so they could not only perform a Bayesian update with information gained from the environment, but also with information gained from other agents. The resulting global flocking behaviour is then analysed in regard to how well it resembles the basic boids rules.

## Introduction

Flocking behaviour is a natural phenomenon found in a diverse selection of life forms, such as birds, fish, herd animals and insects. And, as demonstrated by Dyer et al. [8], in specific circumstances even humans exhibit similar behaviour. One of the first models to create this behaviour in a computer simulation is the *boids* steering model, introduced by Reynolds [14]. The model is a prime example of a powerful artificial life idea, namely how local self organisation can create emergent global phenomena. Originally developed to animate the movement of fish and birds for graphical presentation, the boids model has developed into a "de facto" standard for flocking algorithms.

The three basic rules, alignment, separation and cohesion, are agent based and local, so they allow every agent to determine its own actions by itself, using only local data:

- Alignment: steer towards the average heading of local flock mates
- Separation: steer to avoid crowding local flock mates
- Cohesion: steer towards the average position of local flock mates

This model, or variations thereof, are not only the basis for many current flocking and swarm simulations, but are also a powerful example for how simple, local rules can lead to the emergence of complex, life-like properties.

What we want to probe further in this paper is how the global phenomenon of self-organised flocking can be explained; but instead of motivating the individual atomic rules, we intend to challenge the notion that those rules are necessarily atomic. As an alternative, we offer a model where the individual agent's actions, and the resulting global flocking behaviour, is created and motivated by obtaining as much relevant information about the environment as possible. This is an additional result of our previous efforts to extend information theoretic-behaviour generation in general, and in particular the biologically inspired *infotaxis* model by Vergassola et al. [25], to a multiagent system. In the original model the sensor inputs from the environment are used, via a Bayesian Update, to update an internal probabilistic model about a specific location. Actions are chosen based on how much expected information gain they provide for the internal model. In the multiagent model, the actions of other, observable agents are treated with the same Bayesian update, and the resulting agent movement starts to resemble flocking behaviour.

In this paper we are first going to describe our model, and how the single principle of maximal information gain can be used to generate agent behaviour. We shall then demonstrate how information, both from the environment and from other agents, is integrated into the Bayesian model of the agent. The resulting behaviour of those models is then analysed by measuring how well it resembles certain basic characteristics of boids flocking behaviour. We also offer a less formal explanation on how the mechanism of information maximisation leads to flocking behaviour, and how this could be generalised.

## Related Work

Information Theory was originally conceived by Shannon [17] to deal with the limits of transatlantic communication; the main focus being the optimal use of a limited commu-

nication channel. But its considerable mathematical versatility, since it can be applied on any system that can be formalised in terms of random variables, also allows for the analysis of a diverse variety of systems in terms of their information theoretic properties and limitations [5].

A recent information theoretic analysis of a boids-like swarm model by [4] demonstrated the ability for information transfer between the flocking agents. Few “informed” agents were capable of steering a swarm. Corresponding results have been observed in the flocking behaviour of human crowds by [8]. If we take a closer look at coordinated systems in nature, it is not surprising that there is a certain degree of mutual information between the organised components. Organisation requires a certain degree of causal dependence, and if we follow the argument of [12], this leads to a certain degree of mutual information between the appropriate variables. Similar conclusion can be drawn for the necessity of information flow, as defined in [2]. The mere presence of some non-vanishing correlation, i.e. nonzero mutual information in nature is, of course, not surprising. However, it is striking that there are many indications that biological organisms tend indeed to operate close to the physical limits for sensory and informational capacities [11, 15]. This can be formulated as an information optimality principle which provides a constructive way to generate behaviours. The use of information theory to model the complexity of cognitive processes [18, 21] has lead to systematic approaches to model agent decision making [22, 23, 6] utilizing information theory in a constructive way, beyond the use as a merely analytic tool. To mention a few examples; it has been used to optimize behaviour in a Reinforcement Learning-like context by [20]. Also, for behaviour generation, there is the predictive information maximization [1] which is related to the dynamical systems *homeokinesis* principle by [7].

Another example is the idea of *empowerment* by [9], where an agent tries to act as to maximise the channel capacity between its actuators and sensors which essentially is an optimization of its sensorimotor niche. [3] demonstrates that this principle on its own can already leads to coordinated multiagent behaviour. Note that this shows how, seemingly in opposition to the original philosophy behind information theory which had been designed to carry no semantics, our current work is based on ideas that one is able to distinguish between relevant and non-relevant information.

The *information bottleneck* perspective by [19] demonstrates how the notion of Shannon information can be imbued with relevance, and this can be achieved either through the presence of goals or reward structures [13, 24] or, alternatively, imprinted by the agent-environment interaction itself [10].

This concept of *relevant information* [13] is one we refer to when we later talk about an agent maximising information. *Relevant information* is interpreted here according to the information bottleneck formalism [19, 13]. It quantifies

not *all* information (i.e. possible reduction of uncertainty) in the environment, but only that information which identifies the selection of optimal actions by the agent. Under this perspective, any information in the environment beyond that is ignored.

## Information Theory

We consider random variables  $X$  which can assume concrete values  $x$ . Write  $P(X = x)$ , or  $p(x)$  by abuse of notation, for the probability of  $X$  assuming the specific value  $x$ . We can now define the entropy  $H(X)$  of the random variable  $X$  as

$$H(X) = - \sum_x P(X = x) \cdot \log P(X = x) \quad (1)$$

This is often used to describe the uncertainty about the outcome of  $X$ . An alternative, equivalent interpretation is to consider  $H(X)$  as the average expected “surprise” or the information gained if one was to observe the state of  $X$ , if all one knows about  $X$  is only its distribution  $P(X)$ .

The entropy has a number of important properties. Among others, as it is an *a priori* uncertainty, the entropy is larger if the outcomes are more evenly distributed than if the outcomes are more concentrated on a particular value — in other words, concentrated values are easier to predict (and less uncertain) than uniformly spread ones.

Consider now two jointly distributed random variables,  $X$  and  $Y$ ; then we can calculate the conditional entropy of  $X$  given a particular outcome  $Y = y$  as:

$$H(X|Y = y) = \sum_x P(X = x|Y = y) \cdot \log P(X = x|Y = y) \quad (2)$$

This can also be generalised to the entropy of  $X$ , given the random variable  $Y$  in general, and is obtained by averaging over all possible outcomes of  $Y$ :

$$H(X|Y) = \sum_y p(y) \cdot H(X|Y = y) \quad (3)$$

This is the entropy of  $X$  that remains if  $Y$  is known. Finally, consider  $H(X)$  and  $H(X|Y)$ , the entropy of  $X$  before and after we learn the state of  $Y$ . Thus, their difference is the amount of information we can learn about  $X$  by knowing  $Y$ . Subtracting one from the other, we get a value called mutual information:

$$I(X; Y) = H(X) - H(X|Y) \quad (4)$$

This is the value we will refer to if we use the term information and it is measured in bits; if one variable is said to have information about another it means that the mutual information between them is non-zero. As the mutual information is symmetrical ([5]), this works both ways, so one variable  $A$  contains as much information about  $B$ , as  $B$  does about  $A$ .

Importantly, note that this original notion of information does not include any semantics and only depends on the joint

distribution of  $X$  and  $Y$ . Therefore, in calculating the entropy and the mutual information measures, the labels of the values of the variables are not relevant.

In the specific model described in the next section, we will maximise the information in respect to a specific location of a resource, but the model is entirely general and the information could correspond to any kind of information about the state of the agent's environment needed for the agent to increase its performance.

## Experimental Model

### Scenario

We consider a model consisting of agents situated in a torus-shaped grid world of size  $n \times m$  with periodic boundary conditions. Each location in this world is in the set  $\mathcal{W} = \mathbb{Z}/n\mathbb{Z} \times \mathbb{Z}/m\mathbb{Z}$ . There is one single location of interest  $F^*$ , defined also over the set  $\mathcal{W}$ . To contextualise, we will call the location the *food source*, but one can interpret it as any other relevant location information, such as position of shelter or mates. The goal of the agents is to determine (not reach) this location in the shortest possible time. The agents' initial location, and the location of the food are randomly generated at the start of the simulation, and each time step an agent can execute a move action which moves it one cell up, down, left or right. The agent then gets new sensor inputs; it is able to see the state of the world in all cells not more than  $r$  cells away from it. Its sensor signal for each cell is a two-state random variable that indicates either that those cells are empty or that they contain the (here unique) food source. After this observation, the agent decides where to move next. This behaviour is repeated until the agent finds the food.

Once the agent finds the food, the agent disappears. An agent that has disappeared does not block other agents, cannot be observed, and its behaviour is not taken into account for the statistical measurements. Note that the food source itself is unaffected from agents finding it.

The above scenario determines the basic properties of our setting. Now, as we are interested in flocking behaviour, for an effective evaluation, the simulation will be run continuously, so the agents have time to form a swarm. Thus, instead of reinitializing the simulation every time one or all agents find the food source, at each time step there is a 3 % chance that the food will be randomly relocated. In this case, all agents' internal model is reset, so they start a new search. Those agents which have disappeared because they found the food will also be put back into the world in the location they previously disappeared from. The purpose of this is to allow swarms that have already formed to continue their coordinated movement.

### Agent Behaviour

In our model, the agents determine their actions by using an internal probability distribution  $F$ , which stores informa-

tion about the world. This internal distribution implements a Bayesian model for the location of the food source. More precisely  $F$  is also defined over  $\mathcal{W}$ , and  $P(F = f)$  corresponds to the probability of the food source being in location  $f$ , given the agent's current information.

Initially, all cells have the same probability of  $\forall f \in \mathcal{W} : p(f) = 1/(n \cdot m)$ , since the agent has no information about the location  $f$ . However, as the agent moves around, it can observe different locations in  $\mathcal{W}$ , and discovers that some locations are either empty or contain the food source. If  $f$  contains the food, then  $p(f) = 1$ . If  $f$  is empty, then  $p(f) = 0$ .

In both cases the probabilities of the other locations are normalised accordingly, so the sum of probabilities is always one. This operation is functionally identical to actually performing a Bayesian update with the observable environmental random variables, namely, the food state of the cells within the agent's sensor range.

The remaining uncertainty of the agent about the location of the food source is reflected by the internal probability distribution and can be measured in terms of entropy  $H(F)$ , where  $F$  is the agent-internal random variable corresponding to the expected position of the food.

### Infotaxis Search

To generate the agent's behaviour, we adopt a greedy information gain-maximisation algorithm, called *Infotaxis* by [25]. Infotaxis was shown to provide a biologically plausible principle as to how a moth could use the very sparse information provided by their olfactory sensors to determine the source of pheromones inside a wide area. The main idea is to act in a way that increases the expected gain in information at each time step. We adapted the infotaxis approach for our discrete grid world scenario.

Infotaxis behaviour is generated by the following steps:

1. Determine which action  $a$  will likely lead to the largest reduction in entropy  $H(F)$ , the uncertainty regarding the position of the food source.
2. Take action  $a$  and update  $F$  with the resulting sensor input.
3. If  $H(F) > 0$ , then repeat from step 1.

In step 1 the agent has to determine the likely reduction of entropy based on  $F$ , the agent's current "knowledge" about  $F^*$ .

Depending on the position  $w \in \mathcal{W}$  of the agent, there is a set  $\mathcal{S} \subseteq \mathcal{W}$  of the locations that are visible to the sensor of the agent. The visible locations are those within the agent's sensor range, meaning they are  $r$  or less cells away from the agent's position. If the agent, starting from the current position, takes the action  $a$  from its set of available actions  $\mathcal{A}$ , it will enter a new state  $w_a$ . In this new state the agent can now sense a new set of locations, denoted by  $\mathcal{S}_a$ .

To calculate the expected entropy reduction of action  $a$ ,  $\Delta H(a)$ , two cases have to be considered. In the first case, the actual location of the food source  $f \in \mathcal{W}$  would be inside the newly observed set of positions  $\mathcal{S}_a$ , inside the sensor range after the action  $a$  was taken by the agent. The agent assumes that this occurs with the probability of

$$P(f \in \mathcal{S}_a) = \sum_{f \in \mathcal{S}_a} P(F = f) \quad (5)$$

in reference to the agent internal model  $F$ . In this case the agent's uncertainty after carrying out action  $a$ ,  $H(F_a)$  would be reduced to zero, and the reduction of entropy would be the difference  $H(F) - H(F_a) = H(F)$ .

In the other case, the location  $f$  of the food source is not in  $\mathcal{S}_a$ . This occurs with a probability of  $1 - P(f \in \mathcal{S}_a)$ . In that case, we have to calculate an updated probability distribution for  $F$ , called  $F_a$ . According to Bayes' rule,  $P(F_a = f) = 0$  for all  $f \in \mathcal{S}_a$ , the resulting probability for all observed, empty locations to contain the food source is zero, and the remaining locations are normalized accordingly by:

$$\forall(f \notin \mathcal{S}_a) : P(F_a = f) := \frac{P(F = f)}{\sum_{w \notin \mathcal{S}_a} P(F = w)} \quad (6)$$

This divides the remaining non-zero probabilities, by the sum of their probabilities, normalizing the overall sum of all probabilities to 1. This updated version of  $F_a$  can then be used to calculate the reduction of entropy in the second case, which is given by the difference  $H(F) - H(F_a)$ . If we put all this together, the expected reduction of entropy for taking action  $a$  is:

$$\Delta H(a) = P(F \in \mathcal{S}_a) \cdot H(F) + P(F \notin \mathcal{S}_a) \cdot (H(F) - H(F_a)) \quad (7)$$

To summarize, each step the agent selects the action  $a$  that maximises  $\Delta H(a)$ . If several actions lead to the same expected entropy reduction, the agent selects one of them at random. The sensors are then updated as described above, and this behaviour is repeated until the food source is located. Essentially, this behaviour implements a version of Vergassola et al.'s *infotaxis* search and we will refer to it as such in the subsequent text.

## Social Bayesian Update

Earlier studies of single agent *infotaxis* behaviour in [16] demonstrated that the agent's actions contain information about the food source location. If we look at Fig.2, we see how the probability of the food source location is distributed conditioned on an agent moving north. More importantly, every agent which has to take in (a minimum amount of) relevant information to attain a certain performance level also *must necessarily* encode at least that amount of information

Figure 1: Graph showing  $P(F|A = north)$ , the probability distribution of  $F$ , the food source position, given a specific agent movement (in this case north). The data was obtained from 10000 single agent simulations in a  $20 \times 20$  grid world, agent position is (11, 11). Note that there is a peak north of the agent, meaning that it is more likely for the food source to be directly north of the agent when it moves north.

in its actions, and this is the case even if it does not have an explicit intention to communicate. This *digested information*, as discussed in [16], has several properties which are interesting for an observing agent with similar goals:

1. Actions *must* contain relevant information, even if the agent does not want to communicate
2. Better agent performance requires more, or the same amount of relevant information
3. The actions of an agent are likely to exhibit a higher density of relevant information than other parts of the environment
4. The actions of an agent might contain information that is not available in the current space or time.

From these properties it follows that a reasonable next step in our information maximisation model would be for the agent to use this digested information and incorporate it in their internal probability distribution. We extend the model so the agent can now, for all cells in its sensor range, detect whether one or more agents are in that cell and where they came from. So, the four new sensor states for each cell are agent that moved in from the north, ... south, ... east, ... west. Each observed move will lead to an adjustment of the assumed internal probability distribution, using a similar

form of Bayesian update already used to integrate the information from the environment. This adjustment of probabilities can be comfortably integrated into our existing infotaxis search.

Note that for the now described simulation all agents are equipped with those new “social” abilities and all of them use the other agents’ actions to update their internal world models. But they only use this ability if they accidentally encounter another agent. They do not deliberately seek out other agents.

## Bayesian Update

Let  $F$  denote the agent’s current internal probability model for the location of the food source  $F^*$ , and  $a$  the state of the random variable  $A$  that encodes the last move action of another agent it’s observing. The agent then use Bayes’ Theorem to update the probability distribution of  $F$ , with the observed action  $a$ .

What the agent is interested in is the probability of the food source to be in a specific location, given the evidence of another agent’s action and relative position  $P(F^* = w|A = a)$ . According to Bayes’ Theorem this is calculated for every potential location  $f$  of the environment as:

$$P(F = f|A = a) = \frac{P(A = a|F^* = f)}{P(A = a)} \cdot P(F = f) \quad (8)$$

Whenever an agent encounters one or several agents it uses this formula to adjust its internal probability  $P(F = f)$  for every location of  $f \in \mathcal{W}$ .

- $P(F = f)$ , the *a priori* probability, is the internal model of the agent for mapping the probability distribution of  $F^*$ , as gained by their own experience so far;
- $P(A = a)$  is the probability of an agent taking the move action  $a$ . Rotational symmetry suggests a probability of 1/4 for each action  $a \in \{north, west, south, east\}$ . Measurements in our single agent simulation confirm this. This is a normalisation factor, so the overall sum of probabilities is still one.
- $P(A = a|F^* = f)$  is the probability of another agent performing action  $a$  if the food is in position  $f$ . Note that the position  $f$  in this case will always be calculated in relation to the position of the observed agent. So, the question we are asking is for example “If the food is known to be 3 cells north of the agent, what is the probability of the agent performing move action  $a$ ”. We then record all the cases in the past where an agent has been observed 3 cells south of a food source together with the action it took.

To obtain these statistics for the computer simulation, we observed 10000 single infotaxis agents searching for the food. Note that the agents we used were non-social and thus

“blind” to the actions of other agents. They behaved according to the “Infotaxis” part of this paper. So, even though all the agents in the infotaxis simulation have the ability to sense other agents and update their internal world models, they still calculate their Bayesian update under the assumption that all others were non-social agents. We used the data obtained from non-social agents to create the statistics for the probabilities  $P(A = a)$  and  $P(A = a|F^* = f)$ .

After the agent updates  $F$ , it resumes the previously described infotaxis behaviour to generate its next move action. Note that agents which have successfully located the food stopped moving and were neither perceivable by other agents, nor blocking them. This was done to increase the challenge since it would have been trivial for another agent to infer from seeing another non-moving agent that the food must be within sensor range of that agent. As a result, the agents could not “cheat” by observing any agents which already knew where the food was.

This model, which includes the Bayesian update not only based on environmental variables, but also on other agents they encounter will be called the *Social Bayesian* model. Apart from the update of the internal model before the next infotaxis action is chosen, it is identical to the infotaxis model.

## Measurements

While flocking behaviour might be intuitively visible at this point in our model, defining an objective overall measure which quantifies the emergent flocking behaviour seems difficult. Instead, we aimed to measure the immediate effects of behaving according to the boids rules should have. We defined the following three measurements:

### Alignment

To quantify the *alignment* of the different agents, we added up all the agents’ movements and took the length of the resulting vector and normalised it. I.e., every agent  $x \in \mathcal{X}$  has an associated vector

$$\vec{v}_x \in \{(1, 0), (0, 1), (-1, 0), (0, -1)\} \quad (9)$$

corresponding to the last direction it moved in. The global alignment is then calculated as the length of the sum of all agent’s vectors, divided by the number of agents:

$$alignment = \frac{|\sum_{x \in \mathcal{X}} \vec{v}_x|}{|\mathcal{X}|} \quad (10)$$

This results in a value between 1.0 and 0.0. The maximum value is reached when all agents move in the same direction, and the lowest value of 0.0 is attained when the movement of all agents is distributed evenly between those moving north and south, and those moving west and east, respectively. Note again that agents which have found the food are not taken into consideration for this measurement, since

it would be irrelevant to measure how well aligned they are, once they are not moving anywhere.

This measurement are taken for every simulation step, and an average over all simulation steps is calculated for the whole simulation.

### Cohesion

To measure *cohesion*, we simply count, for every agent, how many other agents are within the agent's sensor range for any given time step. This value is then averaged over all agents, and over all time steps, and the result we call the local agent density, or simply density. This value, different from the global alignment, is only taken locally, and reflects how well agents keep other agents within their own sensor range.

### Separation

The hardest value to measure is *separation*, since it basically quantifies an objective of what should not happen. To approximate this, we measure how often one agent tries to enter the cell of another agent, and thus colliding with it. In this case, the agent trying to move will simply fail doing so. The resulting number of overall collisions is then divided by the number of time steps, providing an average amount of collisions per round, or simply collisions. This number is of course also dependent on the number of agents in the simulation, but this correlation if not linear, is therefore not normalised with respect to agent number. Thus, one needs to take care to only compare values where similar amounts of agents have been involved. Again, agents who have found the food are not considered for collisions detection.

### Results

All measurements were taken in a open ended simulation where the food had a 3 % chance of being moved every time step. When this happens, all agents' internal models are reset, and those agents who have already found the food are put back into the simulation. The simulations were run for 100,000 time steps, with 20 agents, in a  $20 \times 20$  torus-shaped grid world. As a baseline for comparison, we also measured those values for a group of agents that chose their actions at random, only stopping if they chanced upon the food source.

	Alignment	Density	Collisions
Random	0.23	1.03	0.72
Infotaxis	0.29	1.33	1.31
Social B. Update	0.39	1.68	0.49

Table 1: Flocking indication measurements taken for three behaviour models. (Random, Infotaxis, Social Bayesian

If we move from the random behaviour to the single agent infotaxis search, we see both the local agent density and the number of collisions increase. Since agents are not yet reacting to each other in the plain infotaxis model, this seems to

Figure 2: Two screen shots from a social infotaxis simulation with 15 agents, sensor range 5 in a 50 x 50 world. The grey box is the food source, the black boxes are agents. The lines indicate the vector of movement in the last 9 turns, in steps of 3.

be a result of the improved search algorithm. If we measure how long it takes, on average, for a *random* agent to find the food (ca. 450 time steps), and compare it to the time it takes an *infotaxis* agent to find the food (ca. 70 time steps), we see that the infotaxis search has a much better performance, resulting in agents actually finding the food before it changes position. This in turn leads to a local concentration of agents, which is likely to result in increased density and collisions. Note, however, that if we look at the alignment indicator we also see, that even for a group of agents that moves at random the average alignment is not 0.0, but 0.23. This is a statistical effect and not surprising, since it would actually take coordination to ensure that all agent's movements are always balanced between the different directions.

The interesting comparison is now between the two simpler models and the Social Bayesian Update. In the latter, we see a further increase in alignment, indicating that a high number of agents now move in similar directions during most of the simulation. Keep in mind that to achieve an average of 1.0, all agents would have to move in that same direction, in every turn. We also get a further increase in local agent density, while at the same time the number of collisions is reduced. So while there are now even more agents within the sensor range of each other, the agents manage to collide much less.

### Interpretation

We presented a model where the agents' behaviour is motivated by one single principle or goal, namely to gain as much information about a relevant variable in the environment. To achieve this, the agents take any kind of sensor variable, be it an environmental variable, such as the state of a grid world cell, or the action variables of another agent, and performs a naive Bayesian update on its internal proba-

bilistic model about said relevant variable. The agent's own actions are chosen in regard to which of them provides the greatest expected reduction of entropy, based on the agents' own internal model.

In this section, we would now like to discuss possible explanations on how this information maximisation model leads to the three different rules which create the boids-like flocking behaviour.

### Alignment

When an agent is controlled by non-social infotaxis behaviour moves, then its action contains information about the relative position of the food source. If we take a look at an agent moving north (due to rotational symmetry, the actual direction is exchangeable), then the food is more likely to be in a position north of the agent, and less likely to be in a position south of it. This effect, even though the agent does not know where the food is, results from the fact that the agent knows where the food is *not*. As seen in Fig. 2, the probability distribution has its highest peak directly north of the agent, and the minimum of the distribution is in the area south of the agent. Both peaks flatten out the further the cells are away from the agent.

Another agent who observed the first agent move north would perform a Bayesian update on its own assumed probability distribution of the food source. Everything else being equal, this would lead him to "believe" that the food is more likely to be north. The resulting move action would also be to rather move north than in any other direction. A flock of agents, each observing each other, could thereby create a "travelling wave" of high probability immediately outside of their sensor range, driving them all in a similar direction.

The generalised principle here is that an agent 1 observing actions by an agent 2 assumed to have similar goals would lead the original agent 1 to conclude that agent 2 has information that would make such an action reasonable, and in turn, this would make the same action more reasonable for agent 1.

### Separation

Whenever agent 1 observes an agent 2 moving in our grid world model, it performs a Bayesian update for the position of the food source. The biggest impact of this update is on the probabilities of the area immediately around agent 2. The cells of the world agent 2 observed in its previous turn are definitely empty, so most of the current area around agent 2 cannot contain any new information for the observer. So while observing another agent is an efficient way to gain information, the immediate environment around that agent becomes informationally unrewarding afterwards. An information-driven search would therefore try to steer away from the immediate area around an observed agent.

In general, if an agent 2 in a specific position reveals information it gets from being in that position to agent 1, then

the more information agent 1 gets from that agent, the less informationally interesting does being in that position become.

### Cohesion

In our current model, most of the cohesion seen in our agent groups seems to be a direct result of the high amount of agent alignment. If agents that meet each other move into a similar direction, with similar speed, then they also happen to stay together. In general, it would actually be reasonable to include a further term into the infotaxis mechanism which would account for the amount of information gained from other agents. Following from the "digested information" principle, it is informationally advantageous to keep other agents in sensor range, to be able to use them for a Social Bayesian Update. Seeing another agent, and being able to use the information in its actions increases each agent's expected entropy reduction.

All in all, if we take into account both separation and cohesion, the best solution in terms of information gain seems to be to keep other agents just inside your own maximum sensor range.

### Future Work

Since all agents observe each other we suspect there is the distinct possibility that a positive feedback loop can emerge, which detaches itself completely from the environmental information. As an example, an agent might take, for lack of better information, a random action; for example to move up north. Another agent might observe the first, and if it did not know anything apart from the fact that another agent moved north, he also would move north. The first agent in turn might now see the second, observe that the other agent moved north, and take this as good reason to also move north. This vicious feedback circle then continues, reaffirming both agents internal beliefs that "they are doing the reasonable thing". This phenomenon warrants further study, since it could illuminate how in social settings seemingly reasonable assumptions lead to strong "convictions" that are utterly wrong and detached from reality.

Furthermore, it might also be interesting to move the present model from a grid world scenario into a continuous world. This would not only create more realistic animations, but would also be necessary to establish that the observed effects are not just artefacts of the grid world model. The challenge here would be the extension of previously described information theoretic tools to the continuous domain.

### Conclusion

We found that information-based social observation mechanisms are able to reproduce several postulated mechanisms of flocking. This is confirmed both by qualitative observation as well as using quantitative measures. Starting with the assumption that every agent needs to obtain some kind

of relevant information from the environment to act intelligently, then most of the arguments follow directly from that. Infotaxis seems to be not only conceptually grounded, but both biological plausible ([25]), as it leads to behaviour that is very similar to actual moth behaviour, and reasonably efficient for some scenarios; its performance in these scenarios is close to that of an optimal strategy ([16]). Our extension to also include the information offered by other agent's actions is well motivated by the properties of "digested information", and the result is a performance increase beyond the level achievable for a single lone agent ([16]).

At this point in the argument, we already observe emergent flocking behaviour, only motivated by one single utility, the maximum information gain. Note that the relevant information we have been discussing does not necessarily have to be the location of a food source. It could refer to the position of predators, or the location of mates or other types of desirable states, and might lead to similar flocking behaviour via similar mechanisms. The *relevant information* hypothesis can also be applied to a wide variety of agent types, whether birds, fish, herd animals or humans, and could offer a possible *ab initio* explanation for an immediate evolutionary gradient leading to flocking behaviour for a diverse spectrum of organisms.

## Abstract

This paper presents the first implementation results of a novel Unitronics (Unicellular Electronics) architecture based system that uses a bio-inspired prokaryotic model. It is a programmable cellular FPGA-like system inspired by unicellular bacterial organisms, and transposes self-healing and fault tolerant properties of nature to electronics systems. An e-puck object avoidance robot controller was built to demonstrate all the underlying theories of our research, the validity of the bio-inspired model and the capabilities of the Unitronics architecture that it facilitated. The robot successfully demonstrated that it was able to cope with multiple, simultaneously occurring faults. Integrity of the system is continuously monitored on-line, and if a fault is detected its location is automatically identified. Detection will trigger a self-repair mechanism and only when it is complete will normal system operation resume.

## Introduction

Bio-inspired system design is a relatively new emerging field for the realisation of electronic systems. It attempts to learn from processes and characteristics of living things, such as self-replication and self-repair properties, adapting them to electronic systems. Bio-inspired systems depending on this type of motivation can be classified in two categories: Eukaryotics (multicellular) or Prokaryotics (unicellular) systems.

The early 90's saw the first attempts [1, 2] to construct bio-inspired electronics systems using a cellular array type architecture. They were based on properties and characteristics of and used mechanisms found in multi-cellular eukaryotic organisms. Here, similar to nature, all the cells of the system, in order to configure them for a specific function, contained a full or a partial copy of the organism's DNA (genome). This approach has invariably resulted in a large amount of DNA memory in each cell. The task of the memory is to store the genetic behaviour (DNA) of each cell of the system, in the form of configuration bits (genes) for both its functional characteristic and for the necessary interconnects. Embryonics and the POETic projects are examples of eukaryotic bio-inspired systems [3, 4]. CellMatrix offers an alternative approach for cellular implementation of systems [5].

Self-healing properties, immunological protection and learning abilities are amongst the advantages offered by the eukaryotic model. All previously proposed Embrionic systems suffer from several disadvantages:

- Inefficient functionality vs. silicon area requirement due to

large genome redundancy.

- Storing large amount of redundant information (each cell required a copy the entire DNA of the system or a large part of it) increases the probability of hardware faults and information mutation in the memory cells.
- Inefficient self-repair: row or column elimination kills an unnecessarily large number of healthy cells in response to the occurrence of a single fault.
- Demanding routing resources, especially for long-distance communication.

We suggest that if a model with at least similar performance advantages but based on a simpler form of biological life could be developed, then there is a chance that it might provide a solution to the above problems. We believe that the Unitronic artificial system, which is inspired by primitive unicellular beings called prokaryotes, in particular, bacteria, with its structure and characteristics does indeed offer the answer. It combats the problem of high genome redundancy, thus increases system reliability and is in all respect superior to all Embrionics based systems.

The novel artificial prokaryotic model we have proposed [6, 7] is a solution to build efficient fault tolerant hardware systems. It offers: efficient optimisation of genome redundancy, smaller silicon area, smaller memory for the storage of redundant (back-up) configuration information and requiring less logic support [6]. In our prokaryote model, the cell is only required to store its own configuration bits and some non-configuration bits that support self-repair and not a large part or the entire DNA of the system. Self-repair is achieved by a simple cell elimination process. A new self-test methodology was proposed [8] that offers an acceptable overhead compromise between time and hardware redundancy and guarantees that not only functionality, but all interconnect lines of the cellular system, are also tested.

## Prokaryotic Bio-inspired Model

The prokaryotic bio-inspired model is described in details in [6, 7] with a recommended self-test method given in [8]. This section summarises the main features of the model and the proposed self-test.

The prokaryotic bio-inspired model offers a multi-layer architecture of programmable universal cells. Each cell consists of a function unit (FU), a communication block and a memory block. The latter contains the configuration bits (gene) of the cell that define the required behaviour of both the function unit and that of the communication block, and non-

configuration bits which assist self-repair if a fault is detected. Since the task of the gene in the configuration register (CR) is to code the behaviour of a cell so it is termed as a *coding* gene, while the gene in the non-configuration register (non-CR) that assists self-repair is a *non-coding* gene. Thus each cell's genome could be viewed as consisting of one coding and one non-coding gene. The non-coding genes are assisting the functionality and the recovery of the coding genes both for the cell in which they reside and for other cells.

In a multi-layered prokaryotic model, cells form clusters, which in turn form colonies and on the top level biofilm communities are formed by colonies. Although the individual bacterial cells' genomes, in a family of species, are the same, due to continual evolution that takes place, mutation will differentiate them. Disregarding these small amounts of differences there will always be a strand in their DNA which they all share and is common to them all. Similarly therefore, in an artificial system family, clusters could be formed with cells that demonstrate similarity in their configuration bits. These cells, although they are unique and different in their own rights, do display similarity through a shared value (C<sub>sv</sub>) that is common to every cell in a cluster. Characteristics of artificial cells are stored in the form of bits in their configuration register and form its configuration vector (C<sub>cv</sub>). Therefore every cells' configuration vector is made up of a value that the cells share (C<sub>sv</sub>) and is common to them all, and by a differential value ( $\Delta g$ ) that distinguishes the cells from another. The configuration vector of a cell can therefore be described by Equation 1.

$$C_{cv} = C_{sv} + \Delta g \quad (1)$$

or generally as:  
 $C_{cv} = f(C_{sv}, \Delta g)$

where  $f$  refers to the evolutionary function and in the simplest form could be considered as XOR or subtraction functions.

Cluster forms the first community layer. It is a convenient collection of cells to aid self-repair. A cluster is a community of genetically related entities that need not have any functional relationship. In the simplest form, two different types of clusters may be defined: as shared value cluster (sv-cluster), and gene difference value cluster ( $\Delta g$ -cluster). The first one refers to those cells in the colony that have the same shared value of their configuration bits and hence originate from the same species. The second one refers to those cells that have the same genetic difference from their base species. Components of cells and clusters are shown in Fig. 1.

Fig. 1. A colony made up of inter-related clusters and cells

A colony layer is obtained where a correlation between different clusters exists. Colonies are groups of correlated cells that facilitate self-repair. Similarly to clusters they are genetically and not functionally grouped hardware entities. Our artificial colonial layer is equivalent with the biological mixed bacterial colony and is made up of several sv-clusters (species). When a new daughter cell for one of its species is created the species shared value is differentiated by  $\Delta g$ . This differentiation process in nature amongst different bacteria occurs through the horizontal gene transfer mechanism (HGT). Here genes are transferred from one bacterium to another that changes their characteristics (e.g. acquire antibiotic resistance). HGT, in an artificial system, provides a correlation mechanism between different sv-clusters, so that  $\Delta g$  of a cell in one sv-cluster can be used to evolve the gene of another cell in another sv-cluster. In this case the shared value of the new cell is differentiated with the  $\Delta g$  from another cell, Fig. 2.

Fig. 2. Prokaryotic Bio-Inspired Model.

## T-Space

Let's suppose that an artificial system, as shown in Fig. 3a, consists of  $x$  number of cells, where  $x = n \cdot m$  and the configuration vectors of the cells are  $C_{cv1}, C_{cv2}, \dots, C_{cvx}$ . In this case the genome of the system ( $G$ ) could be described by a set of genes of the individual cells as:

$$G^p = \{g_1, g_2, \dots, g_x\} \\ = \{C_{cv1}, C_{cv2}, \dots, C_{cv(m,n)}\} \quad (2)$$

where  $g$  stands only for the configuration vector ( $C_{cv}$ ) part of the cell's memory and excludes the non-configuration bits. In system's genome  $G^p$  also shows how this  $x$  set in the physical space is defined by  $T_{sv}$  and  $T_{\Delta g}$  addresses.

If we now also include the non-coding genes (non-configuration vector) of the cells in their genome  $G$ , then the HGT (horizontal gene transfer function) function will map the coding genes from physical space (equation 2, Fig. 3a) to a new set of two dimensional T-Space (Fig. 3b), that is defined

by Tsv and T<sub>Δg</sub> address tags.

$$G^T = HGT(G^P) \quad (3)$$

Fig. 3. Example of cells' placement : a) physical, b) T-Space.

With this HGT function, inspired by bacterial communities and differences in its species, artificial cells in clusters can also be defined by a common strand and their differences. Thus grouping of cells into sv-clusters and  $\Delta g$ -clusters will show their similarities and differences, which are also identified by the Tsv and T<sub>Δg</sub> address tags. If tag combinations are unique, then to refer to any specific and individual cell in the array, instead of physical addresses tags could be used. The HGT function will transfer the gene of the  $i^{\text{th}}$  cell of array, addressed by  $i$ , from the physical space into tag space as:

$$g(Tsv, T_{\Delta g}) = HGT(\text{Cell}^i) \quad (4)$$

where  $g$  is the configuration vector (Ccv), the coding gene of the cell. The Tsv shared value tag (Csv) identifies a group of similar cells. The T<sub>Δg</sub> differential parameters tag refers to a group of cells that have already been differentiated with the same  $\Delta g$  that  $i^{\text{th}}$  cell needs to be evolved with. Therefore equation 4 could be rewritten as:

$$\begin{aligned} Ccv_{(Tsv, T_{\Delta g})} &= f(Csv_{(Tsv)}, \Delta g_{(T_{\Delta g})}) \\ Tsv &= \{1, 2, \dots, v\} \\ T_{\Delta g} &= \{1, 2, \dots, w\} \end{aligned} \quad (5)$$

Where  $v$  is the number of shared values and  $w$  is the number of differential parameters (gene differences).  $v$  could also be considered as the number of different species of cells which collectively define the system. Function  $f$  in equation 5 could be any simple logical or algebraic function such as XOR, summation or subtraction of the shared value and the differential parameter. This equation precisely describes the functionality of every cell during its normal, test and self-repair modes of operation using a configuration vector (Ccv), a shared value (Csv) and a differential parameter ( $\Delta g$ ). Tsv and T<sub>Δg</sub> tags together assign a unique address to every cell. This address is only a 'soft' entity and is not used as a sequential physical address location of cell placements in the unitronic architecture. Instead cells based on their tag addresses are grouped to achieve the best possible compression and correlation solution for clusters and colonies. The number of cells in the array is always  $x = n \cdot m$ , where  $n$  and  $m$  may have different values to  $v$  and  $w$ . This means that tag addresses do

not refer to a physical cell because such cells do not actually exist in the array.

Shared value (Csv) given in equation 4, is a non-existent entity and there are no cells in the unitronics array that include such value in their memory. It is the result of a compression operation and a feature of the bio-inspired prokaryotic model. Genome of the cell ( $G$ ) can be defined as:

$$\begin{aligned} G(Tsv, T_{\Delta g}) &= \{g(\text{coding}), g(\text{non-coding})\} \\ &= \{(Ccv_{(Tsv, T_{\Delta g})}), (Tsv, T_{\Delta g}, \Delta g)\} \end{aligned} \quad (6)$$

Biofilms are the top layer of bio-inspired prokaryotic model. This is another software entity that expands T-space from 2 to three dimensions. Here colonies are grouped so that a faulty cell in one colony may be correlated to other cells in other colonies. In this case, to facilitate the repair of faulty cells, a larger search area is available in the T-Space world.

### Self-Repair

Although each and every cell has its own BIT (Built-in-Self-test), colony is the lowest level that supports system self-repair. Functional system operation is synthesised to cell and not community level (cluster, colony, and biofilms). Each cell in the array, through its individual configuration vector (Ccv), is programmed to do a specific task so that the cells collectively execute the required functionality and define overall system operation. If faulty operation is detected community layers will provide system recovery self-repair support.

For the sake of the foregoing discussion let us consider the system's genome, consisting of Ccv,  $\Delta g$ , Tsv and T<sub>Δg</sub>, as a software entity, and all the functional, communication elements of the cells and their physical memory requirement for genome storage, as hardware entities. Faults may develop in both the software and in the hardware part of system. If the fault is hardware related then its associated cell will need to be killed and operationally eliminated from the system. In this case through the process of cell division a new cell, of the same species (same Csv) as the faulty one, should be 'given birth' during which, to recover the system, a repair process will take place.

Cell division requires a 'new' cell which during the repair process will be configured the same as the eliminated faulty cell. Since, unlike in nature, our current technology does not facilitate birth of hardware cells, artificial systems must have some redundancy through the availability of spare cells. If a system consists of  $n$  available cells of which a specific application uses  $m$  cells, then the number of available spare cells is  $n-m$ .

Consider that cell  $k$  (between cells 1 to  $m$ ) is detected as faulty (Fig. 4). In this case all cells located between  $k+1$  to  $m$  are shifted one cell forward to cells  $k+2$  to  $m+1$ , where cell  $m+1$  is part of the system's redundant available cells. Cell  $k+1$  will act as a 'spare cell' and will replace the faulty cell. Cell division is a two step process:

- Shifting prepares a spare cell adjacent to the faulty one.
- Calculating and loading the shared value of faulty cell into the spare cell.

These will be followed by a differentiation process where from the shared value the cell's configuration vector (Ccv) will

be evolved.

Lack of the shifting process is the only difference between hardware and software fault repair. If several faulty cells simultaneously develop a fault then, following their elimination, the same shifting process will take place and the number of available redundant cells will be accordingly reduced. During shifting, cells are individually checked for integrity and simply by-passed if they were previously killed, while their neighbours will serve as spare cells and will take over the functionality of the faulty ones.

An example of a system consisting of  $n$  cells is shown in Fig. 4b. Here the implementation of a specific application requires  $m$  number of cells and the remaining ones are redundant cells acting as available spare cells. Fig. 4b shows the situation when two cells simultaneously develop a fault. The faulty cells (shown in black) are killed (Fig. 4c) and all cells are shifted to prepare a spare cells next to the faulty ones.

Fig. 4, Shifting process of self-repair mechanism.

We mentioned previously that clusters are communities of software related cells that have the same shared value, or the same differential parameter. The genome ( $C_{Gen}$ ) of a  $sv$ -cluster is made up as a union ( $\cup$ ) of the genes ( $g$ ) of its individual cells and can be expressed as:

$$C_{Gen}(T_{sv_i}) = \cup g(T_{sv_i}, T_{\Delta g_j}), \quad (7)$$

$$i \in \{1, 2, \dots, v\},$$

$$j \in \{1, 2, \dots, w\}$$

where  $j$  refers to the individual cells in the cluster having the same shared value addressed by  $T_{sv_i}$  and  $i$  refers to the  $i^{th}$   $sv$ -cluster,  $T_{sv_i}$ . These clusters are shown by the vertical lines in the Fig. 5. A similar equation can be formulated for  $\Delta g$ -clusters that have the same differential parameters:

$$C_{Gen}(T_{\Delta g_j}) = \cup g(T_{sv_i}, T_{\Delta g_j}), \quad (8)$$

$$i \in \{1, 2, \dots, v\},$$

$$j \in \{1, 2, \dots, w\}$$

where  $i$  refers to the individual cells in the cluster having the same differential parameters addressed by  $T_{\Delta g_j}$  and  $j$  refers to the  $j^{th}$   $\Delta g$ -cluster,  $T_{\Delta g_j}$ . These clusters are shown by the horizontal lines in Fig. 5. It also shows an example of how the physical placement of a faulty cell in the array differs from its placement in T-Space.

Every cell in Fig. 5 has its place both in the  $sv$ -cluster and

in the  $\Delta g$ -cluster. When faults are detected, for as long as one healthy cell exists in both  $C_{Gen}(T_{sv_i})$  and in  $C_{Gen}(T_{\Delta g_j})$ , the gene of faulty cell can always be recovered with  $T_{sv_i}$  and  $T_{\Delta g_j}$ . Fig. 5 also shows that cells do not need to be physically sorted when comparing their locations in T-Space.

Fig. 5, An example of faulty cell, its physical placement in the array, and in the T-Space.

Equation 7 shows that how, in a prokaryotic model based system, clusters compress the system's genome. Every cell in the appropriate clusters of  $C_{Gen}(T_{sv})$  (vertically sorted in Fig. 5) is expressed with a same shared value and some differential parameters. The self-repair process uses this shared value during cell division by copying that of the faulty cell into the spare cell. It is only the differential parameter ( $\Delta g$ ) that distinguishes the cell now from other cells in the cluster. The healthy configuration vector can be recovered by differentiating this shared value with the faulty cell's  $\Delta g$ . It can be extracted from the  $\Delta g$ -cluster of  $C_{Gen}(T_{\Delta g})$  by  $T_{\Delta g}$ , where the faulty cell belonged. Since all cells in a  $sv$ -cluster have the same  $C_{sv}$ , it is readily available from any of its cells. It is a calculable entity and therefore requires no storage. Finally, the configuration vector of the faulty cell can be calculated as  $C_{cv_i} = C_{sv_i} + \Delta g_j$  (Equation 5). For safety and for easy self-repair purposes neither  $\Delta g$  nor  $T_{\Delta g}$  is saved in the cell's own non-configuration register but another cell will host them. In this way, every cell in the cluster has a back-up memory in the form of a non-configuration register that stores information for other cells.

Self-repair process takes place in three steps:

- Cell division.
- Identifying the species of the faulty cell, the  $sv$ -cluster and the actual shared value.
- Differentiating the shared value with  $\Delta g$  obtained from,  $\Delta g$ -cluster.

Steps 2 and 3 can only be executed if the faulty cell's tags remains healthy. Since the bit requirement of the tags is considerably less than that of  $C_{cv}$  and  $\Delta g$ , this condition is not difficult to meet. However should the tag values still mutate, additional safety storage is provided by fault tolerant RAMs in an external backup memory.

## Self-Test

The bio-inspired self-test we are proposing is based on two characteristics of biological systems:

- In nature, the DNA is a double helix, a duplicated sequence of complementary genes. It means that both sequences define exactly the same organism with exactly the same features. Therefore one strand is sufficient for the growth and development of an organism [9].
  - Transposons (formally termed *jumping genes*) are sequences of DNA that can move around to a different position within the genome of a single cell. Such mobile genetic elements can move within the genome from one position to another using a “cut and paste” mechanism [10].
- These two characteristics found in nature can be used to inspire the development of a bio-inspired self-test model for artificial systems by observing that:

- If we could guarantee that by configuring the processing elements of an artificial cell with both its gene and complementary gene, their functionality would remain the same and
- That using the concept of the *jumping genes* mechanism could offer a solution to switch over and substitute input signals of such processing elements and interchange their outputs.

The DNA is a double helix of two complementary genetic sequences. Both sequences will configure the cell for exactly the same function. Fig. 6 shows the placement of cells for the proposed artificial prokaryotic cell when the cell is configured by the sequence of the original genome and by its complementary (\*) one. Because of the nature of the sequences it is sufficient to store only one of them in the cell's memory.

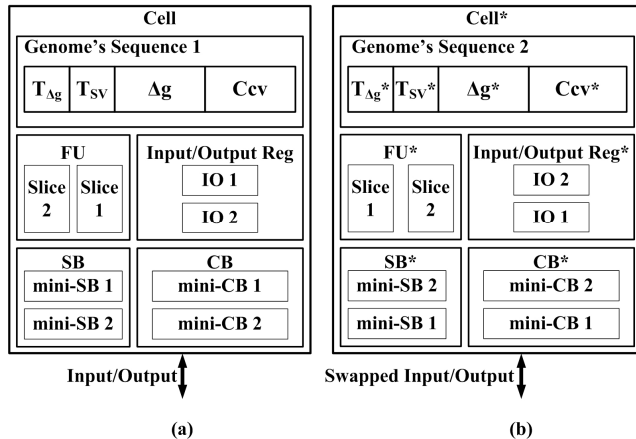

Fig. 6, A cell configured in two different modes, normal and test modes.

All functional components of the cell, such as FU, SB, CB and IO registers, are in pairs (Fig. 6). In normal operation they are cascaded to implement a higher order function. For instance, a SB is divided to two mini-SBs. Each mini-SB has a simple switching function, but joined together they can implement more powerful functions. If the controlling genes of mini-SB 1 and 2 are switched over, their functionality will also be switched over. Applying rules i. and ii. to Fig.6 a new test methodology is created. Configuration vector Ccv and its Ccv\*

complement will respectively configure the circuit for a normal (Fig. 6a) and a complementary (test) mode (Fig. 6b).

Cells of the array execute their assigned functions in one machine cycle. The cycle however is divided into four discrete sequential activities:

- Update of inputs.
- Normal mode of operation
- Switch over genes and switch over inputs and outputs.
- Test mode: check results
- Switch back genes, and inputs and outputs
- update outputs (cell passed) or kill cell (cell failed)

During a machine cycle both the functionality of the cells' components are switched over and also their external signals are swapped round. Only such simultaneous swap and switch mechanism can guarantee correct functional set-up and input data for self-test. Detailed description of this algorithm is given in [8].

In normal mode of operation all cell output results are saved but not yet propagated. In the following test mode all cells are subjected to input swap and functional change over. These results are also saved. If it is found that the two results correspond then their outputs are released and normal functional operation can continue. If however the outputs differ then self-repair is requested. Only once this is complete and error free operation is recover, will normal system operation resume.

## Unitronics Architecture

Embryonics, inspired by multi-cellular eukaryotic organisms, was the first project that attempted to map biological processes to electronic hardware. A newly emerging field that uses models of prokaryotic organisms such as bacteria to create bio-inspired man-made systems is a related but different architecture. Here, we name the artificial electronic systems inspired by these unicellular creatures, 'Unitronics' [6, 7, 8]. The Unitronics system uses two different types of cells; core cells (C-cell), surrounded by peripheral cells (P-cell) around its perimeter (Fig. 7). The basic architecture of both cell types is based on the block diagram of Fig. 6, except that P-cells do not have a function unit (FU).

Core cells are configured to implement specific functions, as defined by the genes in their configuration register. Peripheral cells on the other hand only manage the input and output information flow, including signal swapping during test mode. Unitronics adapts a 'see-of-gates' architecture (Fig. 7) similar to that used by commercial FPGAs but partitions the system into prokaryotic islands. Islands are formed by groups of C-cells surrounded by P-cells.

Peripheral cells (Fig. 8) of the array provide an interface between the island of C-cells and the outside world. They consist of two flip-flops and a signal controller. They have four bi-directional pins, two of which (P1 and P2) provide communication with the peripheral bus (P-BUS), and the other two (E1 and E2) provide communications with the global bus (G-BUS). Signal directions in E and P are defined by the appropriate configuration bits for the P-Cell. The flip-flops receive their data either from the External (E) or from the Peripheral (P) bus lines, under the control of two multiplexers. External communication can be disabled in order to swap data

of P1 and P2. This is accomplished by the two flip-flops; connected in this case as a circular shift register.

Fig. 7, Schematic diagram of Unitronics.

Fig. 8, Peripheral cell, P-Cell.

During test mode, data from the P-lines are loaded into the flip-flops are swapped round, and placed back onto the same lines. As a result the lines now have swapped data, as compared with what they had before. Fig. 8 shows only those components of the peripheral cell that provide data switching between P1 and P2 lines.

The array has 2 different types of buses: G-BUS, P-BUS and P-BUS (Peripheral Bus). G-BUS is used for distant communication between C-Cells in different islands via their own P-Cells where signal swapping is also possible.

P-Cells provide flexible connection between any two lines of the G-BUS to any two P-BUS lines. Lines are grouped in pairs, so that once a line is selected as input/output from G-BUS to P-BUS, the second line provides switch over when (e.g. in test mode) required. For self-repair there are additional redundant spare P-Cells.

P-BUS, on entering the array of C-Cells, is divided to C-BUS (Configurable Bus) and L-BUS (Local Bus). They are interconnecting wires, lines and channels, similar to commercial FPGAs. C-BUS provides the required cell to cell

interconnect. It is configured by the core cells according to their functional and communicational requirements. Lines of the configurable bus can be grouped, cut, joined and swapped. The bus also supports cell elimination during self-repair if a cell developed a hardware fault. In this case, the faulty cell is killed, its functionality is shifted to the next cell along the configurable bus and all preceding cells are also shifted until a healthy stand-by cell is found. The L-BUS, though can be divided to sub-sections, usually passes through the cells and only makes connection to those with which long distance data communication is required. It is local to the island, and would normally connect to the P-BUS only at the first and the last cell of the island.

C-Cells are the processing and communication elements of the system and as such they provide processing Function (F), signal Routing (R), information storage as Memory (M), and switching as Void (V) tasks. The two slices of the cell can work in tandem and undertake any combination of the above tasks as for instance FF, FR, MV, RM and etc. The detailed architecture of configurable bus is beyond the scope of this paper, but its important characteristics are indicated in Fig. 6. The cell's Connection Box (CB) manages how the cell should be connected to the network of other cells in the island. Inputs to the cell's Function Unit (FU) are provided either from the bus via the CB or from the cell's neighbours via dedicated neighbouring connections lines.

FU includes two 2-bit slices. Each slice is supported by the cell's genome, which is essentially an LUT. It can either define the precise function the slices should execute, or can configure them for signal routing. Slice function can either be logical or algebraic. When for example a cell is configured as RF then slice 2 will undertake signal routing, while slice 1 will execute a function on its output. FF set-up enables the cell for a more sophisticated function.

The cell can be used as a memory to implement registers, counters and, in case of a distributed memory, an 8, 16, 24 or 32-bit RAM. It is called a distributed memory because one cell can only provide upto two memory locations. The configuration bit (Ccv) register is not an addressable memory. To allow such functionality a distributed memory feature has been designed. In this case another cell is used as a memory controller. When the cell acts as a "Void" it provides a connection between C-BUS and L-BUS. If a cell is used for M or V the functionality of its slices' is reduced.

In summary the Unitronic architecture, inspired by biological colonies and the circulatory system of a Biofilm, is a network of colonies supported by adequate routing and communication facilities for the cellular array. Both hard and 'soft' entities of the architecture demonstrate biological inspiration. Cells, islands and the circulatory system are the hardware components, and clusters, colonies and biofilms are the 'software' components of the Unitronic system (Table 1). There is no physical location in the array that can be identified as being a cluster, or colony. Both are 'soft components' providing immune protection for the system for fault detection and repair. The architecture in Fig. 7 is a substrate where cells, cluster, colonies and biofilms are grown in the islands located in the network of voids and circulatory system.

	Software	Hardware
Cell (C-Cell, P-Cell)	Yes	Yes

Cluster	Yes	No
Colony	Yes	No
Biofilms	Yes	No
Island	No	Yes
Circulatory System	Yes	Yes

Table 1. Hard and 'soft' entities of Unitronics

## Robot Controller Demonstrator

In this example, to demonstrate the self-healing and self-repair capability of Unitronics, the timer part of a movement controller for an e-puck object avoidance robot (Fig. 9a) from EPFL [11] is implemented on a Unitronics array. The block diagram of the robot control system, operating in normal environmental conditions is shown in Fig. 10. The Unitronic timer part is synthesised on a Xilinx XUPV5-LX110T development board (Fig. 9b) [12], while the movement part of the controller and the interface between the robot and the Unitronics system is provided by Matlab. Using hardware co-simulation, data from the Unitronics array is transferred to Matlab in a 2-bit data. One bit defines whether a right or left turn is required from the robot, while the other is a fault indicator for the Unitronic system.

Fig. 9. a) e-puck, b) XUPV5-LX110T

Fig. 10. Block diagram of the robot controller system

The timer is a 16-bit up counter the implementation of which required eight Unitronic cells. Fig. 11 shows the cells' genomes that implement the timer. The slices of all the cells, in this example, are configured as function-function (FF) and define a full adder. In reality the circuit offers a 16-bit full adder, but with inputs set to '0' and carry-in set to '1', it behaves as a 16-bit counter. MSB bit of this counter describes whether robot should turn right or left. Combination of turning

right and left makes the robot to move in a figure 8-like manner. Since the genome of every cell is the same, their identical Csv translates into one sv-cluster and their  $\Delta g$  (equalling to zero) into one  $\Delta g$ -cluster.  $T_{\Delta g}$ , and  $T_{cv}$  tag values are chosen arbitrarily as "10" and "11" respectively.

Since all cells are located in the same sv-cluster and in the same  $\Delta g$ -cluster, fault recovery is always guaranteed for as long as there is one healthy cell in the system. This example uses the simple algebraic function in Equation 9:

$$C_{cv}(T_{sv}, T_{\Delta g}) = C_{sv}(T_{sv}) + \Delta g(T_{\Delta g}) \quad (9)$$

Since in this example  $\Delta g = 0$  means that  $C_{cv} = C_{sv}$ . Consider a situation when seven out of the 8 cells are faulty and only one functions correctly. If we assume that all tags are correct and cell 5 is the faultless cell then after eliminating the faulty cells the next step is a shift process. With this, if the cells are sequentially placed along the bus, cell 1 will assume the position of cell 5 and the remaining cells occupy positions cell 9 to cell 15 of the stand-by cells.

Cell No.	Cell's FU		Cell's Genome			
	Slice 2	Slice 1	TAg	Tev	$\Delta g$	Ccv
Cell 8	FA	FA	10	11	0000000000000000	000340C00406969
Cell 7	FA	FA	10	11	0000000000000000	000340C00406969
Cell 6	FA	FA	10	11	0000000000000000	000340C00406969
Cell 5	FA	FA	10	11	0000000000000000	000340C00406969
Cell 4	FA	FA	10	11	0000000000000000	000340C00406969
Cell 3	FA	FA	10	11	0000000000000000	000340C00406969
Cell 2	FA	FA	10	11	0000000000000000	000340C00406969
Cell 1	FA	FA	10	11	0000000000000000	000340C00406969

Fig. 11. Unitronic timer implementation (values shown in hex)

The next step is to search in the sv-cluster space and identify the faulty cell's shared value. This is achieved by sending a token that will locate the first faulty cell, in this case cell 15. In order to find the shared value of this cell its  $T_{sv}$  tag is sent to all cells in the cluster. Since only cell 12 is healthy, the tag requests the extraction of its shared value using the rearranged form (i.e.  $C_{sv} = C_{cv} - \Delta g$ ) of equation 9. This here will coincidentally yield the same as the  $C_{cv}$  value of cell 12 and be released to the bus. All those cells which need the recovery of their shared value and have the same  $T_{sv}$  as cell 15, will receive it. In this case it will affect all cells of the cluster except cell 12. The final step of the repair process is to differentiate it with all the faulty cells'  $\Delta g$ . Since  $\Delta g$  is zero for them all, their configuration vector can now be simultaneously recovered, using equation 9.

In this example cluster identification is trivial due to the repetitive nature of the cell functions required. This in larger digital systems becomes more difficult. These however are typically composed of regular building blocks, i.e., registers, counters, multipliers etc; where this regularity can be exploited to simplify cluster formation. Our fault recovery mechanism is applicable to circuits with any complexity. Since motion cannot be demonstrated on paper the actual

behaviour with run-time fault detection and fault repair is shown under the following youtube link <http://www.youtube.com/watch?v=GO0YfVf0tMw>

Another example of a PD controller is shown in Fig. 12. The waveform illustrates the actual behaviour of the hardware (not simulation results!) and the fault recovery process of the controller. The PD controller was also implemented, also as an interim step before VLSI implementation, on a Xilinx XUPV5-LX110T development platform. The controller required 40 Unitronic cells and a ‘soft’ fault was injected in the genome of cell 3.

Fig. 12, Implemented robot controller fault recovery.

During the operation of the robot controller a fault was inserted into cell3. Fig. 12 shows the fault recovery process of the implemented system:

1. Fault is injected at *fault injected* point into the system.
2. The effect of the fault causes the gene to mutate at *CodingGenes\_ConfigurationVector*.
3. Simultaneously self-test using input data and control sequence complementation recognises it, identifies the faulty cell and initiates self-repair.
4. Self-repair requests the mutated faulty cell's  $C_{SV}$  at *sv\_Cluster\_Request*. For this  $T_{SV}$  at *Put\_Tsv\_on\_BUS* identifies the cluster and the cells that share the same portion of the configuration vector with the faulty cell. With the aid of the cluster's cells,  $C_{SV}$  is calculated at *Shared\_Value\_is\_available*.
5. Recalculation of the faulty cell's corrupted  $C_{CV}$  configuration vector also requires its  $\Delta g$ .
6.  $\Delta g$ 's address  $T_{\Delta g}$  is triggered at *Put\_dgTag\_on\_the\_BUS* in order to locate the same  $\Delta g$ .
7. When  $\Delta g$  is also available, using Equation (9) the faulty cell's  $C_{CV}$  can be calculated (*dg\_Value\_is\_available*='1').
8. With its recovery, on-line repair of the faulty cell is complete and the recovered correct response result of the cell is now allowed to propagate to its final output.
9. Normal system operation (at *System repaired*) in the next machine cycle resumes as if fault never occurred.

## Conclusion

On-line fault detection and fault repair capability of our Unitronics architecture, based on the bio-inspired prokaryotic model, is demonstrated using an e-puck object avoidance mobile robot. Implementation of the robot required 8 Unitronic cells appropriately interconnected and then mapped onto a Xilinx XUPV5-LX110T development board. The fault

tolerance model of the system guarantees that “if similarities and differences between healthy and faulty cells are known then, full recovery of any Unitronic implemented system is possible”. The system is able to cope with and repair any number of simultaneously occurring dynamic (SEU) or static (hardware) faults. The amount of fault repair only depends on the number of spare cells the system is equipped with. Its fault repair uses significantly less memory for gene storage and considerably less hardware overall for target system implementation than any previously proposed bio-inspired architecture.

In future work we plan to undertake a more detailed performance analysis as a function of the number of errors, investigate the implementation of more complex digital systems, and look at the implications for cluster formation. Additionally, we plan to investigate implementing higher level fault tolerance techniques using Unitronics as the substrate.

## Abstract

Rodents are optimal real-world foragers that regulate internal states, such as security, arousal, energy, etc., maintaining a dynamic stability with their surroundings. Free exploration is an interesting scenario as rodents display behavioral patterns that are very different from being random, even in the absence of reward. Our aim is to understand foraging behavior by implementing an artificial rat that behaves as real ones do. We depart from the hypothesis that rodents, when performing free exploration, may be minimizing the unpredictability of the environment in terms of internally mapping its structure and discovering all the actions that it can afford. This drive for exploration is counterbalanced by a drive for security. Building from a self-regulation model based on the Distributed Adaptive Control architecture (DAC), we implement a biomimetic control that uses this predictability principle to generate behavior. We validate the controller by solving a benchmark task in which the agent learns to displace a movable obstacle to discover unexplored areas of an arena.

## Introduction

In this paper we take a behavioral approach to the deeper understanding of what it means to survive, explore and forage in complex environments, specially focusing on rodents. We provide a biomimetic control based on self-regulation that uses predictability as main principle to generate behavior, map the environment and discover the actions that the environment can afford. In a benchmark task the agent learns to displace a movable obstacle to discover unexplored areas. In free exploration, rodents exhibit a structured behavior following a specific pattern. If the environment is unknown, rats start the exploration following the walls, establishing a preferred corner and traversing the arena occasionally (Dvorkin et al., 2008). An example of rat trajectory in a squared arena can be seen in figure 1.

The question arises if this structured but still complex behavior can be explained by a minimal set of basic principles. Predictability has been exploited as a possible candidate for driving behavior and learning mechanisms of artifacts (Duff and Verschure, 2010; Weiller et al., 2010). As a more general principle, predictability has also been considered in the

free energy principle in the form of the minimization of surprise (Friston et al., 2006). In the free energy principle surprise is defined in statistical terms and can be minimized both by the behavior of the artifact as well as by adapting the internal model of the artifact.

All these approaches have a limited sense of the real consequences of what it means to act in a world. For instance, scenarios where the agent's actions can change the state of the external world, i.e. the state of objects in the environment, are not considered. Moreover, the described optimization algorithm (Weiller et al., 2010) and free-energy principle (Friston et al., 2006) are conceptually far from being biomimetic implementations and don't deal with fundamental physiological mechanisms such as self-regulation.

Here we explore predictability together with security as an internal drive for free exploration. Predictability in our case will depend on the agent ability to map the environment and discover the affordances available in it. Affordances, as introduced by Gibson (1986), are considered to represent all the action repertoires available to an agent in an environment. The more the agent learns about the possible actions in an environment and their consequences, the better it can predict the next sensory state he will be in. The environment will not be surprising any more when the agent knows its structure and knows what it can do in it.

The robotics community has also shown an interest for the predictability driven learning (also called curiosity) through object interactions (Oudeyer et al., 2007; Ugur et al., 2007). Our main contribution is to provide a biomimetic solution by introducing in a self-regulatory loop, the necessity of making the environment a predictable place. We build from previous work on the Distributed Adaptive Control (DAC) architecture (Verschure et al., 2003; Duff and Verschure, 2010). DAC provides a continuous sensorimotor loop combined with memory, organized in a layered structure. We have investigated affordances and the acquisition of sensorimotor contingencies in the context of DAC (Duff and Verschure, 2010). In (Sánchez-Fibla et al., 2010b) we have equipped the lowest layer of DAC, the reactive layer, with a self-regulatory process based on the physiological notion of

allostasis. Self-regulation was decomposed into a minimal number of homeostatic loops and allostasis was the meta-process that controlled stability of the system at a higher level, changing the desired values (the objectives to reach) of each subsystem. We validated the model by comparing the generated behavior with the one displayed by rodents in different environments. In the case of free exploration of a squared arena, only two subsystems were considered: security and arousal. Security was the subsystem controlling the distance of the agent to a familiar place, like the home-base, and arousal controlled the exposure to the open space. Each subsystem in the allostatic control was defined by a gradient (in accordance to motor schema based behaviors, see introductory book of behavior-based robotics by Arkin, R. C. (1998)), an actual value and a desired value. The security and arousal gradients were assumed and predefined in (Sanchez-Fibla et al., 2010b), here we adapt the complete sensorimotor loop to be able to learn those gradients as the agent explores the environment. To do so we directly link arousal to unpredictability following the principle that an unpredictable space will induce a higher state of arousal. The drive to explore/discover the environment is thus considered equivalent to the urge for higher arousal. Therefore behavior is driven by security and predictability of the environment being regulated inside a sensorimotor loop.

Building from (Sanchez-Fibla et al., 2010b), we state that exploration in this simple scenario is also driven by the agent's ability to predict the environment in two aspects: its structure and its affordances. To further develop this hypothesis we enrich a squared arena environment with the presence of an object, in our case a cube. To understand behavior it is important to include elements that allow an agent to exploit affordances. For this purpose, we validate

Figure 1: Trajectory plot of a rat. The plot displays the trajectory of a rat when performing free exploration in a squared arena. Axis units are in centimetres. According to the model that we presented in (Sanchez-Fibla et al., 2010b), this would correspond to a low aroused rat, in the sense that the traversals of the middle of the arena are scarce.

our controller with a benchmark task where an object in a squared arena is obstructing an alley that accesses a hidden room. The paper structure is as follows: first we describe in the methods section the allostatic control and how we modify it for the task that we want to solve. In the results section we compare the implemented controller based on minimizing unpredictability to a random controller. In the discussion we point out the links of the model to the behavioral studies of rodent

## Methods

In this section we describe the self-regulation mechanism driving the agent. We present a process for mapping the environment and discovering the available affordances as they are a prerequisite for minimizing the unpredictability of the environment. We then explain in more detail the arousal subsystem as it contains the main changes from previous studies (Sanchez-Fibla et al., 2010b) and (Sanchez-Fibla et al., 2010a).

### Allostatic control revised

We have proposed a biomimetic architecture of perception, cognition and behavior, called Distributed Adaptive Control (DAC) architecture, which aims at explaining how the interaction of different structures along the neuraxis can give rise to adaptive behavior (Verschure et al., 2003). In the latter, drive based behavioral control is modelled subserving perception and cognition from the perspective of the interaction of appetitive and aversively motivated behaviors. In this case the reactive regulation between these two orthogonal behavior tendencies was achieved through predefined rules for conflict resolution; i.e. aversion and avoidance supersedes consumption and approach. Hence, in this system the relationship between these two drive systems was fixed and could not be dynamically regulated.

In (Sanchez-Fibla et al., 2010b) we included in DAC the ability to regulate drive based behaviors with the objective to identify a solution that scales with respect to the number of behavioral subsystems, that provides a common currency for the regulation of behavior in order to unify multiple levels of a real-world cognitive architecture and that is biologically valid. Animals are driven by internal variables such as hunger, temperature, security, etc. which have to be maintained within certain limits in order to be stable and predictive over changing environments. We follow this behavioral driven top-down approach instead of modelling the low level interactions of homeostatic processes (as for example the homeostatic regulations happening in the Endocrine system (Moioli et al., 2009; Xu and Wang, 2011), which we could consider to be a more bottom-up approach than the one followed here). For this, we decomposed self-regulation into a minimal set of homeostatic subsystems (such as arousal, security, energy, etc.) that can be plugged together orchestrated by what we named allostatic control in (Sanchez-Fibla

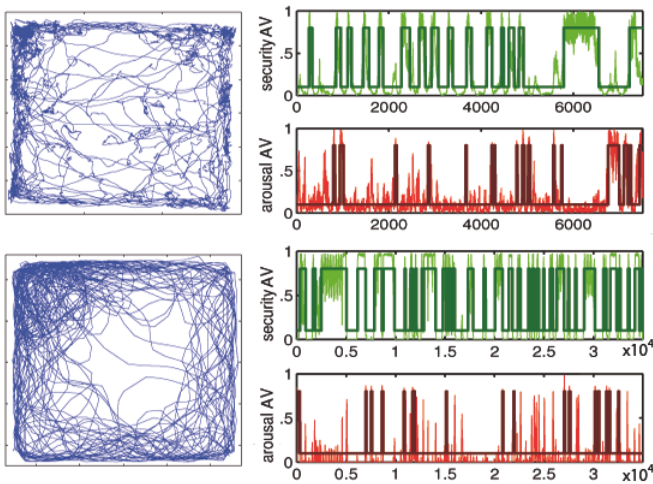

Figure 2: Rat-robot behavior comparison. On the top row we plot the trajectory of one rat along with its security  $AV$  time series (in green) and the arousal  $AV$  time series of the same session (below, in red). The bottom row corresponds to the generated behavior of the allostatic control system described in (Sanchez-Fibla et al., 2010b). First we plot the trajectory of the robot next to its security and arousal time series.

et al., 2010b). Each homeostatic loop consists of a gradient, an actual value ( $AV$ ) of the agent in that gradient, a desired value ( $DV$ ) and a regulator able to perform the appropriate actions to bring the actual value closer to the desired one. See for example the security subsystem in figure 3 where all these elements are shown. Objectives of different homeostatic loops may be conflictive, is in that stage that allostasis enters into play. We define allostasis as the regulation through changes of the desired values so that stability of individual homeostatic loops can be achieved or compromised and changing through time. In (Sanchez-Fibla et al., 2010b) we used a probabilistic changing policy of desired values also dependant of its level of content (the difference between  $DV$  and  $AV$ ).

The assumption in (Sanchez-Fibla et al., 2010b) was that behavior of a rat in a squared arena is driven by the constant equilibrium of its need for security (the distance to the home base or preferred corner) and the need for exploration conveyed by its need for arousal (exposure to the open space). An example of a trajectory generated by the model can be seen in figure 2, bottom row. The security gradient was maximum at the top left corner and the arousal was a fixed gradient having its maximum in the middle of the arena. The time series of the  $AV$  values of both subsystems are shown in the right and corroborate that the allostatic control system interleaves stays in the preferred corner with occasional traversals of the arena.

In (Sanchez-Fibla et al., 2010b), both the security and the

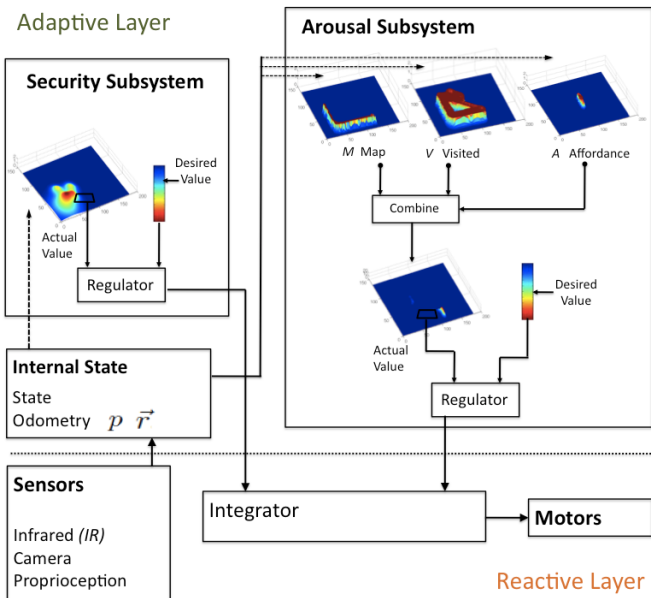

Figure 3: Allostatic control in DAC. The adaptive layer contains the main ingredients for the self-regulatory loop managed by the allostatic control. See text for further explanation.

arousal gradient are predefined. Here we learn the arousal gradient following the assumption that arousal is directly linked to unpredictability. Thus a high desired value for arousal corresponds to a high level of exploration. However when the rat explores the environment it is also increasing the predictability of the environment: meaning that its drives are influenced by its necessity of knowing the structure of the arena and all the possibilities that the environment offers in terms of affordable actions. Thus, we consider that the need of increasing arousal is directly related to the notion of curiosity.

As in the squared arena setup of (Sanchez-Fibla et al., 2010b), we continue to decompose self-regulation into two minimal subsystems, security and arousal, but now arousal is redefined as a conjunction of the need for mapping the structure of the arena and the need for discovering its affordances. Security is represented by a gradient  $S$  that is maximum in a preferred place of the agent (Sanchez-Fibla et al., 2010b). Arousal is calculated using three gradients that we now list;  $M$  the map gradient of the environment, the one which the agent uses to accumulate evidence of the presence of walls and obstacles.  $A$  the affordance gradient where the agent accumulates evidence where the environment affords an action,  $V$  the visited gradient that the agent fills during exploration. From these three gradients  $M$ ,  $A$  and  $V$  we build an arousal map that plays the role of a saliency map of places that remain worth visiting. The arousal gradient is the one used by the arousal subsystem. An schema of the DAC

Figure 4: Simulation environment. A squared object originally placed in the middle of the arena, its being pushed by the epuck robot. Its "pushability" has been detected and the affordance gradient  $A$  has been updated accordingly.

architecture reduced to the allostatic control loop is shown in figure 3.

Original DAC is organized along three levels of control of increasing complexity: reactive, adaptive and contextual. We don't need contextual control for the tasks that we solve here. The reactive layer provides a pre-wired repertoire of reflexes. The adaptive layer acquires representations of sensory events and associated responses supporting the acquisition of simple tasks. In the adaptive layer we acquire the different internal structures like the gradients  $M$ ,  $A$  and  $V$ .

Security and arousal subsystems propose their motor actions, through a regulator process which computes a motor plan that could bring closer the actual value and the desired one. In (Sanchez-Fibla et al., 2010b), this computation was done having access only locally to the gradient around the position of the robot. This does not need to be so. We assume now that the gradients are sensory motor representations acquired by the adaptive layer and thus the regulator can have global access to its values. The outputs of both subsystems are then linearly summed (represented by the "Integrator" box of figure 3) and sent to the motors.

A difference from (Sanchez-Fibla et al., 2010b) is that the gradients that we use are computed during the exploration and not assumed and given to the model. In the following sections we explain how we compute them.

### Mapping the environment

We describe here how the agent builds the map gradient  $M$  while it explores the environment. When implementing controllers in a mobile robot, usually because of their limited sensor models, we face the difficulties of estimating the world state with their local sensing capabilities. Here we use the e-puck robot (Mondada et al., 2009), its infrared ( $IR$ )

Figure 5: Top view of the e-puck sensor model. We indicate the position of the top/down camera and the angle in degrees of the 8 infrared sensors ( $IR^1 \dots IR^8$ ).  $IR^5 \dots IR^8$  have negative angles with respect to the front direction of the robot. For instance,  $IR^8_\alpha = -18^\circ$ . The direction and position of the robot are denoted by  $\vec{r}$  and  $p$ , respectively. We also plot a possible  $\vec{IR}_{mean}$  computed from the IR reading when approaching a squared object. See text for further explanation. In the bottom right part of the picture we show a general view of the e-puck robot.

sensors, indicated in figure 5 and motors. We assume the robot has an odometry model that can estimate its position and direction in the environment:  $p$  and  $\vec{r}$ . If we are thinking of a biomimetic solution, we could implement a grid cell system that would provide odometry plugged together with a place cell system that could synchronize to precise locations with the help of external cues, an approach that has been proven effective in (Milford and Wyeth, 2008). Also In (Wyss et al., 2006), a neuronal network is trained for acquiring place cell activity from one single camera input stream.

Using this information, we describe now how we compute the gradient that will capture the structure of the environment (see algorithm 1). Whenever the front  $IR$  sensors detect the presence of a wall or an object, the evidence of the presence of this object can be added to corresponding gradient  $M$ . In figure 5 we show the e-puck sensor model. Red lines represent the range of the  $IR$  sensors. The  $IR$  sensors have a decay and we have assumed is quadratic. This decay has to be compensated to correctly estimate the position of the border of an object. This compensation is computed in line 2 of the algorithm and then multiplied by an arbitrary grid unit constant (in this case 30). We denote  $IR_{val}^i$  the value of the  $IR$  sensor  $i$  normalized to take values from 0 to 1, being the latter the closest that an object can be sensed.  $IR_\alpha^i$  is the angle of the sensor with respect to the direction of the robot. The operator  $\angle$  used as super-index denotes the vector rotation operator. In line 3 we compute the point of contact by summing the radius of the robot and the computed distance in the direction of the  $IR$  sensor with the

agent position  $p$ . We then add a gaussian in the  $M$  gradient map at the computed point  $p_{map}$  with sigma  $\sigma$ .

---

**Algorithm 1: Mapping()**

---

```

for  $i = 1$  to  $4$  do
1  if  $IR_{val}^i > 0.65$  then
2     $dist \leftarrow 30(\frac{1-IR_{val}^i}{0.25})^2 \tilde{d}^{\angle IR_{\alpha}^i}$ 
3     $p_{map} \leftarrow p + (radius + dist)\|\tilde{d}\|$ 
4     $M \leftarrow M + g_{\sigma, p_{map}}$ 

```

---

The visited gradient  $V$  can be trivially filled by adding evidence in the agent position  $p$  at each time step. Due to objects placed in the environment that can act as obstacles when approached from one direction, and can be pushed from another, the agent can add in  $M$  evidence of presence of a wall when it is in fact not the case. For this reason, we add a decaying mechanism that uses the information in the visited gradient  $V$  to bring down to 0, areas in the  $M$  gradient where there was evidence of a wall but can in fact be visited and traversed.

### Affordances in the environment

We discuss in this section how an agent can discover the affordances of an environment. From the action repertoires that an object can potentially serve (its affordances), we restrict ourselves to the "pushability" of an object, that is, knowing when an object can be moved or it is a fixed part of the environment. In SLAM the agent learns about the world through passive exploration of the environment, that is, no real action of the agent can change the state of the world, except its position. In some cases dynamic obstacles are considered but their appearance or disappearance is not dependant on the agent's actions but governed by external interventions, as in (Kawewong et al., 2010). To extend SLAM to include the usage of affordances one could simply use another sensor modality to detect the sliding direction. One could think of using optical flow or tactile sensing. Sliding detection is a prerequisite for an agent to be able to distinguish from two situations: pushing unmovable objects and pushable objects. Detecting an object in front of the agent while having full forward speed would mean that the object is being pushed if there is a consistency of the signal sent to the motors and the detected optical flow main direction. In the other case where the agent detects an object in front, the motors are running forward but no consistent movement is detected by the optical flow would mean that we are sliding in front of a static obstacle/wall/object. In the custom e-puck simulator, we give global access to the agent to its real direction of movement. This vector could be computed, with the described mechanism using a camera pointing to a chessboard-tiled floor. The agent then compares this direction vector to the signal it is sending to the motors and can know when it is pushing a movable object or just being

blocked by an obstacle or a wall. This detection mechanism is used by the agent to fill gradient  $A$ . Whenever it detects that it is pushing an object, instead of accumulating evidence in the gradient map  $M$  (as in previous section), it does so in the affordance map  $A$ .

This accumulation is sufficient for the task that we want to solve here, which is guiding exploration. It would be not enough if we wanted to map the position of movable objects and know its position and orientation in the environment. For this purpose we have investigated in another paper in preparation, object-centred representations.

The agent can estimate the center of the object and its contour. There is a straightforward way of estimating the center and that is using a weighted mean of the vectors at each  $IR$  sensor direction. We call this vector  $\vec{IR}_{mean}$  and we show an example of it in figure 5 and also 4. We compute it with the following vector sum:

$$\vec{IR}_{mean} = \sum_{i=1}^8 IR_{val}^i \vec{r}^{\angle IR_{\alpha}^i}$$

Then the center of the object can be estimated by summing  $\vec{IR}_{mean}$  to the current agent position:  $p_{obj} \leftarrow p + \vec{IR}_{mean}$ .

The agent can also estimate the contour of an object by turning around it and mapping its border using the  $IR$  sensors and the described mechanisms.

### The arousal subsystem

The arousal subsystem combines the map  $M$ , the affordance  $A$  and the visited  $V$  gradients to generate another gradient that can be interpreted as a saliency map of places worth visiting, places where predictability of the environment can be increased. As  $M$ ,  $V$  and  $A$  are built while exploring the environment, the resulting gradient can only consider the visited gradient border. We cannot assume that the agent knows a part of the environment that has not been explored yet. For capturing the visited border we choose random points having  $V(i, j) > 0.01$ . If a random point satisfies this last condition we add a Gaussian weighted by a saliency value into the new gradient. The saliency value inversely depends on the sum  $\sum_{i,j} V(i, j)$  around a predefined radius. This will promote the fact that places that have not been visited yet have high saliency. We also weight the saliency by the sum of the map gradient  $\sum_{i,j} M(i, j)$  and  $\sum_{i,j} A(i, j)$ . This last condition considers parts next to the walls or objects that have not been mapped/pushed yet. We then give preference to points that are close to the agent current position. This combination of gradients to compute the resulting saliency is represented by the box "Combine" in figure 3.

## Results

We validate the arousal subsystem based on the predictability principle using a benchmark task designed for mobile

robotics (implemented in a custom simulation environment). The agent has to map and explore the totality of an environment in which a hidden alley has been obstructed by a pushable object. A snapshot of the used environment is shown in figure 6. It consists of a squared arena joined with a smaller rectangular chamber through a small alley. In the initial state, the squared object is placed obstructing the alley connecting to the hidden part of the arena, as shown in the figure. Superimposed in the arena we show the trajectory of the agent in one trial (dashed red line). The movement that the square displayed during the trial is plotted with a series of blue square contours.

To be able to benchmark different controllers solving the mapping task we introduce two measures:  $r_{mapped}$  and  $r_{visited}$ . These allow us to quantify how much the environment has been mapped and how much it has been explored respectively. The  $r_{mapped}$  and  $r_{visited}$  measures take values between 0 and 1 whether the whole environment has been mapped/visited, then  $r = 1$  or the agent has just been inserted in the environment  $r = 0$ .  $r_{mapped}$  is computed by counting how many points in the arena shape have activity in the map gradient  $M$  and then dividing by the total number of points. Similarly,  $r_{visited}$  is computed by counting the number of points in the environment that have been covered by  $V$  and dividing by the total number of points.

We define a random controller that allows us to benchmark the exploration and mapping capabilities of the described controller. The random controller builds an arousal saliency map (described in previous section) by choosing a random point in the border of the visited gradient.

In figure 7 we compare the  $r_{mapped}$  and  $r_{visited}$  measures for the random controller and the described arousal subsystem. One trial is sufficient to show that the environment is mapped quicker with the improved arousal subsystem. While in the random controller case,  $r_{mapped}$  and  $r_{visited}$  increase in a rather monotone constant way, in the improved controller case we observe a quicker increase in the begging until reaching a flat part between iterations 4000 and 7000 (corresponding to the explored square arena part). When the hidden alley is discovered the measures increase again. In the random controller case, the hidden chamber of the arena is not discovered during the shown 12000 iterations.

## Discussion

Little is known about rodent's ability to exploit affordances. Nevertheless it has been shown their ability to internally represent objects, proven by the fact that rats lose interest of objects which they have been able to interact and gain interest of objects which they did not encountered before. This is what it is called the novelty preference in (Ennaceur, 2010).

Experiments show that object properties are accessible to rodents along various dimensions such as shapes, textures, odour, color and brightness. Although this vast range of recognition characteristics, rats show a preference for ob-

Figure 6: One trial of the robot task. The dashed red line corresponds to the trajectory of the robot. The blue squares correspond to the movement displayed by the squared object when pushed.

jects that have affordances for common rat activities, for example, in (Chemero and Heyser, 2005) it is found that rats prefer objects they could climb onto to those they could not. Similarly, rats show interest for the manipulation (e.g. grasping, pushing) of objects that could interfere with accessing new unexplored areas of the arena, alleys, corridors, and thus could be rewarding in a later state. These facts have informed the realization of the benchmark task that we solve in this paper and also have opened future directions for generating new benchmarks and experimental tasks using rodents.

It's worth noting the absence of reward function in our paradigm. This fact set us apart from classical Machine Learning approaches. Self-regulation is the responsible of building the reward function indirectly, combining all the objectives of the different subsystems.

Several neuronal based computational models exist that address the issue of reproducing rodent behavior focusing on navigation and relating it to the hippocampus, see for example (Sheynikhovich et al., 2009). We addressed this issue from this perspective in (Sanchez-Fibla et al., 2010a). This was not our aim in this research. Same applies to the mentioned research on homeostasis as a low level regulatory process present in the Endocrine System (Moioli et al., 2009; Xu and Wang, 2011). Here we wanted to focus on the unpredictability minimization principle that drives exploration introducing affordances as a new dimension to be considered.

## Conclusions

We have presented a biomimetic controller based on the self-regulation of two internal variables: security, defined as the distance to a familiar established place, and arousal, in terms

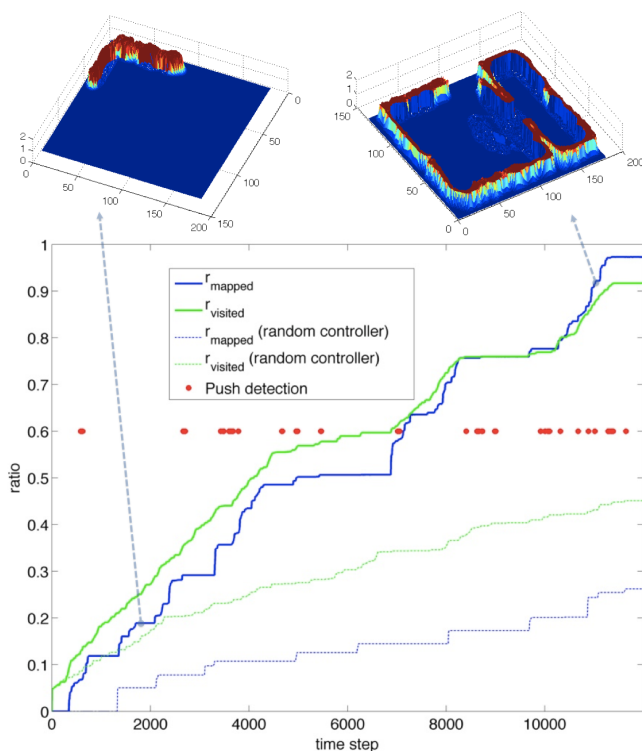

Figure 7: Simulation results. The x axis corresponds to the simulation time steps. Solid lines indicate the environment mapped measure (in blue) and the visited measure (green) for the modified allostatic control. Dashed lines correspond to the same measures for a random behaving controller. Red dots indicate the time steps when the agent detect that it was pushing an object (during the allostatic control session). Two snapshots of the gradient map being built are shown on top.

of the predictability of the environment. This implementation is based on the hypothesis that rodents, when exploring an environment, may be interleaving its need for security and the minimization of the unpredictability of the environment, in terms of internally mapping its structure and exploiting all the actions that it can afford. We use a simulated epuck robot to validate our controller and expose an agent to an environment with a squared object. In a final benchmark task, the object is obstructing an alley having access to a hidden part of the environment. We show that using the described controller the agent is able to map more rapidly the environment and the actions it can afford than a simple random controller.

A future step would be to compare the model with experimental data of rodents performing free exploration in environments that afford actions: push objects, push doors, etc.

## Abstract

Previous work has shown that a pheromone-based visual saliency map can be computed by a swarm of simple agents inhabiting the robot's input image. It was also shown that, with a proper set of behaviours controlling the agents, the saliency map can be used to localise trails present in the robot's visual field. Under the assumption that the robot starts its autonomous operation already on the trail, this paper extends that work by enabling the agents to learn online an appearance model of the trail. The learned model is then used to increase the level of pheromone deployed in the regions of the input image that are more probable of belonging to the trail. This is motivated by the well-known importance that a priori object knowledge has to improve visual search. The outcome of this extension is a self-organising behaviour capable of detecting trails in 98% of the evaluated situations, outperforming the original work. The agents being simple their computation is fast, resulting in a 12 Hz performance. Thus, by introducing a parsimonious learning mechanism, this paper contributes to increase robustness of swarm-based robot vision systems.

## 1. Introduction

An important sensory modality for autonomous robots is vision. However, the richness of vision comes with the price of complex processing. The complexity inherent to vision calls for fine and contextualised focus of computational resources on the most relevant stimuli obtained from the environment. This process is called visual attention, which has been extensively studied in humans (Oliva and Torralba, 2007; Wolfe et al., 1989). By focusing perception: (1) computation, and consequently, energy are more efficiently used; (2) the robot becomes less sensitive to noise and perceptual aliasing; and as a consequence of the previous two, (3) faster robot motion, lower cost, and reduced robot size are enabled.

Models of visual attention typically assume the existence of a sensory-driven bottom-up pre-attentive component (Treisman and Gelade, 1980; Itti et al., 1998), which is modulated by top-down context aware pathways (Tsotsos et al., 1995; Neider and Zelinsky, 2006). The use of top-down modulation is important when bottom-up saliency information is insufficient to focus attention in the presence

of distractors. These distractors are other objects or perceptual aliasing in the environment that happen to detach from the background at least as much as the object being sought. However, top-down information (e.g., expected colour and morphology of the object) is quite dependent on the environmental context. As a result, adapting this knowledge is key when facing unstructured environments.

Visual attention ultimately drives the motion of sense organs, e.g., eyes, towards the relevant stimulus source. This is called overt attention. A faster process is the one of mentally focusing particular aspects of the sensory stimuli. This is called covert attention and its modelling is the focus of this work. Studies on human subjects support the hypothesis that multiple covert attention processes co-exist in the brain (Doran et al., 2009).

In previous work (Santana and Correia, 2010, 2011), we have explored the idea of existing multiple covert attention processes to model visual attention on autonomous robots as the product of a self-organising process supported by a set of virtual agents inhabiting the sensorimotor space of the robot. In particular, we have devised a model where the action selection process is used as top-down context knowledge to guide visual obstacle detection. In that work, agents perform local covert visual attention loops, whereas the self-organising collective behaviour maintains global spatio-temporal coherence. In a related research line (Santana et al., 2010), we have shown that a swarm of agents is able to create saliency maps using implicit knowledge about the object being sought. The model was shown to be able to detect and track trails in natural environments. This top-down knowledge was defined in terms of the behaviours controlling the agents. Focusing on the shape of trails, rather than in their photometric appearance, is advantageous given trails variability. However, photometric appearance may be useful to compensate for situations where shape information is not reliable. Due to its variability under different contexts, photometric appearance must be considered under an adaptive framework, capable of being tuned to the specificities of the environment. The current paper addresses this problem by including an adaptive mechanism into the agents compos-

ing the swarms responsible for the localisation and tracking of the trail. Concretely, the output generated by the swarm in previous frames is used to supervise the learning process of a trail’s appearance model. In turn, this model is used to modulate the pheromone deployed by the agents, thus helping them concentrate their activity on the image regions whose appearance is more similar to the one of the trail being tracked.

## 2. System Overview

Typically, object-related a priori knowledge is used by top-down boosting of the set of features (e.g., colour) known beforehand to be more representative of the object being sought. Instead, the object’s overall layout, which is a more stable and predictable feature in the case of natural trails, whose local appearance often blends with the background, is used in this work. This type of a priori knowledge is specified indirectly in the proposed model as perception-action rules controlling the behaviour of simple agents inhabiting the robot’s visual input. These agents are called p-ants (from perceptual-ants) and represent local covert attention processes. Their self-organising collective behaviour results in a saliency map of the input image, and thus, in a global covert attention process.

Fig. 1 depicts the base model (Santana et al., 2010) of this work. In short, at each new frame **I**, two conspicuity maps,  $\mathbf{C}^C \in [0, 1]$  for colour and  $\mathbf{C}^I \in [0, 1]$  for intensity information, are computed (Santana et al., 2010). The intensity of a pixel in a given conspicuity map signals how much the pixel detaches from the background at several scales (i.e., resolutions), in the scope of a given visual feature. A set of  $n$  p-ants is then deployed on each map. These p-ants interact based on the ant-foraging metaphor for several iterations in order to build two pheromone maps,  $\mathbf{P}^C \in [0, 1]$  and  $\mathbf{P}^I \in [0, 1]$ . The behaviour of these p-ants is designed to exploit some a priori knowledge about typical trails approximate layout. The activation of the pheromone maps is therefore expected to match the trail’s location better than the activation of the conspicuity maps, which are only sensory driven. Additionally, by allowing p-ants on a given pheromone map to also affect the other pheromone map, cross-modality influences are implicitly, i.e., through stigmergy (Grassé, 1959), maintained in the system. This increases robustness by allowing p-ants to exploit multiple cues indirectly, in a simple and fast to compute way.

Rather than blending both conspicuity maps to generate the final saliency map  $\mathbf{S} \leftarrow \frac{1}{2}\mathbf{C}^I + \frac{1}{2}\mathbf{C}^C$ , as typically done (Itti et al., 1998), in this work  $\mathbf{S}$  is obtained by blending both pheromone fields,  $\mathbf{S} \leftarrow \frac{1}{2}\mathbf{P}^I + \frac{1}{2}\mathbf{P}^C$ . This way the saliency map is no longer a result of purely bottom-up sensory-driven process; instead, the bottom-up information is exploited under the context of some a priori knowledge about typical trails approximate layout. The result is a more robust and accurate focus of attention at the cost of a residual computa-

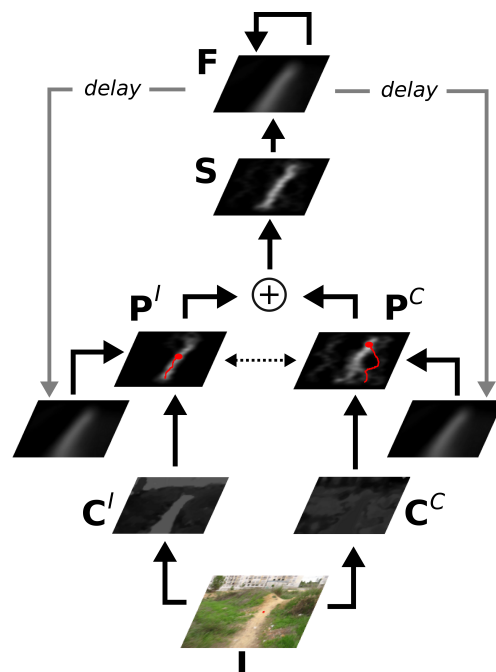

Figure 1: System’s operation overview (Santana et al., 2010). The red overlays in both pheromone fields,  $\mathbf{P}^C$  and  $\mathbf{P}^I$ , are two illustrative p-ant paths. Motion compensation aspects are not represented. Note that the brightest region in the neural field,  $\mathbf{F}$ , correctly corresponds to the trail location in the input image,  $\mathbf{I}$ .

tional overhead.

For across-frames integration of trail location evidence, the final saliency map  $\mathbf{S}$  feeds a dynamic neural field,  $\mathbf{F} \in [0, 1]$ , that is, a 2-D lattice of dynamical neurons with Mexican-hat shaped lateral coupling (Amari, 1977). This coupling implements inter-neuron local lateral excitation and long-range inhibition, which helps the neural field on the production of a single focus of attention (Rougier and Vitay, 2006). In order to decouple the dynamics of the neural field from the dynamics of the robot, the projective transformation estimated between frames is applied to the neural field. Finally, the output of the system is given by the current state of the neural field, in which the higher the activation of a given neuron the higher its chances of being associated to a trail’s pixel (refer to (Santana et al., 2010) for details on dynamical field processing).

In order to allow p-ants’ creation and activity to be affected by history, at the onset of each frame, both pheromone maps are initialised with a small ratio  $\lambda$  of the neural field after being motion compensated,  $\mathbf{P}^I \leftarrow \lambda \mathbf{F}$ ,  $\mathbf{P}^C \leftarrow \lambda \mathbf{F}$ . This induces stability and robustness to noise and temporarily mis-behaved conspicuity maps (i.e., unable to properly discern between trail and background in the presence of distractors), as well as it enables across-frames progressive im-

provement.

With the purpose of reducing the effects of strong distractors when tracking the trail, this paper includes into the swarm-based system an adaptive mechanism. The goal is to learn and update in each frame a simple appearance model of the trail, so that p-ants can strengthen the deployment of pheromone on regions whose appearance match the learned one. The result is a stronger stigmergic behaviour around the true location of the trail. Learning occurs by sampling the region of the visual input corresponding to the region of the neural field with highest activity. That is, the model is updated under the assumption that the trail location estimated in the previous frame is correct.

### 3. Pheromone Maps Computation

This section describes how the two pheromone maps,  $\mathbf{P}^I$  and  $\mathbf{P}^C$ , are built from the two conspicuity maps,  $\mathbf{C}^I$  and  $\mathbf{C}^C$ . For this purpose, a given p-ant,  $p_m$ , is created and associated to a given visual feature  $m \in \{I, C\}$ . The other visual feature is represented by  $m'$ . While being iterated for  $\eta$  times,  $p_m$  will move on  $\mathbf{C}^m$ , influenced by the pheromone present in  $\mathbf{P}^m$ . In the non-adaptive model, while moving, this p-ant deploys pheromone in each position visited in  $\mathbf{P}^m$  with a magnitude  $\epsilon_0$ , and a small portion of  $\epsilon_0$ ,  $v$ , in  $\mathbf{P}^{m'}$ .

After the iterations for this p-ant, a p-ant associated to the other visual feature,  $p_{m'}$ , is created and iterated following the same procedure. Afterwards, the two p-ants are removed from the system and the process is repeated  $n$  times, meaning that  $2n$  p-ants are created and iterated. As it will be shown, the deployed pheromone is a function of p-ants' sensations across their trajectories on their associated conspicuity maps. Hence, it is influenced by the activity occurring in distant regions of the map. This long-range spatial connectivity allows handling the potentially large size of trails in a robust and parsimonious way.

#### 3.1. P-Ant's Creation

The chances of creating a p-ant  $p_m$  on a given location  $\mathbf{o}_{p_m}$  of the conspicuity map  $\mathbf{C}^m$  depends on the level of conspicuity at that location and on the level of pheromone at the same location in the corresponding pheromone map,  $\mathbf{P}^m$ . Hence, p-ants are progressively and probabilistically deployed where there are more chances of being a trail, under the assumptions that: (1) trails tend to be conspicuous; (2) the trail has been successfully detected in the previous frame (represented by the feedback provided by the delayed neural field state); and (3) that the pheromone accumulated by p-ants deployed in the current frame builds-up mostly around the actual trail's location.

By assuming that trails often start from the bottom of the image, p-ants are deployed with a small randomly selected offset  $z \in [0, 0.1 \cdot h]$  of the bottom of the conspicuity map in question, i.e., at row  $r \in [h - z, h]$ , where  $h$  is the height

of the map<sup>1</sup>. This random small offset reduces sensitivity to any noise potentially present at the map's boundaries.

In order to determine the column where  $p_m$  is deployed, a unidimensional vector  $\mathbf{v}^m = (v_0^m, \dots, v_w^m)$  is first computed. The element  $v_k^m$  of  $\mathbf{v}^m$  refers to the average conspicuity level of the pixels in a small window centred on column  $k$  and with a randomly selected offset with respect to the bottom row of the map,  $r$ ,

$$v_k^m = \sum_{l,j} \frac{\mathbf{C}^m(l,j)}{\delta_w \cdot \delta_h} \quad (1)$$

where  $l \in [k - \delta_w/2, k + \delta_w/2]$ ,  $j \in [r - \delta_h, r]$ ,  $\mathbf{C}^m(l,j)$  returns the conspicuity level in position  $(l,j)$ , and  $\delta_w$  and  $\delta_h$  are the width and the height of the window, respectively. The same windowing process is applied to build a vector for the pheromone field in question,  $\mathbf{u}^m = (u_0^m, \dots, u_w^m)$ . Element  $u_k^m$  corresponds to the maximum pheromone level found in the window:

$$u_k^m = \max\{\mathbf{P}^m(l,j)\}_{l,j} \quad (2)$$

where  $\mathbf{P}^m(l,j) \in [0,1]$  returns the pheromone level in position  $(l,j)$ . The max operator is employed to benefit those regions where the paths of p-ants overlap more often and consequently where there is a higher consensus on the trail's skeleton position.

Using these two vectors in the following test, which is repeated until it succeeds, the chances of deploying a p-ant in a randomly selected column  $z_2 \cdot w$  is as high as the conspicuity and pheromone levels at the deployment region,

$$z_1 < \left( \rho \cdot u_{z_2 \cdot w}^m + (1 - \rho) \cdot v_{z_2 \cdot w}^m \right) \quad (3)$$

where  $z_1 \in [0,1]$  and  $z_2 \in [0,1]$  are numbers sampled from a uniform distribution each time the test is performed and  $\rho$  is a weight factor used to trade-off the influence of both pheromone and conspicuity information. By starting with a small value,  $\rho_0$ , and by linearly growing at each iteration by an amount  $\Delta\rho$ ,  $\rho$  operates as an adaptive process, compelling the system to move from a conspicuity-driven operation (exploration) to a pheromone-driven operation (refinement/exploitation).

#### 3.2. P-Ant's Execution

Before specifying p-ants behaviours, it is necessary to specify their sensory and action spaces. To reduce both sensitivity to noise and computational cost, the sensory input is defined by 5 coarse receptive fields disposed around the p-ant's current position,  $R_1 \dots R_5$  (see Fig. 2). For a given visual feature  $m$  and p-ant's position  $\mathbf{o}_{p_m}$ ,

<sup>1</sup> Rows are indexed in increasing order from the top to the bottom of the map.

iteration a p-ant  $p_m$  selects its action by maximising the following utility function, which incorporates behaviours' votes, pheromone-based interactions, and random fluctuations,

$$a_{p_m} = \arg \max_{a \in A} \left( \sum_{b \in B} \alpha_b f_b(p_m, a) + \mathbf{P}^m(R_a, \mathbf{o}_{p_m}) + \gamma q \right)$$

where:  $\alpha_b$  is a user defined weight accounting for the contribution of behaviour  $b \in B$ ; and  $\gamma$  is the weight accounting for stochastic behaviour, being  $q \in [0, 1]$  a number sampled from a uniform distribution each time the action is evaluated. To match the randomness magnitude with the scale of the image, which is typically smaller for pixels in upper regions of the image, the weight  $\gamma$  starts with an initial value  $\gamma_0$  and exponentially decays by a constant factor  $\gamma_\tau$  at each iteration.

In case an immediate loop is detected, namely, the p-ant moving recurrently from one pixel to another, then the action for the current iteration is randomly selected. Finally, the p-ant's position  $\mathbf{o}_{p_m}$  is updated according to the selected action<sup>2</sup>.

## 4. Adaptive Process

This section describes how (see Section 4.1) and when (see Section 4.2) the appearance model of the trail is learned and updated. To help p-ants disambiguate in situations where the conspicuity information is not sufficient by itself, the learned model is used to promote the deployment of pheromone on regions of the image whose appearance is more likely to belong to the one of the trail (see Section 4.3). To allow learning the model from scratch, some assumptions regarding the initial position of the trail with respect to the robot are made (see Section 4.4).

### 4.1. Appearance Model

The trail's appearance model of the current frame is a simple colour histogram,  $\mathbf{h}$ , of the pixels in the region of higher neural field's activity. To reduce sensitivity to illumination effects, the HSV colour space is used. To further reduce this sensitivity, the H(ue) component is described by 12 bins, the S(aturation) component by only 8 bins, and the V(alue) component is discarded altogether.

This frame-wise appearance model is used to update an across-frames appearance reference model,

$$\mathbf{h}_{\text{ref}} \leftarrow \Theta(\mathbf{F})\mathbf{h}_{\text{ref}} + 1 - \Theta(\mathbf{F}) \mathbf{h} \quad (5)$$

where  $\Theta(\mathbf{F}) = \kappa \cdot \max(\mathbf{F})$  makes the speed the reference model adapts to changes in the trail's appearance proportional to the neural field's maximum activity. This weighted

<sup>2</sup>For the sake of completeness, the pseudo-code of the models here described can be found at: <http://www.uninova.pt/~pfs/ecal2011trail.html>

approach allows the appearance model to be updated more strongly when the system is more sure of its output being a correct segmentation of the trail from the background. This assumption follows from the fact that the more stable the pheromone maps' activity across-frames the higher the neural field's maximum. Hence, the presence of distractors is less prone to affect the reference appearance model.

### 4.2. When to learn

To further reduce the chances of learning erroneous appearance models due to the presence of distractors, the appearance reference model,  $\mathbf{h}_{\text{ref}}$ , is only updated with Eq. 5 if the neural field in the current frame reports the trail as being roughly located ( $\pm 10\%$  of the map's width) at the centre of the image. This is a reasonable heuristic under the assumption that the robot is actively centring itself along the trail in order to follow it.

This learning gating process allows the reference model not to learn the appearance of transient distractors appearing in the sides of the trail. Furthermore, it allows the system to delay the learning phase when the robot does not start centred on the trail.

### 4.3. Adaptive pheromone deployment

In Santana et al. (2010), p-ants deploy a constant level of pheromone along their paths,  $\epsilon_0$  (see Section 3). In this work, instead, a given p-ant  $p_m$  deployed in map  $m$  deposits a non-fixed level of pheromone,

$$\epsilon = \epsilon_0 + \beta \cdot p(T|V_{p_m}) \quad (6)$$

where  $\beta$  is an empirically defined weighting factor and  $p(T|V_{p_m})$  is the probability of the p-ant's path,  $V_{p_m}$ , to belong to the trail (T).

The probability  $p(T|V_{p_m})$  is approximated by the average probability of pixels visited by the p-ant of belonging to the trail. These pixels are represented by the set  $V_{p_m}$ , and their individual probabilities are obtained directly from the normalised histogram  $\mathbf{h}_{\text{ref}}$ , according to a technique known as histogram back-projection (see Fig. 3 for typical results). As the experimental results will show, this simple approach suffices to help p-ants tracking the trail.

### 4.4. The First Frames

The advantages of using learning comes at the price of solving the bootstrapping problem. That is, in the absence of a learned model, the detector has a reduced chance of generating a good output to supervise the learning, which in turn hampers the learning of the model altogether. To solve this problem we start from the assumption that the detector is turned on when the robot is already roughly located on the trail. Therefore, we can assume that in the first frames the trail is centred on the robot's input image.

Figure 3: Pixel-wise trail probability (brightness level) for two typical images.

Bearing this in mind, in the first frames, instead of considering the maps' entire width,  $w$ , when selecting the deployment column of a newly created p-ant (see Eq. 1 and Eq. 2), the adaptive model assumes that the deployment region is constrained by a band centred on the map and with a frame-wise upper-bounded growing width. Concretely, in the first frame, the width of the band is 10% of  $w$ . Then, this width is increased by 0.5% at each new frame until the upper-bound  $w$  is reached. From then on, it remains static. At this moment the learned model is sufficiently mature to help the detector tracking the trail.

## 5. Experimental Results

This section quantifies the improvement the adaptive mechanism brings to the overall method and how well it suits the fast computation requirements imposed by physical robots. In order to measure the performance of the adaptive model, we relied on the same data-set used to evaluate the non-adaptive model (Santana et al., 2010). This data-set consists of 25 colour videos, encompassing a total of 12023 frames with  $640 \times 480$  resolution, which have been obtained with a hand-held camera<sup>3</sup>. This camera was carried at an approximate speed of  $1 \text{ ms}^{-1}$ . The trail detector was evaluated on an Intel T4300 2.1 GHz dual core, running Linux. OpenCV was used for low-level routines. To handle the probabilistic nature of the agents behaviour, a set of 5 runs was performed per video. In some of these videos the robot does not start on the trail, which is important to validate the ability of the detector to delay the learning phase.

Performance is measured as the percentage of frames in which the biggest blob of neural field activity above 0.85 (from a maximum of 1) is fully within the trail boundaries. The system parameters related to the adaptive mechanism,  $\kappa$ ,  $\beta$ , and  $\epsilon_0$ , have been empirically set to 0.001, 0.01, and

<sup>3</sup>The model's output overlaid on these videos is available at: <http://www.uninova.pt/~pfs/ecal2011trail.html>

0.008, respectively. The remainder of the free parameters have been set as in the original model (Santana et al., 2010).

With a success rate of  $92.98\% \pm 0.16\%$  over the 25 videos, the base model already attains an impressive result, operating  $\approx 4$  times better than a classical saliency model and in situations where previous detectors fail (details in (Santana et al., 2010)). However, a single failure in an embodied setup may result in dramatic consequences. Therefore, full success must be pursued. With the adaptive mechanism, the model reaches a success rate of  $97.94\% \pm 0.17\%$  over the 25 videos, and a 100% success rate in 12 of the 25 videos (see Table 1). Conversely, the non-adaptive model obtains a 100% success rate only in 6 of the 25 videos. Fig. 4 shows frames from some videos belonging to the 25 video data-set where the non-adaptive model fails to detect the trail, whereas the adaptive one succeeds. Although typically transient, these failures could drive the robot off trail. They usually occur when the assumption that trails are conspicuous structures fails due to the overall scene configuration. Sometimes it also happens that a sudden camera motion is not captured by the motion detection method, resulting in a mismatch between the neural field and the environment.

In terms of computation time, the non-adaptive model runs at 13 Hz whereas the adaptive one runs at 12 Hz. Note that only roughly 8% of the computation time refers to swarm-based activity - the remainder includes robot motion estimation, neural field update, and conspicuity maps computation. The conclusion is that the adaptive mechanism, which improves the method's accuracy, adds little computational overhead.

It is important to point out that the dependency of the overall process on an appearance model makes the learning process a critical one. This is reflected on the need for a learning bootstrapping process and for trail's appearance transitions to be smooth. That is, the improvement in performance is obtained at the cost of introducing assumptions, which are, nevertheless, acceptable under a trail tracking framework.

## 6. Discussion

Rather than static structures, like neurons, agents are better viewed as active information particles that flow and change in the system. Hence, using agents, the design focus is on the process and not so much on its supporting substrate. Additionally, agents being sensorimotor coordinated units can exploit the benefits of active vision (Bajcsy, 1988; Ballard, 1991) at the information processing level. These include the ability of agents to actively select and shape their sensory input so as to increase noise-to-signal ratio and increase their discriminatory power, to augment rotation and scale invariance, and also to exploit sensorimotor history with the purpose of inducing long-range influences and in the limit of improving their own behaviour (Scheier et al.,

Figure 4: Examples of situations where the adaptive method outperforms the non-adaptive method. The red blobs represent the estimated trail location, which corresponds to the neural field activity above 85% of its maximum. In the adaptive case, besides localising the trail, the red blob is well aligned with its orientation. This means that the system is able to output both position and orientation of the trail.

1998; Nolfi and Marocco, 2002; Beer, 2003; Floreano et al., 2004; Sporns and Lungarella, 2006; Mirolli et al., 2010). Furthermore, the use of multiple agents in the task of modelling cognitive behaviour exploits biological knowledge obtained from similar processes that can be found in Nature.

In our line of research, we have used a model inspired by *swarm cognition* of social insects, whose considerable similarities with brain cognitive function are becoming widely recognised (Passino et al., 2008; Couzin, 2009; Marshall and Franks, 2009; Trianni and Tuci, 2011; Santana and Correia, 2010; Turner, 2011; Trianni et al., 2011). In this work, the ant foraging metaphor previously used was extended with learning capabilities, resulting in a system that can better adapt to different environmental contexts.

The use of learned appearance models to swarm-based object tracking has already been explored in the context of PSO-based models (Zhang et al., 2008). However, our work is the first applying learning to the problem of swarm-based trail detection and tracking. This is an important difference as the appearance of trails change more drastically than the one of typical objects. Furthermore, our model uses the appearance model to modulate pheromone deployment, a concept inexistent in PSO models.

## 7. Conclusions

This article proposes a model to incorporate an adaptive mechanism into a swarm-based trail detector previously published. The goal of this mechanism is to allow the detector to learn and exploit appearance models of the trail being followed. Experimental results confirmed the ability of the adaptive model to outperform the non-adaptive one, under the assumption that the robot starts its operation already on the trail.

The learned trail’s appearance model is used to modulate the swarm operation, rather than, to directly classify the input image as in a convolution-like typical computer vision operation. First, this approach allows the system to exploit synergistically both appearance and shape information, which is pivotal to handle sudden trail’s appearance changes. Second, this multi-modal approach allows the use of simple appearance models, i.e., histograms. Third, the appearance model and the behaviours controlling the agents being simple enable a fast to compute system.

With a bottom-up self-organising approach, the model is capable of handling highly unstructured trails without exhibiting a high computational load. In fact, we have shown in previous work (Santana et al., 2010) that the non-adaptive model performs in situations where previous detectors employing classical computer vision techniques would fail. In this work, we have improved the previous model by introducing elementary learning of the photometric appearance of the trail. All this leads us to conclude that swarm-based models are an interesting alternative to classical computer vision techniques. This means that besides contributing with

a useful model to improve off-road robot navigation, this work intends to encourage the artificial life community to employ their bulk of knowledge at the service of the high impact problem of synthesising robust and fast computer vision systems.

An interesting future development would be to expand the learning capabilities to other aspects of the model. An example is the adaptation of the weights controlling how much each agent's behaviour contributes to the overall behaviour. It would also be interesting to learn the behaviours themselves. An additional aspect that might be considered is the emergence of hierarchical organisation among the agents. Finally, the method's ability to deal with strong camera motion must be evaluated on a physical robot embodiment.

## Abstract

Understanding the evolutionary mechanisms that promote and maintain cooperative behavior is recognized as a major theoretical problem where the intricacy increases with complexity of the participating individuals. Costless pre-play communication [1] with signals that have no preexisting meaning (also known as cheap-talk) might not, on the face of it, be expected to do much. With the current extended abstract, here we would like to present a new analysis of this problem. This analysis has been recently reported in [Santos, F.C., Pacheco, J.M., Skyrms, B.: *Co-evolution of pre-play signaling and cooperation*. *J Theor Biol* 274 (2011) 30-35] [2].

Here, we show how pre-play signaling leads to profound changes in the evolutionary dynamics of cooperative games, favoring cooperation in finite populations. Cooperation freely emerges from the co-evolution of signals, assigned meanings and actions which are not built-in in the individual, addressing in a general framework the study of central aspects of Human evolution, from the self-organized drive towards an individual adoption of a given signaling system to the emergence of the latter [1].

We analyze two important metaphors of cooperation: The Stag-Hunt (SH) (or coordination) game and the Prisoner's dilemma (PD). We show how, on coordination dilemmas, individuals willing to cooperate learn how to use the information encoded in each signal to identify other cooperators, reducing the risk of facing defection upon a cooperative act. In addition, the existence of a large number of signals enhances the tendency to cooperate, as it enlarges the portfolio of available signals that cooperators may use at profit to coordinate. Since mutual cooperation is always the best possible outcome in coordination dilemmas, cooperators who are able to discriminate between their own strategy and the one of others are robust against the invasion of mutants. Consequently, the emergence of evolutionary stable strategies (and signals) requires that these strategies are *i*) cooperative, *ii*) discriminative and *iii*) self-reinforcing, that is, they cooperate with individuals who adopt the same signal.

Remarkably, the enhancement of cooperation through signaling also applies to games where deception constitutes a profitable option, and where defection is the only stable strategy, as in the PD. In the presence of pre-play signaling, those strategies that opt invariably to defect are no longer stable in the PD. However, the same remains true for any type of cooperative strategy. Let us suppose that mutant arises who can utilize an unused signal. The mutant sends the signal, cooperates with others who send it, and defects against the natives - who do not send it. All goes well for the invaders until another mutant arises who sends the signal and then defects. Thus, in the absence of any evolutionary stable strategy, the fate of cooperation emerges from the conflict between deception by fake signaling and development of reliable "secret handshakes" [3].

Finally, all results are shown to be strongly dependent on the number of signals available. In particular, cooperation can emerge as a result of the arms race between *i*) the exploration of new signals by cooperators (to avoid being cheated by defectors) and *ii*) the search of cooperative signals by defectors (to deceive cooperators). By increasing the number of signals, cooperators have a larger portfolio of signals to pick from, something they learn to use to their own advantage. This result illustrates the advantages of a complex signaling system (or incipient language system). Language, even if minimal may open a route to cooperation. Indeed, signaling systems, together with a rich communication portfolio, may give rise to a developing mechanism of intention recognition, from which future behaviors may be assessed and trust bonds established.

## Abstract

In this paper, we propose an experimental and computational model to challenge the dynamic body boundary problem, as seen in the rubber hands illusion and phantom limbs. Our strategy examines an agent's "attention shift". A computational model (Iizuka & Ikegami, 2005) was used to explore how a body and sensor can be made inseparable. A model agent was required to determine the number of vanes on a windmill by touching the windmill blindly with a stick. By adding an additional windmill to the first one, we investigated the agent's shift of attention, i.e. the agent could either determine the vanes on the first windmill, or the second windmill by using the first one as a tool. In other words, an agent's body image can shift from its arm tip to the boundary between the first and second windmill. We then introduced an experiment with a real windmill model to test the hypothesis shown by the theoretical model. Subjects were tasked with determining the number of vanes on the second windmill. We found that sensory-motor correlations between their actions and perceptions of the movement of the windmills were helpful for the attention shift but still not enough to extend their body boundaries.

## Introduction

### A Model to Bridge the Gap between the Self and the Environment

In order to overcome philosophical and scientific problems such as the "hard problem", which asks how and why certain neural processes give rise to subjective experiences (Chalmers 1996); or the symbol grounding problem, which asks how symbols get their meaning (Harnad 1990), we need a radical new framework or model to recast the dichotomies of mind and body, subject and object, agent and the environment, and perception and action.

How we model our cognition is directly connected to how we understand it. Studies on embodied robots and simulations are based on sensory-motor ideas that attempt to describe our psychological processes from sensory-motor connections and interactions with the environment (Walter 1950, 1951; Braitenberg 1984; Pfeifer & Scheier 1999; Brooks 1991a, b). For example, Walter (1950, 1951) discusses cognitive, play-like, and social behaviors by synthesizing artificial vehicles, while Braitenberg (1984) made conceptual robots to discuss the higher functioning of cognition. However, even if the above approaches succeed in shedding light on sensory motor experiences through interaction with the environment, the approaches still fails to consider psychological concepts such as body image, ownership, agency and active perception, which play an important role in resolving the dichotomies.

There are many phenomena in empirical neuropsychological studies that can be described with these psychological concepts. Yamamoto and Kitazawa (2001), for example, demonstrated in the arm-crossing experiment that the perceived temporal ordering of haptic stimuli was reversed when the successive stimuli were temporally close enough. Maravita and Iriki (2004) demonstrated that a macaque monkey's body image was extended to the tip of a tool bar when the monkey learns to use it. Ramachandran and Blakeslee (1998) showed that a human body image can be easily created or destroyed by using visual or auditory information. These experiments and others have revealed that body images and ownership have very dynamic natures, something we would like to implement in our system.

Our body image and ownership bridge the gap between the highly abstract sense of "self" and the physical world where our body is situated. Francisco Varela (1979) proposed a principle of autonomy, stressing the idea of a self-generated boundary. He exemplified autonomy as a "self" that emerged from a chemical system through structural coupling with the environment. In his model, it was shown that some reactive particles created a boundary, which regulated internal reactions of the particles, thus maintaining the boundary structure. The circularity of the physical boundary and the internal dynamics

produce the coherence of the self-state. In other words, the self has not been strictly defined but can be described as a dynamic process, and the sensory-motor experiences from the perspective of the emergent self, account for the psychological or highly abstract concepts such as life. One such challenge, with respect to a proto-cell system, can be seen in Suzuki and Ikegami (2004).

Mere sensory-motor modeling surrenders the self because it is pre-defined as a completely different entity to the environment and the boundary is given as the firm distinction between them. Therefore, we provide a new framework for modeling in order to achieve a balance between both ideas of emergent self and sensory-motor flow. In the new framework, we assume no explicit distinction between a sensor and a motor that defines the boundary. An interface between an agent and its environment is only dynamically constructed. Exploiting the model, we investigate active perception and body image as dynamic processes in the emergent self. The psychological notions are clarified first in this paper, after which the computational modeling and results are described. We also report some tentative results of a real windmill model, which has recently been made to investigate how human subjects feel their body boundaries.

## Body Image

Our body images are not restricted to the physical boundary that separates our bodies from the external world. When an expert driver drives a car, he/she can traverse narrow streets easily, as though the car were part of his/her own body. Indeed, he/she is aware of the whole car, and when the car runs over a rock, he/she feels as though he/she has stepped on it with his/her foot. Another example is an artificial tooth. We feel uncomfortable and cannot taste food when using an artificial tooth for the first time. However, over time, we adapt to the artificial tooth and learn to taste again. Yet another instance of this can be seen in a blind person's stick. As he/she adapts to its use, the stick changes from mere matter to a real body part, and the person is eventually able to perceive his/her environment with the stick. These examples show that one's body image can be extended beyond his/her physical body boundaries. Body images are formed through interactions between brain, body, tool, and environment. Nevertheless, the dynamic mechanisms underlying the changes of body images are still not fully understood, despite their importance in areas such as medical care, robotics, cognitive development, enactive cognitive science (Varela et al. 1991; Thompson 2007), the "extended mind" (Clark et al. 1998), and "radical embodied cognitive science" (Chemero 2009). We propose a model for body images by extending the windmill model proposed by Iizuka and Ikegami (Iizuka & Ikegami 2005). The windmill model proposed by Iizuka and Ikegami is a computer simulation model to study "active perception" (Gibson 1962).

## Active Perception

A difference between human perception and an artificial system based on current technology is the fact that two modes of perception exist in humans, active and passive modes of perception. When we touch an object with our hands, we perceive the shape, texture, and temperature of the object.

Gibson (1962) reported on experiments in which blind subjects touched different shapes of cookie cutters. When the cutter was pushed randomly on the subject's palm, the subject recognized the correct shape with 72% accuracy. By touching the cutter in a self-guided manner, the subjects recognized the object more than 95% of the cases. The former case is an example of passive perception and the latter case is active perception. This study illustrates that perception does not merely entail receiving information from the outside. It is instead a form of exploration. Moving our hands is not just a method we use to arrive at perception, but rather, the moving of one's hands is an ongoing exploratory process, which we think of as a generic property of perception. Edward Reed (1996) has further developed Gibson's idea, and this idea of perception has become a core principle of new psychology (often called ecological psychology).

Even though the idea of active and passive perception is subjectively apparent and has been studied empirically, it is still difficult to implement the two modes within the context of an artificial model. Iizuka and Ikegami (2005) studied the simulation model of object discrimination, which implement the two modes of perception. The present study further develops this research by studying the changing of body images.

## Computational Model

### Windmill Model for Active/Passive Perception

In this section, we briefly introduce the model for active/passive perception, and in the next section, we propose a model for body images and report results. In the proposed model, the agent consists of a body with a straight arm that can move and touch an object (Figure 1). The object is a windmill with a certain number of vanes, and the agent can rotate the windmill by pushing the vanes. This is what we call an active condition. When the agent perceives the windmill by its arm being pushed by the vane, this is a passive condition. In other words, the windmill has an infinite mass in the passive condition, and the agent cannot change the initial velocity of the windmill by pushing its vane. One of the aims of this windmill model was to examine the difference between the two methods of perception in terms of dynamic systems.

Figure 1: Windmill model for active/passive perception. The agent consists of an arm, a “body neuron”, and internal neurons. The windmill has 5 or 7 vanes. Differentiation of the windmills is made by comparing the activities of neurons 1 and 2.

Firstly, the dynamics of the arm and the windmill are controlled by the deterministic equation:

$$M_a \ddot{\theta}_a + D_a \dot{\theta}_a + F_a + F_{col}(\theta_a, \theta_w) = 0, \quad (1)$$

$$M_w \ddot{\theta}_w + D_w \dot{\theta}_w + F_{col}(\theta_a, \theta_w) = 0, \quad (2)$$

where  $\theta_a$  and  $\theta_w$  denote the angles of the arm and the windmill, respectively;  $M_a$  and  $M_w$  denote the mass of the arm and the windmill, respectively;  $D_a$  and  $D_w$  denote the friction coefficient of the arm and the windmill, respectively;  $F_{col}$  is a function giving the potential of collision; and  $F_a$  is the force of the agent used to rotate the arm.

Secondly, this agent also has a “brain” that consists of internal neurons (Figure 1). The dynamics of these neurons are controlled by a continuous-time recurrent neural network (CTRNN) (Beer 1995). The dynamics of the neural system are expressed by the following equations:

$$\tau_i \dot{y}_i = -y_i + \sum_{j=1}^M w_{ji} g_j(y_j), \quad (3)$$

$$g_i(x) = \frac{1}{1 + e^{-x - b_i}}, \quad (4)$$

where  $y$  is the state of each neuron,  $\tau$  is its time constant,  $b$  is a bias term, and  $w_{ji}$  is the strength of the connection from the neuron,  $j$  to  $i$ . It should be noted that we adopted a sparse structure rather than a fully-connected network. The neurons are arranged in 3 layers.

Thirdly, the agent has a body neuron at the interface between the arm and the internal neurons. The body neuron simultaneously plays the role of sensor and motor. That is, this neuron determines the value of  $F_a$  and the angle of the arm is assigned to the body neuron (Figure 2). The agent has no explicit functional division of sensors and motors. The distinction between moving and being moved becomes implicit. Whether an arm motion is caused spontaneously or

externally, it is internally evaluated by investigating the body neurons and internal neurons. In an empty space, an agent can freely move his/her arm. When an arm hits an object, the collision produces de-coherence of the arm movement, which is interpreted as sensory information.

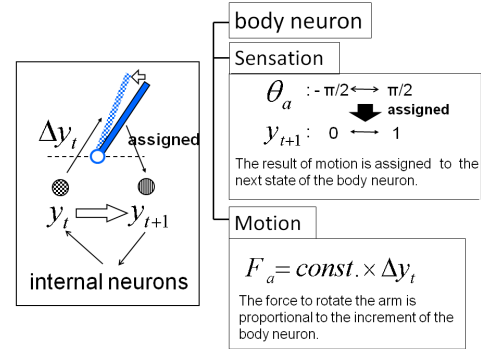

Figure 2: Updating the state of the body neuron, which plays the role of sensor and motor at the same time.  $\Delta y_t$  denotes the increment of the body neuron, which is given by equation (3).  $\Delta y_t$  is used to determine the force to rotate the arm.

**Active/Passive Agents.** An agent interacts with the windmill and distinguishes the number of vanes present (5 or 7) given the two conditions (cf. the beginning of the previous section). Specifically, an active agent distinguishes a windmill by actively touching the vanes. A passive agent does the same task by being pushed by the windmill. In both cases, this differentiation is made by comparing the neural activities of two neurons, neuron 1 and neuron 2 (Figure 1). If  $y_1$  is greater than that of  $y_2$ , the agent distinguishes the windmill as having 7 vanes, and if  $y_1$  is less than  $y_2$ , the agent distinguishes the windmill as having 5 vanes.

To train both active and passive agents, we adopted a standard genetic algorithm (GA) (Holland 1975) by encoding  $w_{ji}$  (the neural weight),  $\tau_i$  (time constant), and  $b_i$  (bias neural states) (cf. equation (3), (4)) into the real-valued strings. These strings are taken as artificial genomes and will be selected according to the fitness value of the corresponding agent (Figure 3). The value is calculated by multiplying the percentage of correct answers. The best-performing agent is preserved in the population without a genetic operation (elitism). The other agents are reproduced from the best agents by adding small random values (without sexual reproduction).

Figure 3: A schematic view of the genetic algorithm (GA) used in this study. We prepared 80 agents with different artificial genomes. The best-performing agent is selected according to the fitness value of the corresponding agent. The best-performing agent is preserved in the population. The other agents are reproduced from the best agents by adding small random values.

**General Observations.** A computational model shows that an agent becomes sensitive to the number of vanes. One difference exists in active and passive classifications: active classification is less stable against time delay compared to passive classification (Iizuka & Ikegami 2005). This is the dynamic system's interpretation of active and passive perception. In the following sections we further extend this model by adding the second windmill next to the first and gear the two windmills to move associatively. Our concern is to study how an agent's discrimination capability can be extended to the second windmill. We shall also discuss the synthesis of body images with the windmill.

### Coupled Windmill Model

In studying the coupled windmill model, we fix the number of vanes of the first windmill to 5 and require the agent to determine the number of vanes of the second windmill (which has 5 or 7 vanes). See Figure 4 for an illustration. An agent now uses the first windmill as a "tool" to determine the number of vanes on the second windmill. If an agent can successfully use the first windmill as a tool, we can say that, for the agent, the first windmill has shifted from an object to a tool. At this time, the agent's body image is thought to be extended to the first windmill. In the following sections, we only focus on the "active" agents, which actively use their arms to rotate the windmill in order to classify the number of vanes present.

Figure 4: A coupled windmill model for studying body images. This agent determines the number of vanes on Windmill 2. In the previous windmill model, Windmill 1 was an object to be distinguished. On the other hand, in the coupled windmill model, Windmill 1 changed from an object to be distinguished to a tool to determine the number of vanes on Windmill 2. At this time, the agent's body image is thought to be extended to Windmill 1.

**Is the First Windmill a Tool or a Mere Object?** The first windmill is proposed to become an extension of the agent's body, thereby shifting his/her body image. If an agent can judge the number of vanes of the second windmill, can we identify this as an emergence of the body image? In this case, even if the agent can distinguish between the windmills, we cannot simply say that the agent has shifted his/her body image. The agent might just distinguish two windmills as  $(5, 5)^1$  and  $(5, 7)$ . In other words, the first windmill might not be a tool but a mere object. We cannot decide which is right if the agent differentiates between two combinations of windmills. These are,  $(5, 5)$ ,  $(5, 7)$ .

To overcome this problem, we required the agent to distinguish not two combinations  $((5, 5), (5, 7))$ , but four combinations, which are,  $(5, 5)$ ,  $(5, 7)$ ,  $(7, 5)$ , and  $(7, 7)$ . We want to compare two different agents to discuss the boundaries of body images. If an agent classifies the four combinations as two groups, which are,  $\{(7, 5), (7, 7)\}$  and  $\{(5, 5), (5, 7)\}$ , then the agent is sensitive to the vanes of the first windmill (this is called Agent 1) (Figure 5). This is because Agent 1 classifies the combinations within the same/different category if the first windmill has the same/different number of vanes and the agent does not care about the second windmill. In contrast, if an agent classifies the combinations as  $\{(5, 5), (7, 5)\}$  and  $\{(5, 7), (7, 7)\}$ , the agent is sensitive to the vanes of the second windmill (this is called Agent 2) (Figure 6). Here, Agent 2 classifies the combinations with respect to the second windmill and does not care about the first windmill. In other words, for Agent 1, the first windmill functions as an object to be distinguished, and the second windmill works as a noise (Figure 5). Or, we might say that the first windmill is perceived as a "figure" by Agent 1 and the second windmill is seen as a "ground". In contrast, for Agent 2, the second windmill becomes an observed object (or a "figure"), and the first windmill is a tool (or a "ground") to distinguish the second windmill (Figure 6).

<sup>1</sup> The first and second components  $( , )$  are the number of vanes of the first and second windmills, respectively.

Figure 5: Agent 1. This agent is sensitive to the first windmill in the classification and does not care about the second windmill. The first windmill functions as an object to be determined, and the second windmill works as a noise, which means that the first windmill is not a part of the body image of Agent 1.

Figure 6: Agent 2. This agent is sensitive to the second windmill in the classification and does not care about the first windmill. The second windmill becomes an observed object, and the first windmill is a tool to distinguish the second windmill, which means that the first windmill is a part of the body image of Agent 2.

**Shift of Attention.** We think that this “shift of attention” is essential in defining the boundary of body image. For example, when we use a word processor for the first time, we pay attention not to the characters on the screen, but to the keyboard. At this stage, the keyboard is still an observed object and our body image is not extended to the keyboard. However, the attention is shifted from the keyboard to the screen as we become accustomed to typing. At this time, the keyboard’s status changes from being a mere object to a real tool, and our body image is extended to the keyboard. In our model, Agent 1 pays attention to the first windmill and does not care about the second windmill, which means that the first windmill is not part of the body image of Agent 1. In contrast, Agent 2 pays attention to the second windmill and does not care about the first windmill, which means that the first windmill is a part of the body image of Agent 2.

**Key Observations** By using a genetic algorithm, we successfully trained agents to become sensitive to the vanes of the first (Agent 1) or of the second windmill (Agent 2).

Changing the number of vanes successively from (5, 5) to (5, 7) to (7, 7) to (7, 5), we see that in the case of Agent 1, neuron 1 and neuron 2 are sensitive to the first windmill and do not care about the second windmill (Figure 7); in the case of Agent 2, neuron 1 and neuron 2 are sensitive to the second windmill and do not care about the first windmill (Figure 8).

For example, from (5, 5) to (5, 7), as in the case of Agent 1, no transition occurs in the neural states. However, in the case of Agent 2, a sharp transition occurs, and the magnitude relation is changed. In contrast, from (5, 7) to (7, 7) in the case of Agent 1, a sharp transition occurs, but in the case of Agent 2, the neural states maintain the magnitude relation.

As far as we know if we change the number of vanes, it won’t give the same result. However, as we already reported, a system properly count the number of the vane, when there is only one wheel (Sato et al. 2009). But counting two wheels case was also tough for the computational model.

Figure 7: Agent 1: the time series of the arm, the first windmill, the second windmill (top) and of neurons 1 and 2 (bottom).

Figure 8: Agent 2: the time series of the arm, the first windmill, the second windmill (top) and of neurons 1 and 2 (bottom).

## Experimental Setup

### Real Windmill Model

In order to test the hypothesis shown by the theoretical model, we have conducted a real experiment and constructed two windmills with crossed metal bars. In this setup we fix the number of vanes on the first windmill to 5 and ask subjects to determine the number of vanes on the second windmill (which has 5 or 6 vanes).

Subjects wear a blindfold and touch the first windmill with only a stick, which is also fixed in space. The stick is introduced to constrain the movement of the subjects. Subjects are requested to determine the number of vanes on the second windmill in 30 seconds. The experiment is repeated over 30 trials.

**Result.** Subjects ( $N=5$ ) come to discriminate windmills about 80 percent accuracy at the end (Fig. 9a). Observationally, in the early stages, the stick and the windmills move randomly but they switch to regulatory behavior in the end in cases of a single (Fig. 9b) and coupled windmill experiment.

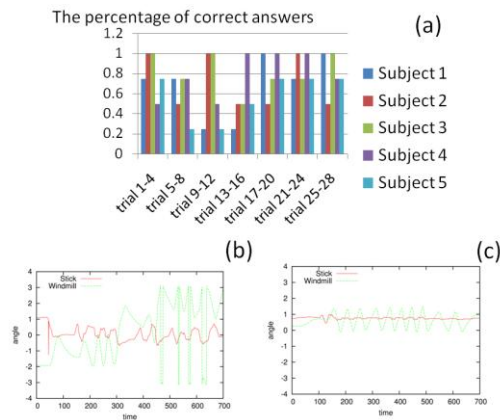

Figure 9; (a) The percentage of correct answers in a coupled windmill experiment. (b), (c) The time series of the stick and the windmill in a single windmill experiment. Movement of the stick changes from random motion (b) to periodic motion (c) as the subjects adapt to its use.

**The body boundary of subjects is still not extended.** Although subjects could count the number of vanes usually, they reported that they just paid attention to the touch feeling of collisions between the stick and the first windmill (Fig. 10a).

Because the number of vanes on the first windmill is fixed to 5, the collision events between the stick and the first windmill increase in frequency when the second windmill has 6 vanes, and decreases if it has fewer vanes ( $\neq 5$ ). With this trick, subjects could count the vanes on the second windmill. In this case, the first windmill is still an object to the subjects so that the body boundary is not extended to the boundary between the first and second windmill.

Figure 10b shows the time series of the positions of the stick and the vane of the first windmill which collide with the second windmill (the red vane in Fig. 10a). The supporting point of

the stick and the windmills are fixed on the horizontal line in Fig. 10a. But the center of the oscillation of the stick and the vane of the first windmill is not on the line (Fig. 10b).

Something is needed to extend a subject's body boundary. Our hypothesis is that subjects need more visual information about the windmills to learn the sensory-motor correlations between their action and the movement of the windmills. But if subjects can see the windmills they also recognize the number of vanes of the second windmill.

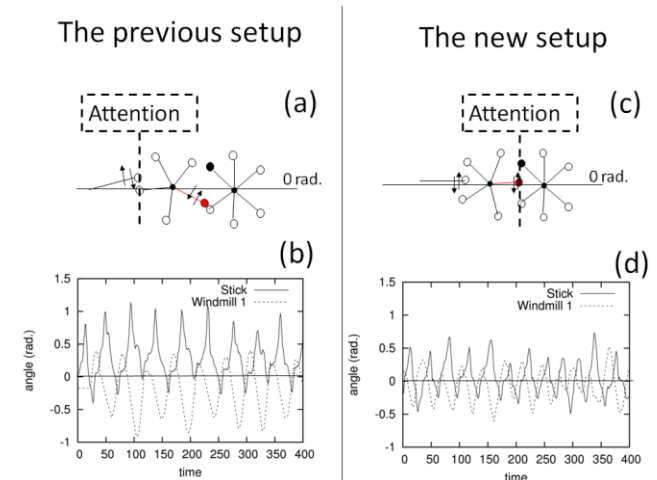

Figure 10: (a) The subjects reported that they paid attention to the collisions between the stick and the first windmill. The supporting point of the stick and the windmills are fixed on the horizontal line. (b) The direction of the first windmill from the supporting point of the stick is 0 radian (the horizontal line in Fig. 10a), but the center of the oscillation of the stick and the vane of the first windmill which collide with the second windmill (the red vane) is less than 0 radian. (c) In the new setup some subjects paid attention to the collisions between the first windmill and the second one and did not care about the collisions between the stick and the first windmill. The supporting point of the stick and the windmills are fixed on the horizontal line. (d) The direction of the first windmill from the supporting point of the stick is 0 radian (the horizontal line in Fig. 10c), and the center of the oscillation of the stick and the vane of the first windmill which collide with the second windmill (the red vane) is 0 radian.

### New Setup

In order to extend the body boundary of subjects, we introduced visual inputs (Fig. 11). A video camera captures the windmills and displays them on the monitor, while subjects do the task, watching the monitor.

Figure 11: New setup. Here, there is a stick, the first windmill, and the second windmill, which is white. There is also a monitor, camera and one black mark attached to a vane on the second windmill. The camera captures the windmills and displays them on the monitor.

Now subjects can observe the global configuration of two windmills and how they move around (the left image of Figure 12). By using a black-white screen and painting the two windmills in different colors, a subject can only see the movement of one windmill at a time.

In the right image of Figure 11, subjects can only see the second windmill. Since we only put a mark on one vane, subjects can't recognize the number of vanes, but they can see the movement of the second windmill.

Figure 12: Two kinds of images on the monitor. The left image has full color. In this case subjects can see all and recognize the number of vanes. On the other hand, the right image is in black and white. In this case, subjects can only see the black mark attached to a vane of the second windmill.

### Observations of the new setup

In the 14th trial, a subject reported that he discovered how to use the first windmill to distinguish the number of vanes on the second windmill. He tried to use one vane on the first windmill (the red vane in Fig. 10c) to oscillate the second windmill. He reported that he felt as if the first windmill was the stick to distinguish the second one. He also reported that he paid attention to the collisions between the first windmill and

the second one and did not care about the collisions between the stick and the first windmill (Fig. 10c).

Figure 10d shows the time series of the stick and the vane on the first windmill which collides with the second windmill (the red vane) in the 14th trial. The center of the oscillation of the stick and the vane of the first windmill is on the horizontal line in Fig. 10c.

A remarkable difference between Fig. 10b and Fig. 10d is the following. When the visual information is available (Fig. 10d), subjects try to use a vane of the first windmill (the red vane) as a "controlling handle" to move the second windmill. As a result, that vane and the stick before the first windmill align in a straight line.

## Summary and Discussion

In this paper, we firstly demonstrated that even simple computational agents can have two different sensitivities to the windmills. It should be worth noting that the agents can ignore the number of vanes of the unattended windmill. An agent becomes either sensitive to the first windmill or the second one, neglecting the other. We claim that this shift of attention from the first windmill to the second is a dynamic shift of the body boundary.

In the real windmill model, we found that there are two ways to distinguish the second windmill. In the previous setup, subjects do the task with a blindfold. In this case subjects could not learn the sensory-motor correlations between their action and the movement of the windmills' vanes, and felt that the first windmill was an object to be distinguished. On the other hand, in the new setup subjects could see the movement of a vane on the second windmill, so some subjects could learn the sensory-motor correlations between their action and visual information of the second windmill. In this case, some found how to use the first windmill as a tool to distinguish the second windmill, and they could pay attention not to the collisions between the stick and the first windmill but to the collisions between the first windmill and the second one.

But this shift of attention is still weak and not enough to extend their body boundaries for most of the subjects. We are now planning to change the material of the ball attached to the tip of the vanes to a heavier material, so that subjects can feel the collisions between the first windmill and the second one clearly. It will help subjects with a blindfold to determine the movement of the second windmill and to learn the sensory-motor correlations between their action and perception. Some reported that due to the noisy setting up of the experiment, it was difficult to predict the movement which prevented the body boundary from extension. Also we are afraid that since the present setting up uses a single stick + a first windmill + second windmill, the discrimination task became inevitably complex. We are improving the point to simplify the structure.

The value of this paper lies in the ambiguity of the first windmill, which is a tool (a part of a subject) and an object (an environment) at the same time. Our insights are beneficial for the biology of cognition, enactive cognitive science, the "extended mind" (Clark et al. 1998), and "radical embodied cognitive science" (Chemero 2009; Dotov et al. 2010). In our

study, the dichotomy of object and subject is rejected and the active role of an observer in perception is considered.

We argue that the ambiguity of the first windmill corresponds to the ambiguity of our body, something that is known in German as *Körper* (a physical living body) and *Leib* (a subjectively lived body) (Thompson 2007: 231). The two aspects of our body are intimately related to changes of our body images. For example, a blind person's stick changes from a mere object (*Körper*) to a real hand (*Leib*) when he/she adapts to it. In our model, on the one hand, the first windmill is observed as a material thing in the world (by Agent 1), which means the first windmill is *Körper* at this time. On the other hand, the first windmill is used to perceive the second windmill (by Agent 2), which means the first windmill functions as *Leib* at this time.

From this point of view, we need to recast the "hard problem". Thompson recasts the explanatory gap between mental and physical as the *body-body problem*: the problem of relating one's subjectively lived body to the organism or living body that one is (Thompson 2007: 244).

Moreover, we are extending the current model to study communications between two agents by introducing one more agent instead of the second windmill. The two agents interact with each other through the first windmill and discriminate each other's neural state. The agents convey and receive messages. At this time the windmill functions as their interface or some kind of "language". Also, these agents eventually conform their neural states with each other. We think this is a kind of primitive communication (empathy or imitation).

In this way we could understand the course of humankind's mental development from active perception to extension of body images, and to inter-subjective communication by extending our windmill model further. We will also employ our model for robot learning by using a servo motor.

# Quantifying Evolutionary Dynamics of Swarm Chemistry

Hiroki Sayama<sup>1</sup> and Chun Wong<sup>1</sup>

<sup>1</sup> Binghamton University, State University of New York  
sayama@binghamton.edu

This paper reports our recent efforts to quantitatively characterize the evolutionary dynamics of self-organizing patterns observed in Swarm Chemistry.

Swarm Chemistry (Sayama 2009) is an artificial chemistry framework that can demonstrate self-organization of dynamic patterns of kinetically interacting heterogeneous particles. A swarm population in Swarm Chemistry consists of a number of simple self-propelled particles moving in a two-dimensional continuous space. Each particle can perceive average positions and velocities of other particles within its local perception range, and change its velocity in discrete time steps according to kinetic rules similar to those of Reynolds' Boids (Reynolds 1987). Each particle is assigned with its own kinetic parameter settings (similar to genotype) that specify preferred speed, local perception range, and strength of each kinetic rule. Particles that share the same set of kinetic parameter settings are considered of the same type. Several model extensions introduced in our recent work, including local information transmission among particles and their stochastic differentiation/re-differentiation, have made the model capable of showing morphogenesis and self-repair (Sayama 2010) and autonomous ecological/evolutionary behaviors of self-organized "super-organisms" made of a number of swarming particles (Sayama 2011; see Fig. 1).

Figure 1. Typical evolutionary processes emerging in Evolutionary Swarm Chemistry (taken from (Sayama 2011)). Time flows from left to right. Four cases with different initial conditions are shown.

Our latest results (Sayama 2011) produced a hypothesis that the introduction of a high volume of mutations and dynamic exogenous perturbations helps a swarm population to break an established status quo and demonstrate more continuous evo-

lutionary exploration. However, the experimental results were evaluated so far by visual inspection only, with no objective measurements involved, and hence the hypothesis was not tested in a quantitative way.

To address the lack of quantitative measurements, we developed and tested two simple measurements to quantify the degrees of evolutionary exploration and macroscopic structuredness of swarm populations. These measurements were designed so that they can be easily calculated *a posteriori* from a sequence of snapshots (bitmap images) taken in past simulation runs, without requiring genotypic or genealogical information that was typically assumed available in other proposed metrics (Bedau and Packard 1992; Bedau and Brown 1999; Nehaniv 2000).

Evolutionary exploration was quantified by counting the number of new RGB colors that appeared in a bitmap image of the simulation snapshot at a specific time point for the first time during each simulation run. Since different particle types are visualized with different colors in Swarm Chemistry, this measurement roughly represents how many new particle types emerged during the last time segment.

Macroscopic structuredness was quantified by measuring a Kullback-Leibler divergence (Kullback & Leibler 1951) of a pairwise particle distance distribution from that of a theoretical case where particles are randomly and homogeneously spread over the entire space. Specifically, each snapshot bitmap image was first analyzed and converted into a list of coordinates (each representing the position of a particle, or a colored pixel), then a pair of coordinates were randomly sampled from the list 100,000 times to generate an approximate pairwise particle distance distribution in the bitmap image. The Kullback-Leibler divergence of the approximate distance distribution from the homogeneous case is larger when the swarm is distributed in a less homogeneous manner, forming macroscopic structures.

We first applied these measurements to two experimental conditions studied before (Sayama 2011): one with low mutation rates and static environments, called "original-low", and the other with high mutation rates and dynamical exogenous perturbations, called "original-high". Results are summarized in Figs. 2, 3 and 4 (marked by circles and squares, respectively). Figure 2 clearly shows the high evolutionary exploration occurring in the "original-high" condition, supporting our hypothesis quantitatively (but the exploratory dynamics generally decline over time). However, Figure 3 shows a downside of the "original-high" condition that it tends to destroy macroscopic structures by allowing swarms to evolve toward simpler, homogeneous forms.

A possible reason for this degradation of structuredness over time was already indicated in (Sayama 2011). Namely, the previous implementation of collision detection in Swarm Chemistry mistakenly depended on perception ranges of particles, so if a perception range of a particle evolves close to

zero, its kinetic properties will no longer change through interaction with other particles, and therefore the near-zero perception range worked as an artificial genotypic attractor.

We fixed this problem by implementing a minor modification to the collision detection rule so that a non-zero collision distance is always maintained. We call these conditions “revised- $\ast$ ” (where  $\ast$  is either “low” or “high”). The effect of this modification on evolutionary dynamics was measured by running a new set of simulations and then applying the proposed measurements to them. Results are marked by diamonds and triangles in Figs. 2, 3 and 4, which quantitatively showed that the “revised-high” condition successfully maintained macroscopic structures at the minor cost of evolutionary exploration.

This work was supported in part by the Binghamton University EvoS Small Grant (FY 2011).

Figure 2. Temporal changes of the evolutionary exploration measurement (i.e., number of new colors per 500 time steps) for four different experimental conditions, calculated from snapshots of simulation runs taken at 500 time step intervals. Each curve shows the average result over 12 simulation runs (3 independent runs  $\times$  4 different initial conditions given in (Sayama 2011)). Sharp spikes seen in “high” conditions were due to dynamic exogenous perturbations.

Figure 3. Temporal changes of the macroscopic structuredness measurement (i.e., Kullback-Leibler divergence of the pairwise particle distance distribution from that of a purely random case) for four different experimental conditions, calculated from snapshots of simulation runs taken at 500 time step intervals. Each curve shows the average result over 12 simulation runs (3 independent runs  $\times$  4 different initial conditions). The “original-high” condition loses macroscopic structures while other conditions successfully maintain them.

Figure 4. Evolutionary exploration and macroscopic structuredness averaged over  $t = 10,000 \sim 30,000$  for each independent simulation run. Each marker represents a data point taken from a single simulation run. It is clearly observed that the “revised-high” condition most successfully achieved high evolutionary exploration without losing macroscopic structuredness.

# Learning by seeing—associative learning of visual features through mental simulation of observed action

## Abstract

Internal representations employed in cognitive tasks have to be embodied. The flexible use of such grounded models allows for higher-level function like planning ahead, cooperation and communication. But at the same time this flexibility presupposes that the utilized internal models are interrelating multiple modalities. In this article we present how an internal body model serving motor control tasks can be recruited for learning to recognize movements performed by another agent. We show that—as the movements are governed by an equal underlying internal model—it is sufficient to observe the other agent performing a series of movements and that there is no supervised learning necessary, i.e. the learning agent does not require access to the performing agents postural information (joint configurations). Instead, through the shared underlying dynamics the mapping can be bootstrapped by the observing agent from the sequence of visual input features.

## Introduction

Internal representation are essential in higher-level cognitive tasks. Following the view of embodied cognition internal models have to be grounded and are therefore nowadays assumed to be directly linked to the action-perception-cycle. Grounded models appear to be a byproduct which originally served a quite specific action and co-evolved in this context (Steels, 2003). But on a later-stage cognition has taken over and the same models could be applied in a more flexible way outside the original context of the grounding action. An example are targeted movements which can be found even in quite simple lifeforms as are insect. Nonetheless, making a targeted movement presupposes an internal model allowing to choose the correct muscle activation to reach a target which was perceived before in a three dimensional space. The ability to use this model not only in the context of one specific type of movements, but to also use the incorporated knowledge—i.e. how muscle activations and target positions are related—in a broader context appears to be essential for cognition. It is assumed that internal simulation is a key mechanism to recruit internal models for high level tasks (Hesslow, 2002). Planning ahead can be understood in this way as using only the internal representation decoupled

from the represented body to simulate behaviors and predict their consequences. This allows to try out possibly hazardous actions and to evaluate possible alternatives or slight modifications. Findings from diverse fields as neuroscience, psychology and behavioral sciences have contributed over the last years and shaped this view (Jeannerod, 2006). It is now more and more apparent that such a mechanism is at the core of cognition, but also subserves—and is grounded in—action and perception. Perception seems to be shaped by the encoded knowledge and when perceiving others performing actions it seems that internal models of the own body are used (Schacter et al., 2007). Perception tries to fit the perceived input to the representation grounded in motor control to make sense of what is perceived in the sense of the language of the own motor system. This becomes of course even more important in cooperation or communication as different roles between different subjects require different representations of what is going on.

A central issue is the multimodal nature of the underlying representational system. It appears that our conceptual system is—besides organizing concepts—binding diverse sets of features from different modalities and on different levels of abstraction. But how is it possible to come up with these connections and interrelate multiple modalities? In this paper, we want to address how associations between an internal body model used for motor control and visual representations can be established in an unsupervised way, i.e. only through observing another agent performing body movements an observing agent can come up with a mapping of the perceived visual features onto its own body model representation (segment orientations). As an example we use a three segmented arm and will first introduce a neural network which allows for motor control and makes targeted movement. In the third section we will explain how this body model can be incorporated into the perception loop and how it can subserve perception as it provides predictions of the movement and helps to disambiguate or filter noisy input. Even though only visual input is accessible when observing another agent performing movements, we afterwards show in principle that it is possible to come up

Figure 1: Graphic representation of a three segmented arm, consisting of upper arm ( $L_1$ ), lower arm ( $L_2$ ) and hand ( $L_3$ ). Vector  $R$  points to the position of the end effector (tip of the hand).  $D_1$  and  $D_2$  describe additional diagonal vectors. The arm is restricted to work in a plane (coronal plane).

with a mapping from the visual features to ones own motor system. The shared governing dynamics are enough to allow bootstrapping this mapping from the sequence of visual features. First results from computer simulations will be presented indicating that this mapping can be established quickly.

### MMC Networks as a Body Model

Mean of Multiple Computation networks are a type of recurrent neural networks (Cruse and Steinkühler, 1993; Steinkühler and Cruse, 1998). They are based on the Mean of Multiple Computation (MMC) principle which is allowing to use known constraints to set up the network instead of training the weights. In principle the constraints are given as equations which form the attractor space. The network is in this way similar to a self-organizing map as the constraints are enforced on any input given to the network. MMC networks have been used in the past for diverse kinematic tasks and we will use a simple example from this domain for explaining the principle. The general approach will be illustrated using a three segmented arm which can be moved around in a plane. The orientation of each segment is described as a two dimensional vector for illustrative purposes. A joint angle representation can be used as is applied usually in robotics and the approach has been extended to three dimensional movements (Schilling, 2011), for describing movement dynamics (Schilling, 2009) and a hierarchical organization in order to represent complex structures has been introduced (Schilling and Cruse, 2007). It is important to note that even though the task used here is quite simple, it is so complex that an analytical solution is not feasible as there are more degrees of freedom to be controlled as there are in the target space (Bernstein, 1967). The arm is redundant. Therefore, even in this simple example all the demanding characteristics are present we are facing in the control of complex movements, e.g. of a robotic or a human arm.

The manipulator is shown in fig. 1. Kinematic equations

Figure 2: The MMC network consists of two identical networks, one for the x-components (black lines) and one for the y-components (grey lines) of the vectors. The units represent the components of the six vectors  $L_1$ ,  $L_2$ ,  $L_3$ ,  $D_1$ ,  $D_2$  and  $R$  of the planar arm. Connections with a positive weight are indicated by a black arrowhead and negative weights are shown as black dots. All connections are bidirectional. The example equation  $x^{D_1} = x^{L_1} + x^{L_2}$  is shown on the right: connections between the three nodes on the right encode all the equations derived, e.g.  $x^{L_1}$  is given through  $x^{D_1}$  and the negative value of  $x^{L_2}$ .

describing the arm can be easily set up. The main idea of the MMC approach is to not compile the kinematic relations into one single equation, e.g. representing the end position of the arm, but to establish a set of local relationships capturing the redundancy of the arm. As illustrated in the figure, additional diagonal vectors are introduced. A local relationship then corresponds to a triangle formed by three vectors, e.g. the first two segments and the first diagonal constitute such a triangle. As each triangle establishes a closed polygon chain, these relationships can be expressed as an equation, e.g. for the example above we will get  $x^{D_1} = x^{L_1} + x^{L_2}$ . (and an analogous equation for the y-component) Overall a set of equations can be compiled following this approach when all possible triangle relationships are constructed. Each vector variable is taking part in multiple of these equations. In the next step for setting up the network, for each variable all equations containing that variable are solved with respect to that variable. In our example, the first segment is contained in one additional equation. Solving these two equations for the first segment variable we get:

$$\begin{aligned} x^{L_1} &= x^R - x^{D_2} \\ x^{L_1} &= x^{D_1} - x^{L_2} \end{aligned} \quad (1)$$

Following the Mean of Multiple Computation principle these multiple computations for one variable are integrated through calculating the Mean value. In order to restrain that abrupt and fast changes in one equation affect the whole process, usually as an additional term the weighted old value is included into the mean computation which introduces a sort of damping (Makarov et al., 2008). As a result in our exam-

Figure 3: Application of the network to solve kinematic tasks. Initially, the network is in a stable state reflecting the current configuration of the arm (see Fig. 1). In a) it is shown how the net solves the forward kinematic task, i.e. when the segment orientations are known the end effector position can be computed. In b) the application for solving the inverse kinematic task is shown. A target position is given as input to the network and the network adjusts the segment vectors accordingly. If an input is given, the corresponding recurrent channels are suppressed (symbolised by the open arrow heads).

ple this leads to

$$x^{L_1}(t+1) = \frac{1}{d}(x^R(t) - x^{D_2}(t)) + \frac{1}{d}(x^{D_1}(t) - x^{L_2}(t)) + \frac{d-2}{d}x^{L_1}(t) \quad (2)$$

This set of equations describe the relations between the variables and can be understood as defining the connections of a neural network. The network is shown in fig. 2. As the resulting network is a recurrent neural net, the activation of the network is developing over time in which the state of the network can be calculated in an iterative fashion. The encoded constraints enforce this behaviour and the attractor space reflects states fulfilling all the kinematic equations. Obviously, when we give a valid configuration of the arm to the network all constraints are met and the network is in a stable state (Steinkühler and Cruse, 1998). The interesting cases are the cases in which we only provide partial information. Acting like a self-organising map the MMC net completes the given input pattern into a corresponding activation of the whole network which matches the requirements. In this way the net is able to solve any kinematic problem.

The forward kinematic problem can be solved straightforward. As an input the segment vectors are fed into the network (fig. 3 a). The corresponding diagonal and end-effector vectors are approached in a few time steps (depending on the damping factor, i.e. the weight of the recurrent connection). Importantly, the input to the network is given to the network the whole time and is directly setting the input variables.

For the inverse kinematic task, we only give as an input the desired end-effector position to the network (shown in fig. 3 b) after initialising the network with a valid starting

Figure 4: Solution of the inverse kinematic problem through the linear MMC model. A planar arm with three segments (i.e., one extra DoF) should point to a given position, marked by a cross, starting from an initial configuration. The state of the arm for every second iteration step is shown.

configuration. Through enforcing the new end effector value onto the network, a disturbance is introduced and the network is not in an attractor state anymore. But over time this activity is spread to all variables. The encoded kinematic constraints enforce that the network settles back on its solution space. The network relaxes to a stable state in which the target end effector value still holds true and the other variables have adopted corresponding values. As an example, we show in figure 4 an example run of the network. Initially, the arm is fully stretched to the right (bright line, end effector position  $x = 0.3, y = 0$ , with all segments having an equal length of 0.1 units). For every second iteration step the current configuration of the arm is shown (dashed grey line), until the 25th iteration in which the arm has reached the target position ( $x = 0, y = 0.2$ , drawn as a solid dark line).

As can be seen in this example—and as has been shown in the past (Steinkühler and Cruse, 1998)—the MMC network is able to solve the inverse kinematic task in only a few iteration steps. We presented the linear MMC network above which has one serious drawback as it allows the variables to change freely. There is no cross connection between the  $x$  and the  $y$  component of the networks. As the  $x$  and  $y$  components of the variables can be modified independently the length of the vectors can change. This is usually unwanted and problematic for the segment variables which should stay of constant length. This problem can be easily solved through a normalisation step. Even though this introduces non-linearities into our network this does not disrupt the overall performance (Steinkühler and Cruse, 1998). In this article we will apply such a normalisation step on the MMC segment variables (not shown in the diagrams) after each iteration step which could be totally circumvented when using other representations like a joint angle represen-

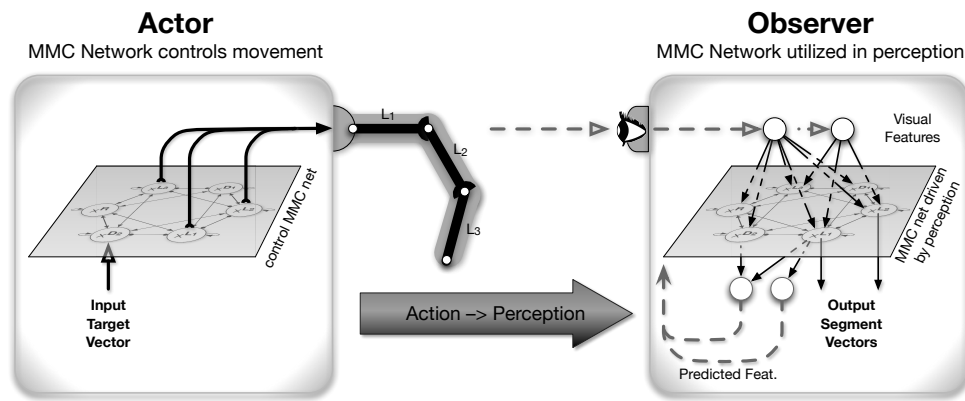

Figure 5: Application of the internal model in action (shown on the left) and perception (right). The internal model is used in one agent for motor control. Given a target vector as input it comes up with a movement to the target. On the other side, an equal internal model is utilized in another agent during perception. The embedded dynamics of movements allow to establish a connection from visual features to body postures and to recognize postures of another actor when seeing them.

tation(Schilling, 2011).

A property one immediately recognises when looking at the behaviour of the network is that the arm is moved in the beginning very fast and later-on dramatically slows down. The distance to the target decreases exponentially. Biological movements, e.g. human arm movements, are characterised by very different properties (Morasso, 1981). Again, we introduced MMC networks in the past which incorporate dynamic influences and which nicely fit to experimental data for human reaching movements (Schilling, 2009).

### Application of the Body Model in Perception

Internal models are used in motor control, e.g. in reaching tasks inverse models transform target points into joint positions or muscle activation. The introduced MMC network implements such an internal model of the own body and allows for making targeted movements. But the same internal models have been found active in other tasks, e.g. perception, planning ahead or communication (Grush, 2004). It appears that internal models are recruited by these other function. While in this way the utilized internal model is grounded in action, it remains unclear how it can be connected to seemingly quite different tasks. As we want to show in this paper, the underlying organisation of the body model is providing enough structure (in time) to allow for establishing such connections. We are focussing on the use of an internal body model in perception of movements. A key question is how humans and even simple animals are able to recognize and understand movements of conspecifics. It has been pointed out that mapping an observed behaviour to ones own body model is essential (Decety and Grezes, 1999). But how can this mapping be established? We want to analyse this relation between perception and motor control through applying our simple body model in perception. As during this learning one has only access to the resulting

perceived visual input, the learning has to take place in an unsupervised manner. Therefore, the acquisition of such a mapping from seeing someone moving around to ones own movement systems seems quite difficult if not intractable. The main idea in our approach is that the introduction of the body model into the processing chain of perception dramatically simplifies the acquisition of a mapping. Both processes share the underlying body model in our setting and in this way the dynamic development of both processes is constrained in the same way. We want to show that this is enough to come up with a mapping and how this simplifies finding the mapping.

In figure 5 it is shown how the two models are connected and how they are incorporated into their respective system. On the left side, an acting agent is shown. Here the internal MMC network model is used in the same way as explained in the preceding section. A target value is set as an input to the model. The network is approaching a solution and at the same time moves the connected arm. The movement of the arm is perceived by the observing agent on the right sight. In a preprocessing step characteristic visual features are extracted from the visual image. The aim is to correlate the visual features with assumed body configuration. This has to be done in an unsupervised fashion as only the evolving visual features are available and the observer has no information on the segment vectors (only in the initial situation in which a resting position is assumed). But the observing agent can exploit its knowledge about the dynamics of the unknown segment vectors as this dynamics are shared between both agents and are encoded in the body model. The general idea is that the observing agent tries to hook the body model up to the visual features and close the loop in trying to predict the visual features. The underlying assumption is that the predicted change of the visual features can only be correctly produced by the dynamics of the observer's body

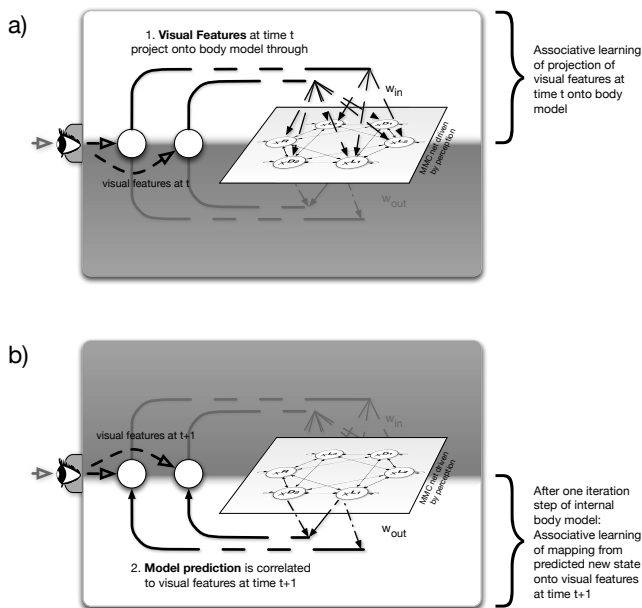

Figure 6: Steps when applying the internal body model in perception and how this allows for learning associations to visual features. At first (in a) visual features are associated towards the current body model activation. After one processing step of the body model connections back to perception are learnt which associate the new predicted values of the body model with the updated visual features. Initially the connections are random and only by accident correlations will occur. These will be strengthened over time and mappings between the two spaces evolve.

model when it is in a similar state as the actor's body model. We want to test this assumption for our simple model and in addition how easily this then allows to bootstrap the connection to visual features from the body model.

The internal model in the observer is used as a predictor. It can be regarded as a hidden mediating layer of a neural network linked to the visual features. The input layer are the visual features at a certain time  $t$  and the task would be to learn projections from these visual features to the body model (fig. 6 a). After one time-step in the mediating body model layer the activations of the body model should be routed back to the visual features which have new values now for time  $t + 1$ . This mapping should also be learnt (fig. 6 b) and as we only have access to the visual features—given as input and output—both mappings have to be learnt at the same time. The basic idea is that this is possible and that the correlation of the sequence of observed features is correlated with the body model dynamics. Hebbian-type learning should be sufficient to identify the associations and establish the mapping (Hebb, 1949). Figure 7 shows a different perspective on the whole network. The network is spread out

Figure 7: Schematic sketch of the network architecture used for learning the input and output mapping between visual features and body model. The recurrent connections of the hidden layer are fixed and setup as a MMC network. As the network shall be used in the same mode as when used for motor control the target vector  $R$  (right) corresponds to the predicted target position estimated from the known dynamics of the network.

into a three layer neural network. The input layer is given through the visual features at a certain point in time  $t$ . The body model constitutes the middle layer. As the dynamics of the two models are essential for establishing a coupling, this network must be driven in the same way as the original network. Therefore, the  $R$  vector (shaded in the figure) does not represent the current end effector position, but the target position of a movement. This is unknown to the network and the network can only observe the current state, but incorporating knowledge about the known dynamics the end state can be easily estimated (see (Schilling, 2009)). The weights are predetermined for the hidden layer as it represents the MMC network, but the activation of this layer is hidden during learning. The output layer represents the predicted output for one timestep later ( $t + 1$ ). Here we have simplified the view on the overall architecture as we are introducing this output level for representing the visual features at time  $t + 1$ . The back projection on the visual features in the overall framework is more complex as the function of these connections depend on the context. In perception the body model is not supposed to re-activate the visual features in general. But in specific cases it would be an advantage to use the prediction, e.g. when part of the movement can not be observed (the arm might move behind an object and is occluded for a short time). Therefore, it must be possible to use this connections in different ways depending on the context and inhibit their reactivation during perception. During learning these connections are essential for correlating the predicted state of the body model to the new visual features. Introducing these new visual features as separate units in an output layer allows us to come up with the simple general structure shown in fig. 7 and to use standard backpropagation-through-time learning (Rumelhart et al., 1986) to learn the two weight matrices at the same time. The feature values from one time step ahead can in this way be used as the target output values.

In a preprocessing stage visual features are extracted from

the perceived image of the arm. We use visual image moments. Image moments (Mukundan and Ramakrishnan, 1998) reflect characteristics of a foreground object in a given image. They capture the statistical regularities of the object pixel and describe in this way shape properties of the foreground object, e.g. size, orientation. The main advantages of image moments are that they provide a descriptive representation and at the same time are inexpensive to compute. They can be easily calculated from a binary pixel-based image with the intensity function  $I(x, y)$  where all object pixels are represented as a one and all other pixel have a value of zero:

$$M_{pq} = \sum_x \sum_y x^p y^q I(x, y) \quad (3)$$

Usually a set of image moments of different orders is used with the order of an image moment given as the sum of the two exponents  $p$  and  $q$  used in the equation above. The zeroth order moment is a count of the object pixel and from the first order image moments one can derive the visual center of gravity (COG, the centroid  $\bar{x}, \bar{y}$  of the object):

$$\bar{x} = \frac{M_{10}}{M_{00}}, \bar{y} = \frac{M_{01}}{M_{00}} \quad (4)$$

Higher order moments allow to compute orientation and shape properties of the object shown in the image.

We are only using the centroid information in our simulations. Using higher order image moments would of course allow for a better reconstruction of the visual image. But the focus of our work is on how the body model contributes to recognizing and tracking the seen arm. Relying only on insufficient information emphasizes the contribution of the body model.

The centroid information can be directly calculated from the segment vectors of the moving arm. The overall center of gravity is constituted as the mean of the individual segment visual COG (we assume uniform length and width of segments). The equations describing the segment COGs can be integrated through calculating the mean value:

$$\bar{x}^{ges} = \frac{1}{3}(\bar{x}^{L1} + \bar{x}^{L2} + \bar{x}^{L3}) \quad (5)$$

## Results

We want to mainly focus on the qualitative result that the network is able to establish input and output connections in a way that both networks activities are coupled. We used a simple back-propagation learning rule on a set of initially random weights. Back-propagation is known for depending on the initial configuration and converging onto local minima, therefore we started a series of simulations for different initial weights covering the whole space of weights. While in many simulations the network converged, it was not sufficiently able to predict the next visual features at all. The

Figure 8: Shown is the initial configuration of the three segmented arm as solid black lines. The 12 targets are shown as white crosses.

network got stuck in a local minima. In these cases a constant value was returned or simply the input value. In the following we want to concentrate on the other simulations which were able to successfully predict the next visual features and want to look what the internal model was doing during predicting sequences. In general, the behaviour of all these networks was similar and in the following we use one example simulation series.

The network was trained from an initial arm configuration (shown in fig. 8 with all 12 targets). Both, the moving arm and the perceiving arm were initialised in this configuration, this means we assume for the simulations that there is a certain resting posture from which all movements start. There are 12 targets around this resting posture and we selected 9 for training and 3 later for testing on generalisation. The input and the output network (fig. 7) were then set to initial values. The perception network was trained on the visual data which resulted from the movement controlled by the movement network (see equation 5): a target was given to the movement network and the visual data before doing one iteration step in the movement control network was used as an input to the perception network. The visual features of the arm after the iteration step of the control network had been carried out was then used as the target value for the perception network which should learn to predict this value from the visual input. A movement lasted 15 iteration steps and the network was trained on a random order of the 9 training targets for 250 epochs (as mentioned above, the weights are not completely random, as we only cover a subset of the whole weight space here, see also discussion). The arm did not reach the target during the 15 iteration steps, but as the movement of the classical MMC is slowing down at the end, we only used the part of the movement containing rich dynamics, i.e. the arm is still considerably moving.

In fig. 9 a movement to an example target is shown for both arms. The body model used in the perception loop is following the leading moving arm. Both networks are in good agreement and synchronized. One advantage of the presented approach is that it extends also to movements not shown before as underlying knowledge about kinematics and body constraints is incorporated in the perception process. Figure 10 shows the behavior of the perception model

Movement of the arm towards (0, 0.3)

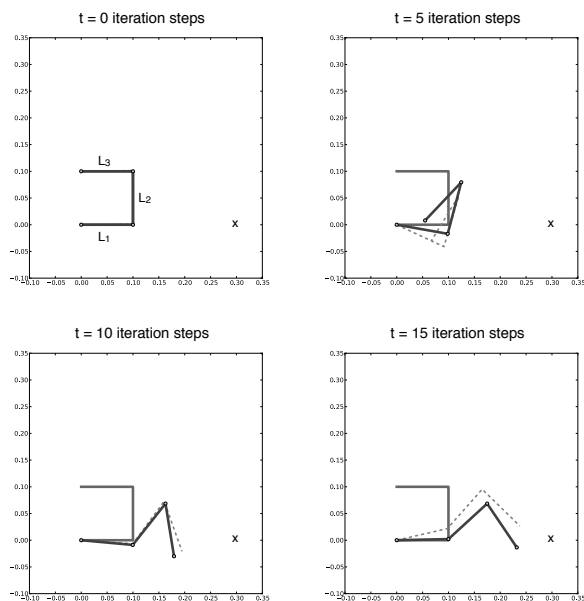

Figure 9: An example of the perceived arm movement. Course of time is going from left to right, top to down. Shown are snapshots of iteration 0, 5, 10 and 15. In the first figure at the left, top the initial configuration is shown in light gray. The moving arm is shown as a dashed line and the current state of the MMC model used for perception is represented as the dark grey line.

when the moving arm is approaching a novel target.

There was no observable difference between targets used for training and novel targets. During each test run the moving arm reached out during a period of 15 iteration steps towards one target from the initial configuration. We are not interested in finally reaching the target as during the last part of the movement the arm is only moving slowly for the classic MMC approach and the interesting part for our comparison is the comparison for the more dynamic starting phase. In general, the two networks converged for the final part of the movement to their respective endpoints. The observing network adopted in all cases a qualitatively similar configuration (as shown in the example, i.e. the segments of both networks are orientated in a similar way). We compared the differences of the single segment orientations to evaluate differences in configurations of the networks states. The difference angle for the segment orientations of the perceived arm and the moving arm were computed for each segment. The mean difference overall segments was 0.125 rad (standard deviation  $\pm 0.396$  rad). Mostly differences of the last segments were responsible for the high variation. This can be explained by the fact that the orientations of the first segment is weighted very high in the computation of the visual features.

## Discussion

We have shown first results indicating that sharing a common principle organizing movement dynamics is sufficient to bootstrap associations from the internal control network to visual features. After successful learning, the body model is coordinated with the motor control network solely through the simple visual features which in themselves would not be sufficient to estimate the manipulator configuration. Until now the simulation results are a first step providing a qualitative finding and the high variation is also a result of the simple visual features used to describe the postures.

One problem with the presented approach is that the simple back-propagation learning method on its own is not able to converge as the method depends on the initial configuration. Therefore, we started a series of simulations with different initial weight configurations (only for the input weights) covering large parts of the weight matrix space. To test that—in the successful cases—the success was not already predetermined through the selection of a suitable weight matrix, we tested the impact of the input network. Even in a supervised case it was not possible to learn the projections of the visual features onto the manipulator variables. The visual features in themselves do not carry enough information to predict the manipulator state. Therefore, the success of the network seems not given through the input transformation, but depends on the interplay between all the parts. In the future, we want to extend our approach and apply a more powerful learning algorithm (like a least-square method) which is able to overcome local minima and does not depend on the initial weight configuration. In addition, we want to perform a correlational analysis of the resulting weight matrices.

Other approaches to learn internal models of the body usually apply a supervised learning method. A nice example is the learning of a visual body model by Spranger (Steels and Spranger, 2008) in which a robot performs actions in front of a mirror and starts learning to associate the proprioceptive features to the observed visual features. Hoffmann et al. (2010) gives a thorough review about other approaches along the same line and on the integration of other modalities into the body schema in robots.

In the future, we will apply our approach in a real world robot scenario in which a robot is at first learning to recognize what another robot is doing when both apply their internal MMC-type body model. The task shall be implemented as a communicative scenario and in a second step a group of robots shall come up with a shared conceptualization of body postures through performing short interactions (language games (Steels and Belpaeme, 2005)). Besides additional preprocessing steps this would require to incorporate more descriptive visual features as are higher level centralized visual moments. The implementation on the robots is done in cooperation with the CSL group (Luc Steels, Paris). In the final system, each agent would have de-

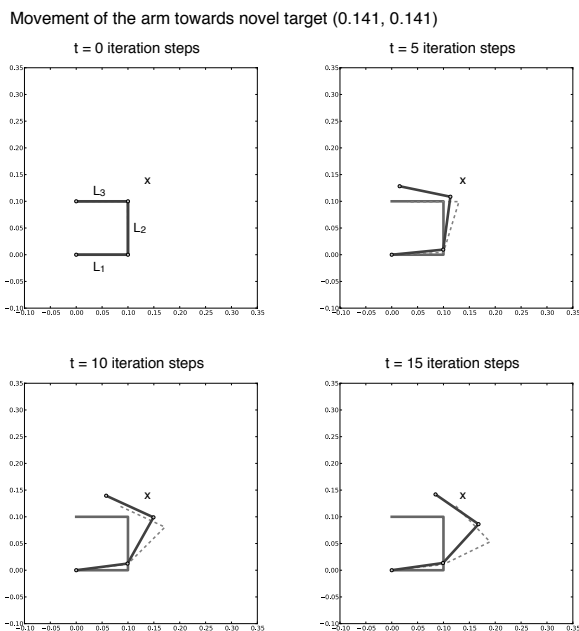

Figure 10: Movement to a novel target. Course of time is going from left to right in two rows. Shown are snapshots of iteration 0, 5, 10 and 15. The moving arm is shown as a dashed line and the current state of the MMC model used for perception is represented as the dark grey line.

veloped a conceptual space from a simple grounded internal representation of the own body which is now multimodal in its nature. Therefore, this internal model and the mapping onto visual features allow to be utilized in perceiving others making movements and coming up with conventional—and in a population agreed on—symbols. This would open the door for a simple form of communication and cooperation inside the rules given through the language game.

## Abstract

We present a developmental model to simulate swimming digital organisms following an animat's cell doctrine. Morphology and control are encoded in one genome concurrently using artificial cells as the basic building blocks for both. Each individual starts with one cell in the middle of a computational environment, and its development is controlled by a gene regulatory network. The cells can differentiate into central pattern generators that control the movements of the resulting individual. After the developmental process, the individual is placed into a physics simulation environment and the distance it swims in a defined time is evaluated. Contrary to most existing models, one genome for both, morphology and control is used and the CPGs representing the dynamic control contribute to the morphology of the organism.

## Introduction

Following the work of Matthias Jakob Schleiden on plant tissues, Theodor Schwann postulated in 1839 that the tissue of all living organisms is made up of individual cells. At first this excluded the nervous system, which was later rectified by the seminal neuro-anatomical work of Ramón y Cajal and others. This principal concept is known as the cell or the neuron doctrine of biology.

In biology, the cell doctrine (including the nervous system) is an integral part of the evolution, development and operation of all living organisms. The cell as the carrier of the hereditary information is not just the basic functional unit of organisms, it is also the basic unit for the evolutionary process. Turning this argument around, we can hypothesize that the direction of the evolutionary process and its diverse results are a consequence of the cell doctrine. More strongly, evolution would have not been successful<sup>1</sup> without the cell as its basic unit. We also note that most of the evolutionary history has been devoted to single cell organisms rather than to multicellular ones.

<sup>1</sup>What does it mean, evolution being successful? To circumvent a philosophical discussion, we will resort to an artificial life perspective, equating success with progress in the criterion chosen for the process.

In artificial life, biological paradigms are frequently sought to facilitate the development of digital organisms or animats. The purpose of this paper is to outline a model that allows the simulation of digital organisms based on basic cell-like units, thus paving the way to an animat's cell doctrine including the nervous system or in more abstract terms the control system of the animat.

Since the seminal work of Karl Sims (Sims, 1994) the co-evolution of the morphology (=body) and the control systems (=brain) of digital organisms has received continuous attention. In Sim's work a developmental model using a directed graph has been used for both neural controller and body plan. The role of the morphology to reach a certain functionality has also been discussed in robotics. The passive walker (McGeer, 1990) demonstrated convincingly how the specific mechanical configuration alone can lead to a walking behavior that closely resembles the one we observe in humans without complex control algorithms. However, not least due to the mechanical difficulties the body is mainly unchanged in most evolutionary or developmental robotics approaches. Evolving the developmental steps of a controller in a static morphology has no justification and its limitations have been recognized, see e.g. (Pfeifer et al., 2007). Although some advances have been made using mechanical cell blocks to enable a changing morphology, the mechanical restrictions are still fundamental (Murata and Kurokawa, 2007; Meng et al., 2011).

In the digital world, we face much fewer restrictions and it is possible to simulate completely cell based animats, see e.g. (Schramm et al., 2009). Several computer models for brain-body co-evolution have been proposed in the literature, see e.g. (Hornby and Pollack, 2001; Miconi and Channon, 2006; Spector et al., 2007). However, models have either been detailed with regard to neural development (Kitano, 1995) or with the development of the morphology (Andersen et al., 2009; Eggenberger Hotz et al., 2003). Using a more abstract representation for the body morphology, Jones et al. (2011, 2008) analyzed the effects of the body plan on neural organization using energy constraints. Bongard and Paul (2000) studied the correlation between morphological

symmetry and locomotive efficiency using a direct encoding. The advantage of being able to evolve a bilaterally symmetric body plan or neural controller has been reported independently in (Mazzapioda et al., 2009; Oros et al., 2009). Bongard (2003) uses a gene regulatory model to develop locomoting animats or animats that should grow to touch an object.

A number of computational models have been developed to model biological gene regulatory networks (see e.g. the review of de Jong (2002)). Artificial embryogeny simulates biological cellular growth and pattern formation starting with one single cell (Andersen et al., 2009; Eggenberger Hotz et al., 2003; Harding and Banzhaf, 2008; Joachimczak and Wröbel, 2009; Doursat, 2009; Kowaliw et al., 2004). Steiner et al. (2008) evolved the structure and the parameters of a gene regulatory network for growing 3D cellular structures that are mechanically stable and lightweight. The model was refined in (Steiner et al., 2009) using cell polarization to represent more complex inner structures. Stanley and Miikkulainen (2003) develop a taxonomy for artificial embryogeny based on cell fate, targeting, heterochrony, canalization, and complexification.

In this contribution, we implement an animat’s cell doctrine by representing the whole body or morphology of the digital organism by cells some of which perform the control of the animat’s behavior. Therefore, the nervous system is an integral part of the morphology and the neurons are basic cells that differentiate during embryogeny assuming their specific neural functionality. Therefore, the system evolves the shape and the control of animats concurrently. Furthermore, the representations of shape and control are not separated, instead morphology and control are phenotypic characteristics of the artificial organisms that are the result of a common gene regulatory network that organizes the cellular growth of the animat. Indeed the separation between morphology and control becomes arbitrary even on the phenotypic level, because the cells that control the behavior also contribute to the morphology of the animat. This straightforwardly results from using artificial cells as the basic structural as well as functional components of our animat.

For the simulation of the cellular neural control we use central pattern generators (CPGs) which represent a higher level of abstraction compared to the spiking neural system employed in (Jin et al., 2008). CPGs facilitate the evolution of an oscillating movement, which makes it easier for the evolutionary process to develop the swimming behavior.

In the next section, we introduce CPGs in general and the specific CPG model used in this paper in greater detail. The following section is devoted to a description of our model of gene regulatory networks (GRNs) and how it is used to represent cellular growth. Thereafter, the physics simulation and the experiments are described followed by a discussion of the results. In the last section, the main findings of the paper are summarized and an outlook into future experiments

Figure 1: The model of a central pattern generator contains two neurons that interact with each other.

$k$	$\omega$	$\rho$	$\lambda$	$\sigma$
0.01	0.3	1	1	1

is presented.

## Central Pattern Generators (CPGs)

Many animals use coupled rhythmic muscle activations for movements. This movement is not controlled by the brain, but by coupled oscillators, the central pattern generators (CPG). It can be shown, that the pattern occurs also after the spinal cord has been separated from the brain (Murray, 2008).

Several models of CPGs exist, e.g. (Murray, 2008; Ijspeert and Kodjabachian, 1999; Verdaasdonk et al., 2006; Chung and Slotine, 2010; Beer, 2009), in general the CPG consists of two neurons which interact with each other, see Figure 1. The difficulty with most models is the stability of the output of many CPGs depending on their connections. The output of the CPGs should ideally be sinusoidal with phase shifts between the output signals of the different CPGs depending on their synapse connections and weights. Each CPG oscillates, they synchronize with other CPGs using their connections, so no global clock is used.

Chung and Slotine (2010) use coupled Hopf-Kuramoto oscillators and show their ability to synchronize almost globally. This model is used for the experiments presented in the following because of its good ability to synchronize. Therefore,  $\mathbf{x}_i(t) = (u_i(t), v_i(t))^T$  and the following equations are used:

$$\dot{\mathbf{x}}_i = \mathbf{f}(\mathbf{x}_i; \rho_i) - k \sum_{j \in \mathcal{N}_i}^{m_i} \left( \mathbf{x}_i - \frac{\rho_i}{\rho_j} \mathbf{R}(\phi_{ij}) \mathbf{x}_j \right) \quad (1)$$

and

$$\mathbf{f}(\mathbf{x}; \rho) = \begin{pmatrix} -\lambda/\rho^2 (u^2 + v^2 - \rho^2 \sigma) u - \omega(t)v \\ \omega(t)u - \lambda/\rho^2 (u^2 + v^2 - \rho^2 \sigma) v \end{pmatrix}. \quad (2)$$

The properties of the model for the simulations in this paper are described in Table 1.

Figure 2: An example chromosome for the development. The first gene (gene 0) starts at the first RU of the genome. Each SU-RU changeover defines a boundary between two genes.

## A Computational Model for the Development of Morphology and Control

The morphological development simulated in this work is under the control of a gene regulatory network (GRN) and physical cellular interactions. The morphological development starts with a single cell put in the center of a two-dimensional computational area of size  $100 \times 80$ . Each cell can die or divide. The cells are not fixed on a grid and underlie physical interactions, i.e. overlapping cells push each other away and cells that do not overlap attract each other with decreasing forces with larger distances.

The GRN is defined by a set of genes, each consisting of a number of regulatory units (RUs) and structural units (SUs). SUs define cellular behaviors, such as cell division, cell death or the production of transcription factors (TFs) for intra- and inter-cellular interactions. Whether the SUs of a gene are expressed is determined by the activity level of the RUs of the gene, refer to Fig. 2. Note that a single or multiple RUs may regulate the expression of a single or multiple SUs and that RUs can be activating ( $RU^+$ ) or repressive ( $RU^-$ ). The activation level of RUs is influenced by the TFs that can “bind” to the RU. If the difference between the affinity values of a TF and a RU is smaller than a predefined threshold  $\epsilon$  (in this work  $\epsilon$  is set to 0.2), the TF can bind to the RU to regulate the gene activation. The affinity values are encoded in the RUs and the SUs that produce a TF and are, as well as all values in the genome, limited to an interval of  $[0, 1]$ . The affinity similarity ( $\gamma_{ij}$ ) between the  $i$ -th TF and  $j$ -th RU is defined by:

$$\gamma_{i,j} = \max(\epsilon - |\text{aff}_i^{\text{TF}} - \text{aff}_j^{\text{RU}}|, 0). \quad (3)$$

If  $\gamma_{i,j}$  is greater than zero, then the concentration  $c_i$  of the  $i$ -th TF is checked whether it is above a threshold  $\vartheta_j$  defined in the  $j$ -th RU:

$$b_{i,j} = \begin{cases} \max(c_i - \vartheta_j, 0) & \text{if } \gamma_{i,j} > 0 \\ 0 & \text{otherwise} \end{cases}. \quad (4)$$

Thus, the activation level contributed by the  $j$ -th RU (de-

noted by  $a_j, j = 1, \dots, N$ ) can be calculated as follows:

$$a_j = \sum_{i=1}^M b_{i,j}, \quad (5)$$

where  $M$  is the number of TFs that bind to the  $j$ -th RU. Assume the  $k$ -th gene is regulated by  $N$  RUs, the expression level of the gene can be defined by

$$\alpha = g(c), \quad (6)$$

$$g_k(c) = 100 \sum_{j=1}^N l_j a_j (2s_j - 1), \quad s_j \in (0, 1). \quad (7)$$

$2s_j - 1$  denotes the sign (positive for activating and negative for repressive) of the  $j$ -th RU and  $l_j$  is a parameter representing the strength of the  $j$ -th RU. If  $\alpha_k > 0$ , then the  $k$ -th gene is activated ( $\delta_k = 1$ ) and its corresponding behaviors coded in the SUs are performed.

An SU that produces a TF ( $SU^{\text{TF}}$ ) also encodes all parameters related to the TF, such as the affinity value, the decay rate  $D_i^c$ , the diffusion rate  $D_i^f$ , as well as the amount of the  $TF_i$  to be produced. Which  $TF_i$  is produced is defined in terms of the affinity value.

$$\begin{aligned} \mathbf{A} &= \mathbf{h}(\alpha), \\ h_i(\alpha_k) &= \begin{cases} \beta \left( \frac{2}{1 + e^{-20 \cdot f \cdot \alpha_k}} - 1 \right) & \text{if } \alpha_k > 0 \\ 0 & \text{otherwise} \end{cases}, \end{aligned} \quad (8)$$

where  $f$  and  $\beta$  are both encoded in the  $SU^{\text{TF}}$ .

A TF produced by an SU can be partly internal and partly external. To determine how much of a produced TF is external, a percentage ( $p^{\text{ext}} \in (0, 1)$ ) is also encoded in the corresponding gene. Thus,  $\Delta c_i^{\text{ext}} = p^{\text{ext}} \cdot A_i$  is the amount of external TF to be produced and  $\Delta c_i^{\text{int}} = (1 - p^{\text{ext}}) \cdot A_i$  is that of the internal TF.

External TFs are put on four grid points around the center of the cell, which undergo first a diffusion and then a decay process. Note, that the external TFs are computed on a grid but the positions of the cells are continuous and therefore not limited to this grid. The internal TFs underlie only a decay process. All internal and external concentrations of TFs are limited to an interval of  $[0, 1]$ .

Figure 3 shows a block diagram of the main components of a GRN in one cell, describing the cell dynamics. The cell dynamics can become coupled through external transcription factors, which underlie a diffusion and decay process and are position dependent. The number of TFs involved in gene regulation of the cellular behaviors is defined by the genome and the parameters in the resulting GRN as well. The number of cells also changes during development, starting with one single cell and two external TFs. The maximum number of cells is limited to 700 cells for reducing computational cost. From a control system point of view, the developmental system is composed of a changing number of

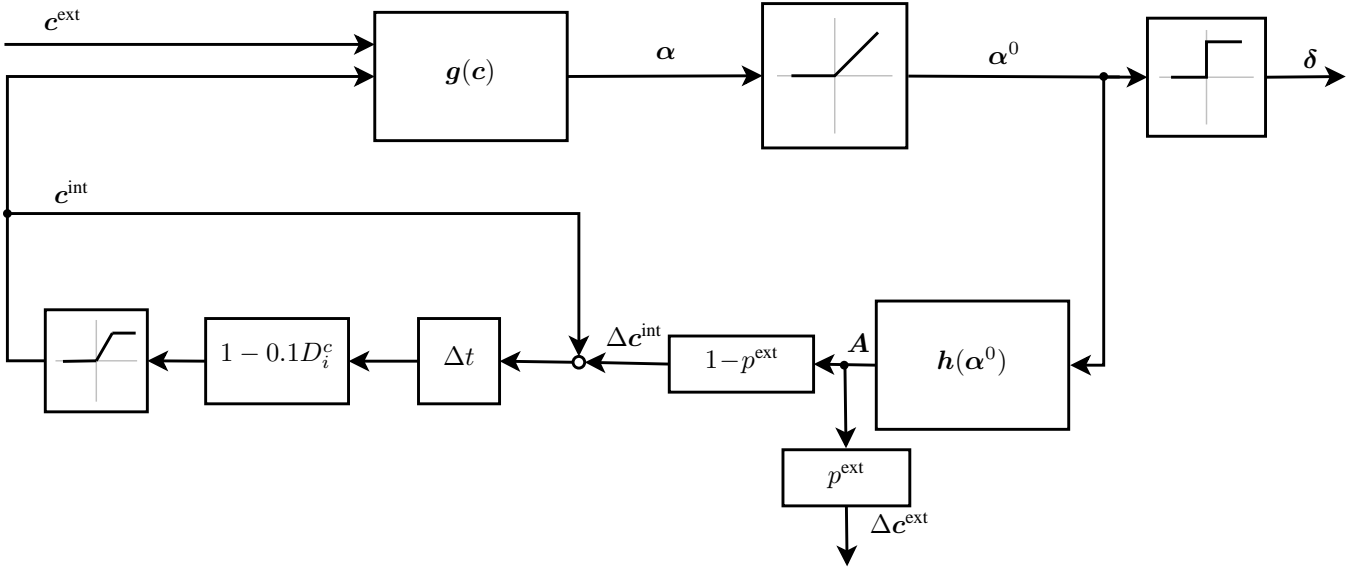

Figure 3: Block diagram of the model of a single cell.

nonlinear dynamical sub-systems with a changing number of system states, and the dynamics of the sub-systems are strongly coupled with each other.

In our experiments, we put two prediffused, external TFs without decay and diffusion in the computation area. The first TF has a constant gradient in the  $x$ -direction and the second in  $y$ -direction.

The SU for cell division ( $SU^{\text{div}}$ ) encodes the angle of division, indicating where the daughter cell is placed. A cell with an activated SU for cell death ( $SU^{\text{die}}$ ) dies at the developmental timestep it is activated. When both cell death and cell division are active at the same developmental step, only cell death is performed.

A cell with an active SU for neuron formation ( $SU^{\text{neuron}}$ ) becomes a CPG for the rest of its lifetime. All cells on the outside of the individual that are not CPGs at the end of the development are termed muscle cells. The threshold for whether the  $i$ -th CPG is to be connected to the  $j$ -th CPG is calculated as follows:

$$\varphi_{ij} = \frac{c_1}{1 + e^{c_2 \cdot (d_{ij} - 10c_3)}}, \quad (9)$$

where  $d_{ij}$  is the distance between the  $i$ -th and  $j$ -th neuron and  $c_1$ ,  $c_2$  and  $c_3$  are encoded in the  $SU^{\text{neuron}}$ . Then, a random number  $p$  ( $p \sim \mathcal{N}(0, 1)$ ) is generated, and if  $p < \varphi_{ij}$ , a connection between the two CPGs will be generated.

There is one additional SU for other possible actions, which are not used in this work. As a result, it can happen that some genes perform no action, that is one cause of redundancy.

The muscle cells contract with the output of one of the neurons of the closest CPG. When the distance to the closest CPG is higher than 8, the muscle cell is passive. A contrac-

Figure 4: Illustration of a body plan consisting of cells connected by springs. The CPGs are depicted in green. The springs on the outside of the body (red) are able to change their natural length, except the springs associated to a CPG.

tion of a muscle cell means a change in the rest length of the associated spring at the outside of the individual (counter-clockwise).

Since each CPG contains two neurons ( $u$  and  $v$ ), an orientation of the CPG is introduced to define to which neuron a cell is connected. The orientation of the CPG itself is defined by the gradient of a TF, which TF is used is defined in the SU for neuron formation. Parameter  $s_4$  in the SU defines an affinity value, the TF with the closest affinity to the affinity encoded in  $s_4$  is used for the orientation of the CPG. Cells which connect to the CPG on its first  $0 - 180^\circ$  are connected to the neuron  $u$  and cells connected with an angle of  $180 - 360^\circ$  are connected to the neuron  $v$  of the CPG.

## Physics Simulation

The physics simulation engine used to simulate the behavior of the animats is BREVE <sup>2</sup>

A simple model for simulating the effects of water forces is added, which has also been adopted in (Sfakiotakis and Tsakiris, 2006). In this model, the water forces for different

<sup>2</sup>see [www.spiderland.org/](http://www.spiderland.org/)

Table 2: Constants for the mechanical simulation environment

Mass of cells $m$	0.5
Radius of cells $r$	0.5
Damping constant $d$	1
Spring strength $c$	5
Normal natural length of springs $l_n$	2
Short natural length of springs $l_s$	1.2
Minimal periodic time $T_{min}$	10
Maximal periodic time $T_{max}$	400
Simulation length $t_{sim}$	500.0

elements  $i$  (sphere of the  $i$ -th cell) are computed as follows:

$$\mathbf{F}^i = \mathbf{F}_T^i + \mathbf{F}_N^i, \quad (10)$$

$$\mathbf{F}_T^i = -\lambda_T \cdot \text{sgn}(\mathbf{v}_T^i) \cdot (\mathbf{v}_T^i)^2, \quad (11)$$

$$\mathbf{F}_N^i = -\lambda_N \cdot \text{sgn}(\mathbf{v}_N^i) \cdot (\mathbf{v}_N^i)^2, \quad (12)$$

where  $\lambda_T$  and  $\lambda_N$  are the drag coefficients for each direction.  $\lambda$  depends on the effective area, a shape coefficient of the element and the fluid density.  $\mathbf{v}_T^i$  and  $\mathbf{v}_N^i$  are the velocities of element  $i$  in normal and tangential direction.  $\lambda_T = 0.001$  and  $\lambda_N = 2.5$  are used in this work. The water forces are computed for cells in the outside of the body plan. The normal and tangential vectors of the body parts ( $i$ -th sphere) can be calculated by:

$$\mathbf{t}^i = \frac{\mathbf{p}^{i-1} - \mathbf{p}^{i+1}}{|\mathbf{p}^{i-1} - \mathbf{p}^{i+1}|}, \quad (13)$$

$$\mathbf{n}^i = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \cdot \mathbf{t}^i, \quad (14)$$

where  $\mathbf{p}^i$  is the position vector of the  $i$ -th cell and  $\mathbf{p}^{i-1}$  and  $\mathbf{p}^{i+1}$  are the positions of the neighboring cells on the outside of the morphology.

$$\mathbf{v}_N^i = \mathbf{n}^i \cdot \mathbf{v}^i, \quad (15)$$

$$\mathbf{v}_T^i = \mathbf{t}^i \cdot \mathbf{v}^i, \quad (16)$$

where  $\mathbf{v}^i$  is the velocity of the  $i$ -th cell.

## Experiments

The goal of the experiments is to evolve individuals that swim the furthest in a desired time. The fitness function for swimming is defined as follows:

$$f_{swim} = - \left| \left( \sum_{i=0}^n \mathbf{x}^i(t=0) \right) - \left( \sum_{i=0}^n \mathbf{x}^i(t_{end}) \right) \right|, \quad (17)$$

so the center of mass of the individual at the beginning and the end of the swimming period are computed and the distance is calculated.

Table 3: Properties of the evolutionary optimization

$\mu$	45
$\lambda$	300
Elitists	3
initial # RUs and SUs	50, 50
$\sigma$	$10^{-4}$
$p_{dup}, p_{trans}, p_{del}$	0.05, 0.03, 0.02

Figure 5: Fitness curves to evolve swimming individuals, their movements are controlled by CPGs.

The size of the individuals is limited, so the number of cells ( $n_c$ ) is constrained between 10 and 500. A penalty of  $600 - n_c$  will be applied if  $n_c < 10$  and a penalty of  $n_c$  if  $n_c > 500$ . If the cells in the developed morphology are not fully connected, a poor fitness of 100 will be assigned.

When the individual consists only of neurons or has no neurons, there will be no movement and the fitness for swimming is therefore set to zero ( $fit_{swim} = 0$ ). If the CPGs are not connected, which means there is no path to another CPG via synapses, the CPGs cannot synchronize and their phase shift is random and therefore depends on the initial values of the differential equation. To avoid that not connected CPGs get established during the evolution, but still not to penalize it too strong, the fitness for swimming is then halved.

The EA setup is defined in Table 3, four different runs with different random seeds have been performed.

## Results

The fitness curves of the four different runs are shown in Figure 5. The resulting individuals all swim between 53 and 82 length units (53.9, 82.3, 53.5, 62.2). Run 2 is analyzed in more detail in the following section.

### Analysis of Run 2

The fitness curve and the morphologies of some individuals from run 2 are shown in Figure 6. An elongated shape de-

Figure 6: Fitness curve of run 2. The morphologies of the best individuals of generation 90, 200, 400 and 999 are drawn.

Figure 9: Tail fin of the best individual of run 2. Blue cells are CPGs, all other cells are black.

velops quickly (generation 90), and subsequently the shape smoothens in later generations. The number of the CPGs also increases and their positions change.

Figure 7 shows the development of the best individual of run 2, while Figure 8 shows its swimming behavior. Most cells first divide, transform to a CPG and die afterwards. Because of the neurons on one side of the individual, the springs on this side do not change their natural length and the movement of the individual is only caused by the springs on the other side of the individual. At the end of the individual a triangle forms which has the appearance and seems to fulfill the function of a tail fin, as shown in Figure 9. It is also interesting that the resulting individual is unsymmetric, contrary to the results of Jones et al. (2008) that show the advantage of symmetric morphologies.

The output of the CPGs are plotted in Figure 10, which shows that the phase shifts between the different CPGs are small. Figure 11 shows the orientations of the CPGs and we can see that some CPGs are turned around which results in a larger phase shift for the muscle cells.

(b) Phase shifts between the sinus curves of the different neurons relative to u6.

Figure 10: Output of all CPGs from the best individual of run 2.

## Summary and Outlook

In this paper, we have proposed a model that follows an animat's cell doctrine, i.e., an evolved gene regulatory network controls the cellular growth of a digital organism whose behavioral control is realized by some of the cells differentiating into central pattern generator cells representing neurons. Therefore, morphology and control of the animat are not merely co-evolved but co-represented by one regulatory system whose parameters are optimized during the evolutionary search process. Both on the genotypic and on the phenotypic level the distinction between morphology and control merely becomes descriptive.

The evolutionary optimization of the gene regulatory network resulted in a simple animat that is capable to perform swimming behavior by plausible movement. Body cells that differentiated into central pattern generators provide the ability to obtain an oscillating pattern with only a few neurons without limiting the connections or requiring long learning phases. In some cases the evolved morphology includes structures resembling tail fins, which seem to ease the functional or behavioral task. In principle, this is similar to the example of the passive walker that we mentioned in the introduction, where the dynamic control is eased by the

morphology of the organism.

Compared to the work of Jones et al. (2011, 2008), which is based on a more abstract representation which is less biologically inspired, the evolved organisms do not exhibit symmetric morphologies. It would be interesting to find out under which constraints symmetry would also evolve in our framework.

The target of this research has been to demonstrate that the evolution of organisms exhibiting simple but meaningful behavior based on an animat's cell doctrine is possible. Finding the right parametrization of the gene regulatory network to develop a suitable morphology that incorporates the adjusted neural control is not a trivial task. At the same time, it is now necessary to analyze the properties of our model in more detail. First steps have been made in Figure 6 where we have observed the evolutionary path of the morphology for one run and in Figure 10 where we have analyzed how

the control is organized with the central pattern generator neurons. One of the next steps would be to relate the evolution of morphology to the evolution of the dynamics of the CPGs and how both are over time represented in the gene regulatory network. Unfortunately, even for digital evolution, the functional analysis of gene regulatory networks is a rather complex task, although promising first results have been obtained for evolving cellular morphologies, see e.g. Schramm et al. (2010).

## Abstract

Since its inception, ALife has moved from producing large numbers of highly-idealised, theoretical models towards greater integration with empirically collected data. In contrast, demography — the interdisciplinary study of human populations — has been largely following the principles of logical empiricism, with models driven mainly by data, and insufficient attention being paid to theoretical investigation. Such an approach reduces the ability to produce micro-level explanations of population processes, which would be coherent with the phenomena observed at the macro level, without having to rely on ever-increasing data demands of complex demographic models. In this paper we argue that by bringing ALife-inspired, agent-based methods into demographic research, we can both develop a greater understanding of the processes underlying demographic change, and avoid a limiting over-dependence on potentially immense sets of data.

– But you are paying a lot of money for the dragon!  
– And what, should we just give it to the citizens instead? [...] I see you know nothing about the principles of economics! Export credit warms up the economy and increases the global turnover.

– But it also increases the dragon as such – I stopped him. – The more intensely you feed him, the bigger he gets; and the bigger he gets, the higher his appetite. What kind of a calculation is it? He will finally devour you all!

Stanisław Lem, *Pożytek ze smoka* [*The Use of a Dragon*] (1983/2008: 186)

## Introduction

After attending the very first Artificial Life conference in 1987, the evolutionary biologist John Maynard Smith famously quipped that ALife appeared to be “fact-free science”. His comment was made in response to early ALife work (see, e.g., Langton, 1989) that tended to be abstract and conceptual, not to mention ontologically ambitious, making no connection to empirical data in the conventional sense.

Over time, the early enthusiasm for highly abstract models in ALife has lessened somewhat, as it has become increasingly clear that making such models empirically relevant involves a highly contentious theoretical commitment

to artificial life as an instantiation of biological life (Silverman and Bullock, 2004). Instead, abstract and conceptual ALife models have come to be viewed as tools for theoretical enquiry (Di Paolo et al., 2000), i.e., ways of explaining the qualitative dynamics of complex systems. At the same time, some modellers under the ALife banner have moved toward a greater connection with empirical data (e.g., Toquenaga et al., 1995; Smith V., 2008). ALife has experienced greater scientific respectability, we maintain, due to the collective recognition that modelling and simulation stand alongside theory generation and data collection in the scientific cycle — or, as Rossiter et al. (2010) put it, models are “first class citizens of science”.

Thus, ALife has been in a somewhat unique position: starting from methods almost completely disconnected from empiricism, the field has gradually moved toward a greater integration with empirical data, while retaining a focus on using simulation as a tool for theoretical investigation. In this paper we consider a discipline which appears to be following the opposite trajectory. Demography — the interdisciplinary study of the development of human populations — has long been a field devoted to predictive statistical modelling based on vast storehouses of data, while theory-building has mostly taken a back seat.

Demography’s intense devotion to data has served the field well when making projections of future demographic change in human populations. Nevertheless, traditional demographic methods struggle to develop well-founded *explanations* of these changes, going beyond simple generalisation of the observables (Burch, 2003). One of the motivations driving ALife’s shift toward greater connection to empirical data has been the recognition that neither theory nor data alone are enough to provide coherent explanations of phenomena. ALife has addressed this dilemma by bringing more data into a largely theory-focused modelling enterprise, and we propose that demography, in order to develop beyond its current epistemological limits, must also make a move towards the centre by incorporating conceptual and theoretical investigation into its heavily data-focused framework.

The scientific benefit to such an approach would be the enrichment of the theoretical foundations of demography. In this paper however we will also discuss another, perhaps more pragmatic, advantage to ALife-inspired demographic models: as a means for escaping some of the burdens of the time-consuming and combinatorially expensive data collection required to continue in the traditional fashion.

We begin our discussion in the next section with a summary of demography's struggles with its data-collection demands. We then move on to suggesting some potential applications of agent-based models for demographic research, describing the relevant strengths and weaknesses of the approach. Next, a detailed analysis of several demographic simulation models allows us to develop a more nuanced understanding of how agent-based models may provide new utility and insight. Finally, we offer our conclusions, and suggest some directions for future work in this area.

### Motivation: Meet The Beast

In the context of large, policy-focused projects in social science, modelling and simulation in some form has become ever more important as a means of providing useful information to stakeholders. Models provide a means of producing predictions or characterisations of complex systems which can give the stakeholder what they need: a target number, a summary of current numbers, or numbers to be wary of. However, many such modelling projects can become quite large and unwieldy. We often find that we require extensive amounts of data in order to feed into a large-scale model (hereafter, for illustrative purposes, referred to as 'the beast'), and the process of collecting that data is inevitably expensive and time-consuming. Plus, as our models get increasingly complex, the beast becomes ever hungrier.

Demography offers a unique predictive potential given the information embodied in the age structure of populations. However, for reasons we will discuss later, these predictions still remain largely uncertain. In an effort to alleviate some of the epistemological limitations, recent work in demography has attempted to bridge the gap between micro- and macro-level analysis (Courgeau 2007 and the MicMac project — see Willekens 2005 and Zinn et al. 2009). Advances in event-history analysis and microsimulations linked with multilevel statistical analysis have been offered as potential solutions to the micro-macro divide. However, such methods still have one major weakness: potentially enormous requirements for data due to the 'combinatorial explosion' of the parameter space. So, even as extended modelling frameworks, such as MicMac, try to bridge the micro-macro gap by producing linked simulations at both levels of analysis, we still find ourselves hamstrung by the need for large amounts of data.

Thus, we see demography reaching for more sophisticated modelling paradigms and for ways to produce more micro-level explanations of factors that drive population

change. Unfortunately, current modelling methods require us to continue 'feeding the beast': pumping models full of ever-increasing amounts of data, each dataset requiring vast amounts of resources (time and money) to collect. This has further impacts on the overall modelling enterprise: turn-around time for producing models grows out of control; stakeholders find themselves confronted with high-incomprehensible models and endless reams of data; and the primacy of post-hoc statistical analyses inevitably leads us toward certain types of models which seem to fit the data well.

In the other part of the methodological spectrum, the use of agent-based models à la ALife in recent years has become increasingly popular in certain areas within the social sciences. Starting from Schelling's (1978) famous residential segregation model, and moving on to Axelrod's *Complexity of Cooperation* (1984), Cederman's (1997) work on international relations, and the current wide spectrum of agent-based models in social science (cf. Epstein, 2008 or Gilbert and Troitzsch, 2005), the prospect of using agents to examine properties of human societies which are difficult or impossible to measure empirically has become increasingly attractive. Understandably, many social scientists are excited by the possibility of examining fundamental properties of social phenomena without being forced to devote excessive resources to primary data collection.

To date, much of the work extolling the virtues of agent-based models for the social sciences have focused on the potential explanatory benefits (Epstein, 2008). After all, by examining the processes occurring between agents, perhaps we can gain a greater understanding of how macro-level societal effects happen (although even this is debatable; see Sawyer 2005). However, we feel that another, perhaps more immediate benefit of agent-based modelling has been largely ignored in the literature: the prospect of escaping the expensive, time-consuming process of continual data collection.

Thus, in this paper we propose that agent-based models, informed by work in artificial life and social simulation, can provide a way forward for demographers who seek to escape the 'hungry beast' of highly data-driven research. This approach allows us to create models which develop a new understanding of population change without undue dependence on excessive empirical data, and create an environment in which models can be continually tweaked and worked on as new information comes to light, rather than simply sitting in stasis until the next wave of surveys comes back.

In the next section we will briefly outline the current state-of-the-art in demography, with focus on the contemporary limits of demographic knowledge.

## Where the Beast Lies: Demographic Knowledge and its Limits

Demography is currently facing major epistemological challenges. In particular, demographers' knowledge seems to have reached its limits with respect to the predictability of future population developments, as well as the ability to combine micro- and macro-level information and to find a compromise between the complexity and simplicity of analytical tools. This section discusses these issues in more detail.

The first problem with the limits of demographic knowledge is the issue of predictability. Amongst social science disciplines, demography has a unique predictive potential. Unlike in economics or sociology, very important information on the future development of populations is already embodied in their own age structures. The main mechanism of demographic dynamics is known, too: human populations change through births, deaths and, if considered at sub-global levels, migrations. However, when considered on their own, these three components of population change remain largely uncertain (Hajnal, 1955; Orrell, 2007). They also differ with respect to their degree of predictability: mortality is considered to be the best-predictable component; migration — the worst; fertility being usually located in the middle (National Research Council, 2000).

In the context of the uncertainty of forecasts, predictability limits have been extensively discussed elsewhere (Keyfitz 1981; Keilman's contribution to Willekens 1990; de Beer 2000; Bijak 2010), with two main methodological conclusions. Firstly, it is argued that demography should embrace uncertainty more closely (Alho and Spencer, 2005), in particular by moving from traditional deterministic projections to probabilistic forecasts. Secondly, there is an agreement that with longer horizons — beyond 10 to 20 years — uncertainty anyway becomes too large to be usefully described in probabilistic terms, and hence there is a need to turn to scenario-based approaches (see also Orrell and McSharry, 2009; Wright and Goodwin, 2009). An open question is, which elements should be included in such scenarios and how should they be constructed?

The second limitation of demographic knowledge stems from the problem of aggregation. Populations are composed of individuals and, as argued by Courgeau (2007), focusing exclusively on macro or micro-level analysis can generate problems with either ecological or atomistic fallacy. Whilst demography until the 1980s was almost entirely pre-occupied with the macro level, and since then increasingly more with the individual level (mainly in a form of the event-history analysis allowing for microsimulations), attempts to bridge both levels are much more recent (Willekens, 2005; Courgeau, 2007; Zinn et al., 2009). Microsimulations, as noted by Gilbert and Troitzsch (2005, p. 8), are predictive simulation tools "based on a large random sample of a population of individuals, [which are] 'aged' using a set

of transition probabilities [...], [so that] aggregate characteristics can be calculated and used as estimates of the future characteristics of the population". Micro-level simulation models, as well as their multi-level extensions, are usually also multi-state, states being for example age groups, educational classes, or states of health. In such models, individuals move between the states according to some transition probabilities, usually estimated on the basis of large-scale representative surveys, population registers or census data.

The main challenge with the multi-level approaches lies with their potentially enormous data requirements owing to the combinatorial explosion of the parameter space at different levels. That is exactly where the beast lies: Burch (2003) identified it to be the realm of logical empiricism, on which demography was — and still is — over-reliant. This philosophy focuses on observable phenomena and attempts to create generalisations solely on an empirical basis. As a result, in contemporary research problems driven by real-life questions concerning more complex phenomena, the beast can quickly become insatiable.

The third epistemological dilemma of contemporary demography stems directly from the previous two. At its core there is a question, whether complex models are more useful to aid prediction and decision making than their simpler counterparts. In terms of predictive performance, there is no evidence that complex models perform better (Ahlburg, 1995; Smith S.K., 1997). If that is the case, there might be a temptation to follow the Occam's razor principle (or the KISS principle in complexity science), disregard the additional subtleties involved in the modelling process and opt for simplicity instead (Bijak, 2010). However, such approaches may not increase our understanding of the underlying mechanisms, and are largely limited to shorter time horizons of decision making. To move beyond that, a different approach to modelling would be required.

From this perspective, the following section discusses the applicability of agent-based models in demography, with focus on how they could address the three challenges mentioned above.

### Agent-Based Demography: Avoiding the Beast

In their seminal book, Billari et al. (2003) present a compelling argument for the use of agent-based models in demography, or what they refer to as 'agent-based computational demography' ('ABCD'). Their enthusiasm for this approach stems from the potential for agent-based models to build theories regarding social processes that underlie demographic change. They describe a new ethos for simulation in demography, in which "the simulation is used first of all to develop and explore theories rather than to evaluate empirically the consequences of given rates/probabilities" (Billari et al., 2003, p. 11).

The suitability of agent-based models for exploring theories is certainly attractive for social scientists, as such mod-

els are well-positioned to examine the link between individual behaviour and higher-level organisation (Silverman and Bryden, 2007). In demography, agent-based models provide a potential platform in which the dynamic relationship between the micro- and macro-levels of a simulated population can be more fully represented. While in recent years multi-level microsimulation models, such as the ones mentioned above, have become increasingly popular, these modelling platforms still fail to capture the influence of micro-level behaviour and agent heterogeneity on macro-level entities, and indeed the feedback of those entities on agent behaviour. Nor do they capture social interactions, formation of social networks, or other elements which may contribute to the social processes underlying demographic change — here, agent-based models are more suitable (Gilbert and Troitzsch, 2005).

Beyond these theoretical benefits, we propose that in the specific context of demography, agent-based modelling offers a possible means to escape some limitations to knowledge imposed by the currently dominant data-based methodological paradigm. The first limitation — the one of predictability — points us toward the potential for using agent-based models for generating scenarios, which would produce useful insights about demographic change over a longer time horizon. A great advantage of agent-based models lies in their suitability for exploring a set of scenarios based upon varied parameter settings. Modellers can develop such scenarios based on variations within a parameter space, which allow them to examine how these parameters affect agent behaviour (and, in appropriately designed models, how those behaviours affect macro-level entities). In the development process, boundaries to the scenarios are limited only by the modellers' imagination rather than by data availability alone.

The second challenge for demographers — the aggregation problem — again points toward agent-based models as a possible way forward. After all, some ambitious social simulations not only include individual agents, but may also include macro-level components and thus allow for feedbacks between individuals, as well as between micro- and macro-level (Billari et al., 2003; Murphy, 2003; Silverman and Bryden, 2007). This would allow the modeller to neatly side-step the problem of focusing exclusively on either the micro- or macro-level, providing an opportunity to evade either ecological or atomistic fallacy. Such models can also conceivably capture downward causation effects and other manifestations of links between the micro- and macro-level, which would be impossible in a model which focuses only on one level or the other. Of course, this second challenge also allows the beast to begin rearing its ugly head. As mentioned in the previous section, the prevalence of the logical empiricist approach in demography places a certain primacy on deriving sensible results *only* from empirical observation (Burch, 2003). This naturally leads demographers to seek

out ever larger and more comprehensive data sets, each more expensive and time-consuming to collect than the last.

We then find ourselves sat facing the third challenge — that of simplicity. The beast gets hungrier for more data, and the sets of numbers which need crunching continue to grow in response. Agent-based models, however, necessitate a different approach: *data* is given less primacy than *parameters*. Rather than extrapolating from a given dataset about a population, social simulations will attempt to *generate* a society using the given parameters. The latter can certainly be informed by real-world data whenever they are available.

Thus, a type of modelling used quite often to represent complex systems might require less numerical data input than traditional methods. In certain contexts, social scientists may not find any data necessary at all — as in Schelling (1978), which demonstrated a possible mechanism for residential segregation based on individual behaviour without requiring any data, and only using a single parameter. Notably, Schelling was able to achieve this by focusing exclusively on a possible mechanism for residential segregation, and did not seek any relationship to empirical data; models for demography would need to have some connection to data to remain connected with real-world data and retain some potential predictive capacity. However, Schelling's model is a useful example in that it shows the potential for reducing the need for a model to be *entirely dependent* on data.

As an additional benefit, agent-based models can more sensibly be informed by qualitative data than traditional demographic modelling methods. Such data often explicitly attempts to “elicit agent models directly rather than inferring them from behavior” (Chattoe, 2003, p. 52).

So, agent-based models can present demographers with a way to avoid the beast and get away from ravenous traditional models which require regular feedings of painstakingly collected data. However, using such models in demography may require a certain shift in focus: agent-based models are better-suited for exploring theories and scenarios than for making firm predictions (Epstein, 2008). Therefore, perhaps we may take inspiration from John Hajnal — himself one of the most prominent demographers of the 20th century — and focus on building models which “involve less computation and more cognition than has generally been applied” (1955, p. 321). In this context, we understand the terms ‘computation’ and ‘cognition’ in the spirit of Hajnal's paper — the former strictly related to data-based predictions, and the latter to the explanation of the underlying demographic phenomena.

As we shall see in the following section, attempts to bolster the power of traditional data-driven models have not always been successful — and agent-based models have already been proven useful in some areas of demography.

## Analysis: Case Studies of Demographic Models

In demography, there are notable examples of models that fell short of their proclaimed aims due to the presence of the data-hungry beast. With respect to approaches spanning the micro and macro levels, an interesting attempt to apply methods from the system dynamics tradition to a demographic problem — migration — was the one by Weidlich and Haag (1988). Their approach was rooted in theoretical physics, in particular thermodynamics, and involved the estimation of individual-level transition rates between different regions (states of the system), based on the construed utility function of individuals and a set of macro-level covariates describing the regions. These quantities were linked through a set of *master equations* — first-order differential equations, describing the probabilities of the whole system moving from one state to another following the relocation of individuals. However, solutions proposed by Weidlich and Haag (1988), despite their mathematical sophistication and elegance, did not become a part of demographers' toolkit. There were several reasons for this. Some reviews of Weidlich's and Haag's book stressed that their method did not take into account heterogeneity of migration with respect to age, sex and past migration history<sup>1</sup>. Other points of criticism were that the approach did not model agents at all, thus not exploring the underlying social complexity in full, and did not provide many examples of empirical applications, mainly due to very large data requirements<sup>2</sup>. Finally, the quasi-deterministic nature of the models made them overly reliant on analytical solutions to the system of differential equations describing the dynamics of the migration system in question.

More recently, the MicMac project, as previously mentioned, aimed to develop a new methodology for dynamic microsimulation in demography (Willekens, 2005; Zinn et al., 2009). The final MicMac model consists of a macro-level part, which examines demographic change at the population level with a top-level macrosimulation (known as *Mac*), together with a dynamic microsimulation model that examines demographic events at the individual level (known as *Mic*). Both components of MicMac generate projections based on transitions between demographic states, but *Mac* generates cohort biographies while *Mic* generates individual biographies. In this way the model aims to bridge the micro-macro gap, providing a comprehensive modelling package which can pinpoint the influences of micro-level demographic events on macro-level demographic change (see also Billari et al., 2006).

<sup>1</sup>Daniel Courgeau's review of Weidlich and Haag (1988). *Population* 46(5), 1991: 1298–1299.

<sup>2</sup>J. Barkley Rosser's review of W. Weidlich's (2002) book "Sociodynamics: A Systematic Approach to Mathematical Modelling in the Social Sciences." *Discrete Dynamics in Nature and Society*, 3, 2005: 331–335.

In practice, however, the beast once again rears its head, and data requirements in this case are substantial. The microsimulation portion of the model (*Mic*) requires a significant amount of detailed micro-level data to implement, especially on transition rates between all possible demographic states for individuals<sup>3</sup>. The macro-level model (*Mac*) also requires extensive data about transition rates in order to run. Given that *Mic* includes 12 variables for each individual, very large amounts of input data are required to produce age- and time-specific transition rates between all possible states.

In turn, from the opposite — agent-based — end of the modelling spectrum, one example of an agent-based model producing some historical demographic insight is the model of the Kayenta Anasazi civilisation (Axtell et al., 2002). The model attempts to explain the rapid decline of the Kayenta Anasazi tribe in Long House Valley in northeastern Arizona, United States. The Anasazi tradition began in the area around 1800 B.C., when maize was introduced as a major agricultural crop. Around 1300 A.D., the population declined rapidly, and eventually there was a mass exodus from the valley.

The model of Axtell et al. (2002) consists of a digital reconstruction of the Long House Valley landscape, constructed using existing knowledge of the environmental conditions at that period in history. The agents themselves represent households, individual people being more difficult to identify with any reliability using the existing archaeological data. Each household has certain rules of behaviour which specify how it will select its dwelling and planting locations during each calendar year based on how successful it has been at satisfying its nutritional needs.

The model seemed to produce a simulated population which closely followed the ebbs and flows of the real Anasazi population in Long House Valley. Interestingly, however, the model shows that some small sustainable population could have remained in the northern part of the valley, even as the environmental conditions started to degrade toward 1300 A.D.; this contrasts with the real population, in which the remaining people joined the mass exodus leaving the valley.

This model thus demonstrates that the demographic changes which affected the Anasazi population in this area can be explained at least in part by an agent-based model with simple behavioural rules. As the environment degrades over time, and the agents must continue to look for fertile ground in which to plant their fields, the simulated population shifts northward, just as the real Anasazi had done. In contrast, a demographic model which did not capture these rules of individual behaviour may have been able to accurately portray the changes occurring at an aggregate level,

<sup>3</sup>See Deliverable D9 of MicMac: "Report on Data Requirements of MIC" by F Willekens, J de Beer and N van der Gaag: <http://www.nidi.knaw.nl/Content/NIDI/output/micmac/micmac-d9.pdf>

but would not be able to explain *why* those changes occurred.

Of course one might ask, how did this model keep the beast from getting out of control? The model clearly incorporated many pieces of information from a variety of disciplines. However, it is interesting to note in this case *how* the beast was fed. Interestingly from a demographic point of view, along with already-available archaeological information, the model was able to incorporate *qualitative* data in the form of ethnographical research: the agents' behavioural rules were formulated by distilling ethnographic knowledge about the Anasazi civilisation into simple rules driving their migration and agricultural activities.

Another example of an agent-based model producing demographic insight is a recent study of marriage offered by Billari et al. (2007). Their model was constructed as an attempt to bridge the gap between two different perspectives which predominate in the study of the timing of marriage in populations: macro-level statistical modelling used by demographers, and micro-level studies performed by psychologists and economists examining the partner (mate) search process. In this context, an agent-based model is seen as a possible way to "account for macro-level marriage patterns while starting from plausible micro-level assumptions" (Billari et al., 2007, p. 60).

The resulting model assumes that the formation of marriage partnerships is the result of social interaction between heterogeneous agents. The model attempts to demonstrate the link between these interactions and marriage patterns by simulating the impact of the availability of mates and the desirability of marriage, which is affected by the influence of relevant others in an agent's social network. The results show that the model can reproduce the hazard functions of marriage observed at the population level in the real world. The performed sensitivity analysis suggests that the results are robust to changes in the relevant simulation parameters.

The findings of Billari et al. (2007) have important implications for demographers wishing to avoid the beast. As the authors note, the model uses substantial simplifying assumptions: placing the agents in a one-dimensional, circular space; leaving out additional social complexities such as courtship or divorce; and focusing only on age and location as agent attributes, ignoring kinship, education, occupation, socio-economic status, or other similar factors. In fact, the simulation almost entirely ignores any empirical data, with the exception of the initial population which is generated with an age distribution reminiscent of 1950s America.

Despite the paucity of data, however, the simulation-based demographic models seem to produce at least plausible micro-level explanations of macro-level phenomena. In the work of Billari et al. (2007) this concerns the influence of social pressure to get married within a social network, and the variation of the size of that network by age is a determinant of the desirability of marriage. In contrast, a macro-level statistical model of marriage timing would not

be able to provide this sort of micro-level explanation — and would require significantly larger investments into data collection in order to function. In turn, the study of Axtell et al. (2002) captured the main factors behind the expansion and twilight of the Anasazi population. On the other hand, even painstaking efforts to reconstruct birth, death and migration rates based on fragmented pieces of historical information would yield demographic predictions that would be too uncertain to be meaningful, if only the levels of uncertainty were honestly admitted in such a model. The beast might be fed and sated — but our understanding of the underlying processes would be no greater.

## Conclusions

Our discussion and analysis have demonstrated that traditional demographic methods, while highly accomplished in producing data-driven population projections, face some major epistemological and pragmatic challenges. The overall focus on data over theoretical investigation has hampered demography's ability to provide explanations of demographic change, while the hunger of the beast of logical empiricism traps demographers in continuous cycles of expensive and time-consuming data-collection.

As we have seen, the application of agent-based methods inspired by contemporary ALife work to demography provides a means to lessen some of these burdens on population researchers. The resultant increased focus on explanation over producing projections from empirical data could allow demographers to develop more coherent micro-level explanations of macro-level demographic change. More pragmatically, the concomitant reduction in data dependence would reduce the hunger of the beast, allowing demographers more freedom to produce varied and ambitious models while also removing the restrictive timetables imposed by lengthy and expensive data-collection processes.

So far, all applications of agent-based models to population change, such as the ones mentioned earlier in our analysis, have been performed separately, abstracting away from the main mechanism and inertia of population dynamics. In particular, existing studies deal with particular components of population change — fertility and marriage (Murphy, 2003; Billari et al., 2007), or migration and residential patterns (Heiland, 2003; Benenson et al., 2003) — separately, without putting them together into a common modelling framework describing the known features of population dynamics. In our view, developing an integrated, multi-level and multi-state agent-based model could overcome some of the philosophical difficulties discussed before, whilst remaining related to the real-world through the empirical data, wherever they are already available. The challenge ahead is thus to build models which would combine various features of demographic processes and yield artificial populations equipped with real-world characteristics. In that respect, agent-based demography is not only interesting as a

research field, but also as a promising venue for answering questions relevant to policy makers. Moreover, it provides the users of the final research output with more possibilities for interacting with the researchers, by engaging in the experimentation with the artificial worlds created. For both parties involved in the process — researchers, as well as the end-users of research — this can bring about a better understanding of the underlying population processes, which itself can be a very important gain from the whole modelling exercise.

From these points of view, agent-based demography seems to be an innovative way of moving the whole research field in a new direction, towards the middle ground on the theory-data spectrum. For the ALife community, this ‘dialectic’ position would open up a whole new, fascinating field of research with direct applications to real-world problems. However, building agent-based models to population questions would require that demographers use more imagination than in pure data-driven modelling, in line with Hajnal’s *credo*. Agent-based modelling can offer a solution, which has to be based on cognition and thinking about mechanisms (Burch, 2003; Chattoe, 2003), while taking into account these pieces of information (data) that are already available. In that respect, the rule of the thumb for agent-based demographers who would like to strike the delicate balance between empiricism and explanation is: we should feed the beast where feasible — but not more.

# A Schematic Representation of Autopoiesis Using a New Kind of Discrete Spatial Automaton

Jean Sirmai<sup>1</sup>

<sup>1</sup>Clinician and Hospital Medical Practitioner, Ile de France.  
jean.sirmai@orange.fr

## Abstract

Autopoiesis, or one's ability to renew oneself, is a meaningful concept for the study of life. Modeling of autopoiesis would enhance its study in relation with other biological properties such as feeding, breeding, being ill, healing, dying, etc. Here, we report the design of a "morphautomaton", a new kind of discrete spatial automaton designed to represent within the same space an unlimited number of various complex, mobile, interacting forms. This automaton uses a simple, single effective formalism to identify and localise those forms and describe their movements, transports, and transformations. We make use here of these forms as symbols to schematically represent an autopoietic individual within its environment. This representation can be made consistent with the laws of thermodynamics and conservation. Using this representation, the study of the physiological properties of this individual could be undertaken. Using this platform, the modeling of other biological properties in relation with autopoiesis should also be possible. These models should allow future comparisons, definition, and classification of these biological properties. Representations using our formalism and similar parameters can be combined. Because it focuses on the physiological analysis of whole individuals, this schematic representation method can be used only when structural analysis has been completed.

## Introduction

The word "autopoiesis" was created by Francisco Varela and Humberto Maturana in 1971 to designate the ability of something to "create oneself" (Maturana and Varela, 1973). The ability of an individual to renew itself while maintaining its shape and organization is remarkable. Indeed, no inanimate objects have such a property, yet living objects often heal and return naturally to their original forms. How do they accomplish this? Where does the difference arise? Could we acquire control of it?

At one time, the idea that living matter differed from inanimate matter seemed obvious. Today, we have identified most parts that comprise living beings, and there is no doubt that these parts are made of the same material as inanimate objects (Goodsell, 2009). While anatomic knowledge is not sufficient to understand the differences between living and non-living, we can hypothesize that the set of physiological processes performed by these parts give the whole its properties (Schoenheimer, 1942; Schrödinger, 1944; Kleiber, 1947). Thus, here we search within this paradigm for a mechanical explanation of autopoiesis.

We remain far from understanding what roles each piece plays in creating the whole; neither can we perfectly analyze or reconstruct the simplest organisms. We know not what assumptions are necessary to guide such a reconstruction; what we need is not simply a technique but a method or theory providing the guidelines to direct the analysis and representation of our observations. Critical to this theory are the criteria that will enable a strict definition of the properties of the living: feeding, breeding, growing, being ill, healing, dying, evolving, behaving, etc. By removing or modifying some structures and observing changes in the whole, we can distinguish which structures are necessary and sufficient for the existence of these properties. By comparing several living entities, we can acquire an indication of their generality (applying to cell, organism, society) and of their relationships (dependence, anteriority, causality, equivalence, etc.). Indeed, we may go further and study the forms of these entities, to determine whether they can be classified and systematically enumerated, if they derive from each other, and how to most simply represent them.

However, complex systems have unpredictable emergent properties. To gain control over any property of such a system, one must forego, at least initially, studying what might emerge from it, as a system is either controlled or has emergent properties (Liu et al., 2011). Our goal here is to avoid the apparition of any emergent property, while creating an autopoietic representation that may lead to its control. Meanwhile, we wish to retain the ability to later study autopoiesis' associations with division and differentiation to produce systems endowed with the ability to evolve.

To define and control a property, two approaches are possible: synthetic, or "bottom-up" (used here), identifies the property then searches for a mechanism to reproduce it. This kind of approach has been infrequently explored because of several inherent weaknesses, such as its generality, the arbitrary choice of entities to represent the property, or the lack of analysis of physical constraints (Morange, 2005; Atlan, 2011). The majority of modeling works are analytical, "top-down" approaches: beginning with available experimental data, one selects useful parts and tries to reassemble them to reproduce a property of interest. The two approaches, however, are complementary and are needed to validate one another; when these approaches validate the same mechanism, the property becomes correctly established; its full control (i.e., the ability to calculate, reproduce, modulate,

or combine it with others in any particular physical, chemical, or even robotic context) can be envisioned.

To demonstrate autopoiesis, Varela and Maturana worked in a non-experimental, theoretical framework and built a dynamic representation *in silico* by programming a discrete spatial automaton to represent the minimal organization of a biological cell (McMullin and Varela, 1997). They intended to represent a membrane constantly and permanently destroyed and rebuilt through the actions of particles they called substrates, catalysts, and links. The destruction of this membrane was done at random and was offset by new syntheses. This first model was a great launching point for later works (Zeleny, 1977; McMullin and Gross, 2001; Ikegami and Suzuki, 2008; Bersini, 2010). However, Varela's model contains some weaknesses: The definition of autopoiesis (Maturana and Varela, 1980) is not clear and simple and is not fully applied in his later models, as destruction of the membrane, renewal of the catalyst, transmembrane transports, and, therefore, control of the individual's size are not performed by the individual itself. Varela did not use a well-formalized representation platform, but he worked in a time where it was difficult to separate the representation method from the represented object. Most of these works are restricted to chemical materials, and do not consider other potential implementations (e.g., robotic).

To move the study of autopoiesis forward, we propose to reformulate the definition of the property as follows: first, because autopoiesis is dynamic, we may hypothesize that it is a property of a whole that cannot be a unique, static, inanimate block, but that consists necessarily of distinct, interacting parts. To interact, these parts must be mobile. If they are mobile and yet they continue to be part of the whole, then they are joined. What connects them is also an aspect of the whole. The interactions that they continually have renew them. This means each of them can be destroyed by one and re-built by another. Importantly, if all the necessary conditions are met, then the whole can keep its form longer than the parts composing it. Because of continuous movement of its parts and exchanges with its environment, this form and its composition can never be exactly the same; rather, they fluctuate around a mean shape. Indeed, the whole loses this property if it is split or isolated from its surrounding environment, with which it exchanges energy and matter to achieve its renewal. Additionally, if there is a "natural" process of degradation of some of its parts, the whole's renewal speed should remain sufficient to oppose the effect of this process. Importantly, "autopoiesis" should also satisfy McMullin's criterion, which states that two individuals, in direct contact with each other, can reliably maintain their separate identities (McMullin, 2004).

The methods applied to the study of autopoiesis evolved in parallel of the concept itself. Early studies conducted by Tibor Ganti, Robert Rosen, Victor Kunin, Manfred Eigen, and others identified related concepts, but were generally performed using differential equations (Popa, 2004). However, differential equations, developed to describe quantitatively determined and continuous phenomena, assume ideally mixed reactants and are poorly adapted to molecular biology. Instead, discrete spatial automata can associate

logical operations to possibly non-linear and probabilistic numerical calculations and can apply them to irregular and discontinuous distributions of matter (Rao et al., 2002; Broderick et al., 2005; Wishart et al., 2005; Morris et al., 2010). Here we designed a particular new class of discrete spatial automata that can represent a set of complex, mobile, interacting forms whose evolution may schematically represent a phenomenon of interest; we use it to represent an autopoietic individual.

## Methods: Description of the morphautomaton

### Workspace, states, and transition rules

The *workspace* in this automaton consists of a set of regularly arranged, adjacent *tiles*<sup>1</sup>. Each tile has a *state*, which is described as either empty or occupied. A tile is occupied, and thus called a *particle*, when it has at least one *link*. Conversely, an empty tile has no link. By definition, two particles cannot occupy a single tile.

A link represents a directional association between particles. It belongs to one particle and indicates the position of a neighboring one<sup>2</sup>. The state description of the workspace is complete when each tile is known to be either occupied or empty, and, for each occupied tile, the orientation of each link is known. All information required to describe a workspace state can be acquired using only two distinct kinds of *conditions*: one refers to the number of links of a particle (isotropic conditions) and the other the orientation of a particle's links (anisotropic conditions). An isotropic condition contains coordinates for a tile and a number, *n*. The number of links in the indicated tile is evaluated for equivalence to *n*. Further, this condition helps determine whether the tile is empty: empty space is defined by a number of links equal to zero. A positive anisotropic condition contains coordinates for a tile and an indicator of orientation, *p*. This condition assesses whether a link from the selected particle is oriented to *p*. Because of the possibility of superposition (i.e., a particle may have multiple links in any given orientation), a built-in mechanism considers whether there are superposed links. A negative anisotropic condition contains the tile coordinates and *p*, as above, and requires that no link is oriented toward *p* at the specified location.

Each *rule* comprises a set of conditions that, when met, initiates *operations* producing a transition from one state to another (see Figure 1).

---

<sup>1</sup> We avoid the word "cell" because of potential ambiguity with the biological meaning.

<sup>2</sup> Typically, any tile indicated by a link is considered occupied; however, this restriction can be overcome: individual disconnected particles moving at random and containing an available link may then randomly attach to any aggregate. The connection will result in a change in shape and, potentially, identity of the aggregate. Thus, these disconnected particles could be used for representation of damage occurring to various materials, in some cases acting as a sort of "mutagen."

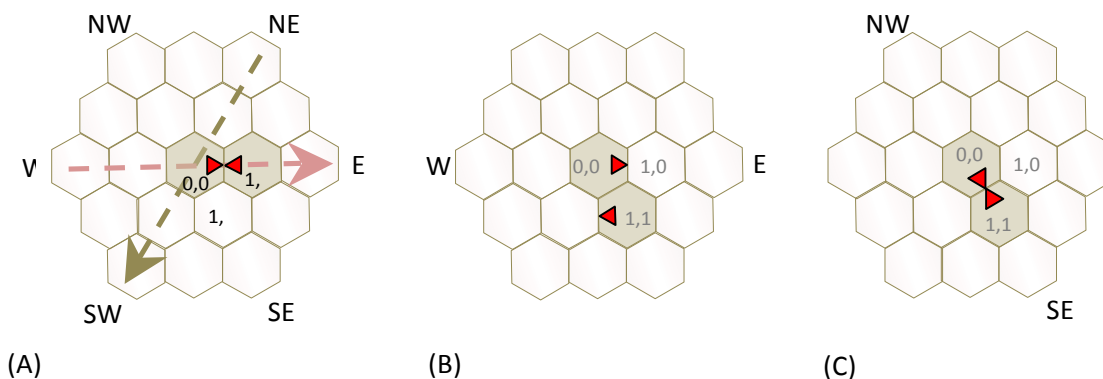

Figure 1. Example of a transition rule that describes simultaneous state change of two particles. A) The workspace above shows the neighborhood of the central cell (0,0). The space contains two dimensions, hexagonal tiling, and two non-orthogonal axes traveling west to east (x) and northeast to southwest (y). The central cell, a particle, contains a link (symbolized by the small triangle) facing east. East of (0,0) is another particle in (1,0), also containing a single link, this time oriented toward the west. The tile below, in (1,1), is empty. The states of other tiles are indifferent; these do not prevent or facilitate the application of a rule whose conditions permit identification of this situation. The following five conditions exist, whose order of evaluation is irrelevant: (a) number of links (0,0) = 1; (b) number of links (1,0) = 1; (c) number of links (1,1) = 0; (d) link (0,0) = East; (e) link (1,0) = West. In our example, all conditions are met, so the rule identifies the situation and thus can be applied. Several operations are then performed in a specific order: The tiles located in (1,0) and (1,1) are swapped using the operation [move]. The result of this translation is shown in B. Two [turn] operations then change the orientation of links of particles (0,0) and (1,1), which produces the result shown in C.

A rule must contain at least one condition and one operation. Possible operations are either *link rotations* or *particle translations*. Link rotations re-orient one link of a tile from one direction to another. Particle translations exchange the contents of two tiles, adjacent or not. If one of the two tiles is empty and the other is occupied, a simple particle translation occurs. However, if both tiles are occupied, a double translation or permutation occurs. The numbers of links and particles are preserved. The number of links in a particle does not change.

The conditions and operations of a rule do not apply to or affect the entire workspace, but only a particle and its local neighborhood comprising the tiles of interest. Rules must refer to the coordinates of the neighborhood to be evaluated and enacted. A selected particle represents the center of the neighborhood, and one of its randomly chosen links provides a reference orientation for this space. These selections define and orient the neighborhood. The choice of the central particle is made at random, and the automaton guarantees that all particles can be selected and none excluded. Each cycle of the automaton evaluates the same rule set in a different neighborhood. The cycle begins upon selection of a particle and one of its links, delimiting and orienting the neighborhood. Rules are then evaluated individually and sequentially<sup>3</sup>. If any one condition is not satisfied, that rule is rejected and the following one is evaluated. If all conditions

attached to a rule are met, then all operations of this rule are performed and the cycle ends. If all rules have been evaluated and none applies, then no state change occurs during this cycle. Once a cycle is completed a new cycle begins. During the evaluation of rules, each tile in the neighborhood can be evaluated for one or more conditions, and, when a rule has been satisfied, can be involved in one or more transitions. Importantly, tiles located outside the neighborhood remain unaffected by this process.

In summary, the workspace contains particles of one-unit size that can be linked and all operations on these particles and their links are performed locally<sup>4</sup>.

## Aggregates

*Aggregates* are groups of *particles* associated by *connections* (Figure 2). A particle is a full tile defined as having at least one link. Connections between particles are realized by the links between them. The simplest connection is achieved by one link between two particles; however, the number of links constituting a connection is unlimited. Links can also be superimposed (i.e., there may be multiple links in either direction between two adjacent particles). Additionally, the

<sup>3</sup> An important feature of this automaton is the addition of a random condition to decide between rules with identical local conditions. Sequential evaluation would normally cause the first of these rules to be applied and those following to be always ignored. The addition of a non-local random condition enables all concerned rules to be applied with equal probability. While rarely used, the random condition is essential for reproducing the randomness of some movements.

<sup>4</sup> Multiple threads can work in parallel and asynchronously on the same workspace. This feature requires that each neighborhood is treated separately, thus no interference exists between them. Whether a single thread operates or multiple threads are simultaneously active, the system's history is constructed in random order. Thus, two successive experiments do not follow the same trajectory. Reproducible results therefore testify to the independence of the model in relation to the mechanics of the automaton.

Figure 2. Two aggregates in motion. One aggregate is a grouping of three particles (a "trimer") and the other is a "chain" that is not entirely visible in the neighborhood (dashed line added for visibility); the chain delimits two compartments. As the chain's connections are asymmetrical, their orientation allows local identification of each of these compartments. Different movements apply to these two aggregates. The trimer, fully visible in the neighborhood, can be moved around by the action of a single rule; the long chain can only be distorted by any single rule. However, many successive distortions, performed at different locations, give the chain a full mobility in all directions. The transition from (A) to (B) does not alter the composition of the compartments, but the transition from (B) to (C), a transport, changes this composition because the trimer passes from one compartment into the other.

connection is called "reciprocal" when each particle in a connection has at least one link pointing to its connected neighbor. It is called "symmetrical" if the two particles run the same number of links to one another. Symmetrical connections are necessarily reciprocal.

The smallest aggregate is a dimer, composed of two particles. Aggregate size is not limited by the tiling used or the automaton mechanism, but may be limited by the dimensionality and the extent of the available space. Further, aggregates can be of any regular or irregular shape: monomer, polymer, chain, ring, bifurcation, helix, knot, cavity, grain, rotor, stator, etc. A good choice of forms and rules can produce representations of many material properties: hardness, flexibility, elasticity, rigidity, fluidity, permeability, etc. These lists are not exhaustive. An aggregate's size or the number and extent of its links are infinite. Further, basic forms can be disjointed or contiguous and combined in various ways. These features mean that this formalism provides open-ended possibilities of creating and combining elementary forms.

The operations performed on aggregates are associations of the basic operations performed by the rules. They can produce *movements* (displacement or distortion), *transformations*, or *transports* (movements from one compartment to another).

Movements can be translations, rotations, or combinations of both, and can be performed on the whole or a specifically identifiable part. They occur easily when the aggregate size is smaller than the neighborhood. When the aggregate size exceeds that of the neighborhood, however, it cannot be moved in its entirety by executing a single rule. However, such aggregates may be distorted. Carried out in multiple locations and repeated, distortions give large aggregates their mobility (Figure 2). The size of the neighborhood can be chosen according to the mechanical properties of the aggregates whose movements are to be represented. Each aggregate has an identity comprised of morphological local traits resulting from the unique pattern of its connections. The number of identifying properties is unrestricted and each identity can be evaluated by rule conditions. For example, one chain may have a linear structure and asymmetric connections of just one link, while

another chain may have symmetric connections, and another, asymmetric connections but with two or three links. As movements translate particles and reorient their links but never break connections, they always preserve the unique identity of each aggregate. By contrast, transformations always break at least one connection and reconnect some particles in another way, modifying aggregate identities. Transports preserve aggregate identities but move them from one compartment to another.

In summary, 1) aggregates are groups of connected particles of various forms whose size is not limited; 2) each one has a specific connections pattern that enables its identification; 3) aggregates are localised (in a compartment or as a limit of a compartment); 4) they can be moved, transported, or transformed; 5) transformations and transports, but not movements, require aggregate identification; 6) movements conserve identity and localisation; 7) transformations break and re-establish links, modifying aggregate identity; and 8) transports respect their identity but modify their localisation.

## Summary

The new type of discrete spatial automaton, which we call a "morph-automaton," (from ancient Greek morphè: form) is relevant because it allows the representation by means of a simple, single formalism of many forms moving and interacting in the same space. Indeed, while this formalism does not limit the diversity of these forms or the variety of operations that can be performed on them, the use of a unique rule structure enables automatic handling of the rules (editing, classification, presentation, optimization).

A number of parameters can be adjusted without changing the principles that underlie morphautomata construction and design. These parameters primarily concern the general structure of the workspace: They define its number of dimensions and extent, the type of tiling used, the existence of edges and the representation of general strength fields (e.g., electromagnetic, gravitational). Some parameters concern the shape and size of the neighborhood. Others parameters include the number of links per particle and the scope of these

links—and, thus, the variety of possible connections. Adjustment of these parameters depends on the phenomena that the experimenter wishes to represent. Importantly, models with identical parameters can be combined. Such operations may be formalized.

The variety of aggregates is unlimited, and, even constrained by the necessity of using discrete forms and limited neighborhood size, proper selection of these forms and of the operations that apply to them can produce schematic representations of a variety of complex heterogeneous materials. The experimenter chooses some of these forms and details when editing the initial state. He selects and describes their movements and interactions when writing rules. These choices depend solely on his assumption and the result he wants to achieve: it is his intention that gives logical consistency and value to the writing of the whole. Further, the experimenter is responsible for verifying the logical coherence of elementary conditions and operations composing each rule and their coherency with other rules and the state.

If the rules associated with each aggregate allow movement in all directions, and the automaton uses a random selection of particles, then the motion of each aggregate, isolated or in relation with others, is permanent and random. Transformations, moreover, have some similarities with chemical reactions. Additionally, conservation and

thermodynamic laws can be represented. Thus, this platform makes possible a schematic representation of certain physical and chemical properties of macromolecules in solution.

## Results: Autopoiesis

### Anatomy of the autopoietic individual

Our automaton has been designed with the intent of representing an autopoietic individual moving at random within its environment. It makes use of five varieties of aggregates. First, we describe the initial state of our workspace for the positions of each instance of the five different types of aggregates used to build the autopoietic individual. This detailed and comprehensive description of the initial state is required by the automaton machinery for the representation to evolve, and it must be edited manually. Required characteristics are those that denote each aggregate's identity, shape, and localisation.

The individual is composed of a membrane enclosing an internal compartment (Figure 3). This membrane is a circular chain made of one-link particles each pointing at the next. Because of a unique sense of rotation, its inner and outer faces are locally identifiable, delimiting two compartments: internal

Figure 3. (A) and (B) represent the same autopoietic individual and its environment in two successive snapshots. Each panel represents the same part of the workspace; the two-dimensional space is covered by a hexagonal matrix whose tiles are either empty or occupied. Full tiles, called particles, have a link, symbolized by a small triangle, which refers to another particle; they are thus associated to form aggregates. One of these aggregates is a circular chain, called a membrane, which delimits two compartments: internal and external. In these compartments are several small isolated aggregates consisting of two, three, or four particles. Aggregates of four particles can be found in the interior compartment only. Several small chains ranging in length from one to four particles are attached at the internal face of the membrane.

The large hexagons, delimited by dots and located at the top right of each image, indicate the size of the neighborhood of a particle where evaluation of the rules occurs. (This part of the figure is superimposed with Figure 1A.) The particle at the center of this neighborhood was chosen randomly, and its link assigns the orientation during rules evaluation (black arrow, letter E see fig 1A). This particle is part of an aggregate consisting of two particles, called a dimer. (B) shows the new position of this aggregate after application of the rule.

Comparison of (A) and (B) shows the effect of many random movements of this type. The positions of most small aggregates have changed slightly. The membrane and small chains have been deformed and displaced, but their lengths are identical. The identity of each aggregate has been preserved, as no transformations occurred. The composition of each compartment was also preserved, as no transport occurred. Even if some traits of this abstract representation may evoke a living cell (which was the initial intention), it is definitely not one. This individual may only be an autopoietic representation: it has some very particular features that no real cell will ever have, and is not intended to represent other properties of real cells.

Table 1: Summary of operations performed by the automaton.

		Action	Conditions
Transformation	1	membrane > chain	Membrane can wrinkle, its continuity can be ensured, a chain at least one-unit length is already there
Transformation	2	chain > tetramer	Chain length is almost four units long
Transformation	3	tetramer > dimers	Other tetramers are in proximity
Transport	1	trimers entry	Enough space available, membrane flexible, no chains attached to the membrane locally
Transport	2	dimers exit	Enough space available, membrane flexible, no chains attached to the membrane locally
Transformation	4	trimer > membrane (one unit) + dimer	Only in the presence of a tetramer
Transformation	5	Trimer > new chain (one unit) + dimer	Only in the presence of another trimer
Transformation	6	two chains one unit each > dimer	Other one-unit chains in proximity

and external. Dimers, trimers, and tetramers are small aggregates, disconnected from others and made, respectively, of 2, 3, or 4 particles. As a particular characteristic of this model, tetramers are found only inside the internal compartment; dimers and trimers are both inside and out. On the inner side of the membrane may be attached small chains comprising 1, 2, 3, 4 or more one-link particles.

In summary, five varieties of aggregates are used in several instances in this representation: membrane, dimer, trimer, tetramer, and chain. Their relative localization and shapes are essential information.

### Physiology of the autopoietic individual

We must now focus only on the transport and transformation of aggregates to understand how their concentration variations and interactions drive the dynamic self-maintenance of the autopoietic individual. Our example makes use of six transformations and two transports (Table 1). The small chains, on the inner side of the membrane, walk at random while remaining attached to the membrane. Because the membrane may wrinkle randomly, to the point where it is possible to remove one of its units while restoring its continuity, these chains gradually grow by taking a membrane unit whenever the membrane is folding next to them (transformation 1). Thus, this chain, initially one particle in length, elongates while remaining attached to the membrane. Once a sufficient size, the chain is transformed into a tetramer that is released into the internal environment (transformation 2). The whole chain eventually disappears in this operation. When several tetramers are side by side, one of them is destroyed and transformed into two dimers (transformation 3). The membrane allows trimers to enter and dimers to exit (transports 1 and 2). In the external environment, a built-in mechanism transforms dimers into trimers. Further, when a trimer and a tetramer are simultaneously present near the membrane, the trimer is converted into a dimer and the membrane takes up the remaining particle; the tetramer is unchanged (transformation 4). When two trimers are simultaneously present near the internal side of the membrane, one of them is converted into a dimer, with the remaining

particle producing a small chain (one-particle length) attached to the inner face of the membrane. The other trimer remains unchanged (transformation 5). When multiple small chain of one particle length are arranged side by side, two of them are moved aside and transformed into a dimer (transformation 6).

### Summary and further analysis

The set of transports, transformations, and movements we have described allows each part of this “cell” (membrane, chains, dimers, trimers, tetramers) to be mobile, linked to others, and constantly destroyed and renewed by others. The whole moves randomly and keeps its size, shape, composition, despite changes in the external environment<sup>5</sup>. The observation that small aggregates move farther than large ones is an indication that this model approximates well Brownian motion. Two individuals simultaneously evolving in the same space maintain their separate identities. Consistent with our definition, this constitutes an autopoietic individual<sup>6</sup>.

Why does this individual retain its size, shape, and composition? To answer this question, we must describe the scheme of regulations guiding our representation, which is, in fact, not specific to the representation above. Indeed, another manifestation hardware or virtual setup (e.g., a cubic matrix using other forms) could be regulated in exactly the same way.

We established several controls for our model. First, synthesis of the membrane is regulated by the concentration of tetramers: the growth of the membrane depends on the presence of a tetramer, but tetramers are produced by the destruction of the membrane. Thus, membrane synthesis cannot occur without previous membrane destruction. The yield from the destruction of tetramers plays a key role in the

<sup>5</sup> As the individual state remains constant, we hypothesize that its global entropy (as a state function) remains unchanged, while that of the environment increases. The representation used here enables their precise calculation, but this has not yet been completed.

<sup>6</sup> A demonstration version and additional documents are available at <https://sites.google.com/site/morphautomaton/>.

regulation of the size of the individual. If the efficiency of this reaction is increased slightly, the number of tetramers decreases. As the membrane synthesis reactions depend on the presence of a tetramer, they become more rare than the reactions of destruction. Accordingly, the size of the membrane decreases. Another effect appears then: as the destruction of the membrane is dependent on the quantity of available membrane, i.e., of its size, this reaction becomes less frequent. A new equilibrium is therefore established when the membrane has reached the size for which these two processes (construction and destruction) become balanced.

Conversely, if we now decrease the efficiency of the reaction of destruction of tetramers, their concentration increases. Therefore, the membrane synthesis reactions that they facilitate become more frequent than the destruction reactions, and the membrane size increases. However, as this size is important, destruction reactions become more frequent. There again, a new equilibrium is established when the membrane has reached the size for which these two processes become balanced.

Additionally, the four processes of synthesis, catabolism, inputs, and outputs are in competition with one another, since the membrane has a finite extent. Several parameters (e.g., the shape of the membrane, the available free space) may favor one process over the others. Finally, many other regulations, unexpected at first sight and unintentionally introduced, directly or indirectly modulate each transformation.

The thermodynamic approach of Virgo and Harvey (2008) proposes a relationship between the amount of energy that can be extracted from the environment and the overall rate at which that energy is used. We searched within our model for such a relationship as a negative correlation between the “activity” of the cell (quantity of metabolic rules executed in a given amount of time) and the potential energy (trimers in the environment) available at the same time, but we did not observe this relationship. However, this first trial must be refined.

This analysis is just beginning. Note, as in physiology, the existence of two kind of regulations whose evolution is either exponential or periodic; the latter probably limits the area where the former can grow.

## Discussion

A schematic representation of autopoiesis was created using a new type of discrete spatial automaton, which is based on the principle of encoding functions through an extensive representation of abstract forms used here as symbols. The identities and localizations of these forms give a complete, static description of the system; the operations performed on them give a dynamic description of the system. While our intent was to represent autopoiesis, this platform is versatile and convenient for representing other biological or non-biological phenomena, especially those observed in any complex population ranging from solutions of macromolecules to swarms or societies.

Despite an as-yet incomplete analysis of this model, it conforms to our definition of an autopoietic individual: each

of its parts is distinct, mobile, linked to the whole, and continuously renewed by one another. In contrast to previous models, the destruction of the membrane, renewal of the catalyst, transmembrane transports, and, therefore, the individual's size are controlled by the individual itself. Additionally, in our model the continuity of the membrane is ensured; the membrane shape, length, and the internal density are effectors and subject to regulations. Indeed, this individual is “robust” since it can adapt to various environmental conditions. In accordance with McMullin's criterion (2004), each individual remains distinct from another one. Thus, we have defined, demonstrated, and described a virtual autopoietic individual. This model represents an important advance in the field, as none of those properties existed in Varela's initial model, where membrane destruction occurred spontaneously and the other parameters were not considered. Further, the original idea of boundary has been replaced by the less-restrictive idea of link. Finally, the concepts discussed here are not restricted solely to biochemistry but could apply to robotics or any other implementation. Presently, this work provides a reference point for the representation of other individuals, their comparisons, their comprehensive “physiological” analysis, the research of a rigorous definition and formalization of autopoiesis, and the potential to undertake the study of the relationship of autopoiesis to other biological properties. This work was developed with a bottom-up approach. The utility of our platform in representing essential interactions of real systems must now be evaluated via a top-down approach.

The purpose of this work was to generate a system, devoid of any emergent property, which could be fully analyzed and controlled. This aim is significant, as clinicians or engineers cannot use devices that may produce some emergent properties beyond their control. Even with an incomplete analysis, we have, indeed, achieved some control in our model. Approaches that aim to produce, starting from scratch, real biological artificial systems potentially able to generate new emergent properties (Rasmussen et al., 2003) or to observe the apparition of emergent structures in virtual systems [i.e., Conway's Game of Life (Beer, 2011) or Swarm Chemistry (Sayama, 2009)] have a different goal: Their aim is to reproduce properties of interest or to explore or generate new ones, but not, at first, to fully explain or control them. Therefore, an analytic phase is necessary before any application of these works can be envisioned.

To consider more fully how this work may be developed and its usefulness as a tool for theoretical analysis, we must place it in context. At the present time, only partial representations of some biological properties are attainable. A complete representation of any living body—even the smallest—with enough definition that the movements of its molecules reproduces its biological properties is out of reach as molecular dynamic simulations require months of computing time to calculate the movements of a small protein during 1 millisecond (Broderick et al., 2005; Shaw et al., 2010). As a consequence, any representations of known biological structures faces the granularity problem: one must decide what real object each bit or tile will represent, creating a potentially endless hesitation between atoms or macro-

structures. Another problem, once this choice has been made, is the lack of compatibility between the representations of several different properties resulting from different analyses, which makes their re-combination impossible to study later (Hucka et al., 2003). The abstract representation proposed here is a consequence of these constraints: it aims to minimize the representation of the structures using a set of abstract forms—similar to symbols—to capture the essentials of the real network interactions.

Notably, four distinct languages were successively constructed in this work (three used here, one remains to be attained). The first deals with the basic representation of space (tiles containing links and associated operations) and offers only the possibility of combining them to represent more elaborate forms. The second language deals with this potentially limitless set of complex forms (made of combinations of tiles and links) and the operations performed on them (identification, movement, transformation, transport). The third language deals with the schematic representation of the system. The only information the symbols in this language should carry is their identity and localisation. The operations describe their movements and possible transports and transformations. The fourth should describe, in their simplest forms, the laws common to any similar system (here, all autopoietic individuals sharing the same set of regulations). As there exists the possibility to combine several representations developed within the same parameters, our platform could be convenient to individually represent distinct properties of biological systems as well as combinations of them.

### Abstract

One of the most important characteristics observed in metabolic networks is that they produce themselves. This intuition, already advanced by the theories of Autopoiesis and  $(M,R)$ -systems, can be mathematically framed in a weird looking equation, full of implications and potentialities:  $f(f) = f$ . This equation (here referred as *Ouroboros equation*), arises in apparently dissimilar contexts, like Robert Rosen's synthetic view of metabolism, hyperset theory and, importantly, untyped lambda calculus. In this paper we survey how Ouroboros equation appeared in those contexts, with emphasis on Rosen's  $(M,R)$ -systems and Dana Scott's work on reflexive domains, and explore different approaches to construct solutions to it. We envision that the ideas behind this equation, a unique kind of mathematical concept, initially found in biology, would play an important role towards the development of a true systemic theoretical biology.

### Introduction

Ouroboros (also written Uroboros), the ancient symbol of the snake eating its own tail, is often taken nowadays to represent self-reference and circularity. In this vein we call in this paper "Ouroboros equation", the ultimate self-referential equation  $f(f) = f$ .

Notice that  $f$  (supposedly a function) applies to itself, as an argument, the result being again  $f$ . So  $f$  plays simultaneously the roles of argument, function and value.

Recall that equation solving in mathematics has a long history, beginning with equations like  $2x = 1$ ,  $x + 3 = 1$ , up to  $x^2 = 2$  and  $x^2 = -1$ .

Each of these equations was solved introducing new species of numbers, some of them meeting strong resistance, like negative and imaginary numbers. Indeed methods developed to construct the irrational  $\sqrt{2}$  and the imaginary  $\sqrt{-1}$  may serve as metaphors to tackle the bigger and subtler challenge of constructing somehow solutions of Ouroboros equation  $x(x) = x$ . Since this equation suggests that  $x$  should be some sort of function, we will write it

$$f(f) = f.$$

in the sequel. However the main motivation to consider Ouroboros equation did not arise from everyday mathematics proper. It arose from various fields ranging from

Logic and Computer Science to Theoretical Biology. For these reasons, we call "Ouroboros avatars", the various manifestations or ways in which Ouroboros equation has emerged in different domains (although "avatar" means in fact "descent" in Sanskrit). We have then avatars of Ouroboros in Logic (Löfgren, 1968; Scott, 1972, 1973), Hyperset Theory (Aczel, 1988), Cognitive Sciences (Kampis, 1995; Kauffman, 1987), Computer Science and Informatics (Scott, 1972; Kampis, 1995; Milner, 2006), Systems Theory and Theoretical Biology (Rosen, 1991; Soto-Andrade and Varela, 1984; Maturana and Varela, 1980; Letelier et al., 2006, 2005), and others, that we review in the next sections.

A most remarkable fact, commented below, is the similarity of methods of constructing solutions to Ouroboros, developed in fields apparently as unrelated as logic (Scott, 1972, 1973) and metabolic systems theory (Letelier et al., 2006, 2005), motivated by the construction of actual mathematical models for untyped lambda calculus and virtual infinite regress in metabolic systems, respectively.

### Ouroboros is not an oxymoron

To begin with, it can be proved that Ouroboros is not an oxymoron, i.e. that the existence of an object  $f$  such that  $f(f) = f$ , belonging to its own domain and range, is not logically inconsistent (Löfgren, 1968; Kampis, 1995). It had been argued nevertheless that this was impossible (Wittgenstein, 1961) or paradoxical (Rosen, 1959). Instead, it turns out that an atomically self-reproducing entity can be axiomatized, and in this sense it really does exist (Löfgren, 1968). In fact Löfgren (1968) has shown that the axiom of complete self-reference is independent from usual set theory and logic, and can therefore be added to it as a new primitive axiom, that it is impossible to derive from the other axioms. Solutions to Ouroboros, as Quine's atoms  $Q = \{Q\}$  (Quine, 1980), appear then as completely self-referential, inapproachable, a perfectly closed class in itself (Kampis, 1995). Varela takes a similar stance, when he introduces self-referentiality from scratch as a third mark for self-indication or autonomous value (Varela, 1975), extending the indicational calculus of Spencer Brown (1969), and

later as a third logical value, besides true and false (Varela, 1979; Kampis, 1995).

Our viewpoint is however that Ouroboros lives indeed outdoors, with respect of our usual logical - mathematical realm, but just outside, in front of the door, say, so that it can be *approximated* stepwise "from within". This intuition has been captured to a great extent, in different guises, in Scott (1972, 1973); Soto-Andrade and Varela (1984), in Varela's further work (Varela and Goguen, 1978) and in Letelier et al. (2006), as we explain below.

## Ouroboros in Self-referential formalisms

As already said, Ouroboros equation  $f(f) = f$  involves self-reference, or more precisely, recursion (for a systematic overview of fields that deal with different forms of self-reference see Kauffman (1987)).

An interesting notion of recursion arises when dealing with its operative issues. This approach, linked with the theory of computing, has a strong relationship with the notion of *application*. It is not surprising that formalisms for abstracting the notions of function and program, like lambda calculus and the theory of recursion, are at the center of these developments.

The paradigmatic theory of functional application is the *simple* lambda calculus (i.e. with no distinction of types) (Barendret, 1984), introduced by Church (1951). In the untyped lambda calculus the equation  $f(f) = f$  has a trivial solution:  $\lambda x.x$ , that is, the identity function. The crucial point here is the absence of typing, something that cannot be realized with the identity function in classical mathematical structures (like vector spaces, groups, etc.), where argument and function belong to different types.

The very essence of the power of this formalism resides in that it overcomes the traditional mathematical notion of function as a set of pairs (input, output), by focusing instead on the composition and evaluation of functions. So formalisms like the lambda calculus are much better suited for the formalization of fields where the process of evaluation is most relevant or even the core of the phenomenon itself. Lambda calculus was disregarded by the logical and mathematical communities until the seventies. What brought their attention to lambda calculus was the work of Dana Scott providing mathematical models for this formalism. The idea is simple (not so much its implementation however...): finding spaces where these objects (lambda terms, that is, generalized functions) may live. To see the difficulties, let us exemplify the hierarchy of objects that can be created from a set  $U$ : functions with zero parameters (these are the elements of  $U$ ); functions with one parameter, that is,  $f : U \rightarrow U$ ; functions with two parameters,  $g : U \times U \rightarrow U$  and so on. All of them can be expressed in lambda calculus, that is, they should be elements of the wanted space  $D$ . In particular, in this typeless environment it should be possible to apply a function  $f : D \rightarrow D$  to itself, as another element of  $D$ .

It is worth reviewing the basic construction in Scott (1972, 1973), where continuity and limits play a central role, by restricting the universe of functions to be considered. The central question is:

"Are there nontrivial spaces  $D$  that can be identified (as topological spaces) with their function spaces  $[D \rightarrow D]$ , consisting of all continuous functions from  $D$  to  $D$ ?"

Scott showed that indeed there are many of them, and called them "reflexive domains". His idea was to start with a space  $D_0$ , with suitable properties (e.g. a continuous lattice), and try to identify its function space  $D_1 = [D_0 \rightarrow D_0]$  with  $D_0$ . A difficult task indeed, but we may notice that  $D_0$  can be embedded in  $D_1$ , by identifying each element  $d_0 \in D_0$  with the constant function in  $D_1$  with value  $d_0$ , and also that  $D_1$  can be projected onto  $D_0$  by sending each (continuous) function  $d_1 \in D_1$  to its minimum value  $d_1(\perp)$  (where  $\perp$  is the least element of the complete lattice  $D_0$ ). Call  $i_0$  and  $p_0$  the embedding and the projection so defined. This allows us to embed in a clever way  $D_1 = [D_0 \rightarrow D_0]$  into  $D_2 = [D_1 \rightarrow D_1]$ , by sending each  $d_1$  to  $i_0 \circ d_1 \circ p_0$  and - dually - to project  $D_2$  onto  $D_1$  by sending  $d_2$  to  $p_0 \circ d_2 \circ i_0$  and so on, to obtain iteratively a double chain of embeddings from  $D_n$  into  $D_{n+1} = [D_n \rightarrow D_n]$ , and projections from  $D_{n+1}$  onto  $D_n$ , for all  $n$ . We obtain then the wanted reflexive domain as the limiting space  $D_\infty$  of this double sequence of continuous maps between continuous lattices.

Regarding our interest here, the later result shows that there is a space where Ouroboros equation at least makes sense, i.e. it "types". To the best of our knowledge, Scott did not consider this equation explicitly, although several notions of his come close to it.<sup>1</sup>

Scott's construction inspired the limiting construction of a self-referential extension of Spencer Brown (1969) calculus of indications by Varela and Goguen (1978), where they endow the collection of all forms that can be constructed in Brown's setting with the same sort of structure that Scott (1972) considered, i.e. chain complete partially ordered sets (posets). In their setting fully self-referential equations like Ouroboros' would have solutions. That is a different way to extend Brown's setting that the one in Varela (1975).

Scott's construction also inspired later the construction of reflexive domains in the context of posets and monotone mappings with suitable continuity properties, carried out in Soto-Andrade and Varela (1984), where the relationship between the existence of fixed points and several instances of self - reference is also discussed (notice that a reflexive domain  $D$  is a fixed point for the function  $D \mapsto [D \rightarrow D]$ ).

Another formalism where Ouroboros equation arises naturally is hyperset theory (also called non well founded set theory). Hypersets constitute an extension of usual set theory, that allow sets to be members of themselves, like Quine's atom  $Q = \{Q\}$  (Quine, 1980; Aczel, 1988). We

<sup>1</sup>See for example Proposition 3.14 in Scott (1972)

meet among them baby Ouroboros like  $f = \{(f, f)\} = \{\{f, \{f\}\}\}$ , that satisfy  $f(f) = f$ , if we identify the function  $f$  with its graph and choose the usual set theoretical model  $\{a, \{b\}\}$  for ordered pairs  $(a, b)$ .

As discussed in Löfgren (1968) and Kampis (1995), self-reference is closely tied to language. Hence it is not surprising that formalisms that allow to break the classical hierarchies between language and metalanguage, or as in hyper-sets, between container and containee, can provide solutions to the Ouroboros equation. Up to now however, these formalisms do not seem to have been meaningfully exploited in the context of biological self-reference and circularity (see Cárdenas et al. (2010) more a more detailed survey).

### Ouroboros in $(M, R)$ systems: Infinite regress face to face

We turn now to Rosen's synthetic insights regarding metabolic circularity, that he developed completely independently of Scott (for a comprehensive survey of references about Rosen's work see Cárdenas et al. (2010)). In his formalism of  $(M, R)$  systems, the collective action of the thousands of catalysts in a metabolic network  $M$  coalesces into a single mapping  $f$  from  $A$ , the collection of all sets of reactants, to  $B$ , the collection of all sets of products, that transforms inputs  $a \in A$  into outputs  $b = f(a) \in B$ .

But in any metabolic system, catalysts are subject to degradation, wear and tear, and therefore need to be regenerated or replaced by the system. To meet this requirement, Rosen looked upon the replacement mechanism as a procedure, denoted by  $\Phi$ , that, from a suitable  $b = f(a) \in B$  as input, reproduces  $f$  according to  $\Phi(b) = f$ . Because the net effect of  $\Phi$  is to select from the relatively large set  $H(A, B) \subset \text{Map}(A, B)$ , of all possible metabolisms, a specific  $f$  such that  $f(a) = b$ , using  $b \in B$  as an input, Rosen calls it a *selector*. Thus, the procedure  $\Phi$  representing replacement appears as a map from  $B$  to  $H(A, B)$ .

Then an  $(M, R)$  system has the following algebraic description based on two mappings  $f, \Phi$  acting in synergy:

$$\begin{aligned} A &\xrightarrow{f} B \xrightarrow{\Phi} H(A, B) \\ a &\mapsto f(a) = b \mapsto \Phi(b) = f \end{aligned}$$

But now, it is possible to go further and demand the system to be capable of replacing the replacer, or selector,  $\Phi$ : a replicative  $(M, R)$  system in Rosen's terminology (this property is also referred as *organizational invariance* (Cárdenas et al., 2010)). More precisely,  $\Phi$  should be generated with the help of a procedure that, given a metabolism  $f$ , produces the corresponding  $\Phi$  that selects metabolism  $f$ , that is a mapping  $\beta : H(A, B) \rightarrow H(B, H(A, B))$  such that  $\beta(f) = \Phi$ , and so on... The big question is then, how can this be, without implying infinite regress?

Rosen's solution to avoid infinite regress, was to posit that the equation  $\Phi(b) = f$  is to have only one solution  $\Phi$  (a

most demanding constraint indeed!) so that the mapping  $\beta$  sends  $f$  to this unique selector  $\Phi$ . In other words,  $\beta$  is "just" the inverse of the "evaluation at  $b$ " operator (acting on functions whose domain contains  $b$ ) so that no further procedure is needed to construct  $\beta$  itself. It is in this sense that Rosen claims that his construction solves the problem of infinite regress. Rosen was however unable to give concrete examples where this hypothesis was fulfilled.

The operation of an *organizationally invariant*  $(M, R)$  system can therefore be viewed as three mappings  $(f, \Phi, \beta)$  acting in synergy:

$$\begin{aligned} A &\xrightarrow{f} B \xrightarrow{\Phi} H(A, B) \xrightarrow{\beta} H(B, H(A, B)) \\ f(a) &= b, \quad \Phi(b) = f, \quad \beta(f) = \Phi. \end{aligned}$$

where  $\beta$  is the inverse of the "evaluation at  $b$ " operator.

Now, if instead of shunning infinite regress, as Rosen did, we look at it "face to face", a recursive construction emerges, whose first step is motivated by the question:

If you have a map  $f : A \rightarrow B$ , can you find a new map  $f_1 : B \rightarrow C$  such that for a suitable  $a \in A$  you have  $f_1(f(a)) = f$  or, equivalently  $f_1(b) = f$ ;  $b = f(a)$ ?

Of course, the answer to this question, taken at face value, when  $A, B$  and  $C$  are plain (unstructured) sets and  $f$  and  $f_1$  are set mappings, is "Obviously, yes", since you have plenty of maps from one set to another which take a prescribed value on a given point. Just take  $C$  to be the set  $\text{Map}(A, B)$  of all mappings from  $A$  to  $B$  and  $f_1$  to be any mapping from  $B$  to  $C$  such that  $f_1(b) = f$ .

However this question becomes more intelligent when stated in a categorical framework, typically when we consider our sets endowed with some sort of structure and have our maps preserve this structure.

Then, if we take our structured sets to be vector spaces, our maps would be linear; if our sets are posets (i.e. partially ordered sets), our maps ought to be monotone (order preserving). If our sets were endowed with a metric, or distance, then our allowed mappings might be continuous, or even "isometric", i. e. "distance - preserving" mappings. Structure preserving mappings are usually called "homomorphisms". For instance, the homomorphisms between vector spaces are linear mappings.

Now we can state the categorical version of our question: In a category (of structured sets and structure preserving mappings, say), given a homomorphism  $f : A \rightarrow B$ , can you find a new homomorphism  $f_1 : B \rightarrow C$  such that for a suitable  $a \in A$  you have  $f_1(b) = f$ , where  $b = f(a)$ ?

The subtlety now lies in the fact that to carry over our obvious set theoretical solution to the categorical setting, we need to find among all mappings  $f_1$  such that  $f_1(b) = f$ , one which is well behaved enough to be a *homomorphism* from the structured set  $B$  to *another structured set*  $C$ . We would be happy then to know that the set  $H(A, B)$ , consisting of all homomorphisms from  $A$  to  $B$ , may be endowed with the same (type of) structure than  $A$  and  $B$ . If it is the case, we would take  $C$  to be  $H(A, B)$ , and we would be

all set up to seek a homomorphism  $f_1$  from  $B$  to  $C = H(A, B)$ , which takes the value  $f$  at point  $b \in B$ .

Recall now that Rosen, to avoid infinite regress, posited the uniqueness of such a function  $f_1$ , called  $\Phi$  in his setup (Rosen, 1991; Letelier et al., 2006).

It is clear however that in the category of sets, where the existence of such an  $f_1$  is obvious, uniqueness is impossible (unless  $B$  is a singleton). Nevertheless, if you change the underlying category (i.e. the stage for the problem) so as to have a category whose sets of homomorphisms  $H(X, Y)$  are much smaller than  $Map(X, Y)$ , i.e. become more and more selective, existence may become less and less obvious and uniqueness may become more and more possible.

We may hope then for the existence of a *turning point* in the choice of our category, at which the sets of homomorphisms  $H(X, Y)$  would have the right size so as to have simultaneously existence and uniqueness of our homomorphism  $f_1$ . Rosen's dream was that such *turning points* (or better, *turning categories*) exist, where his hypothesis would be fulfilled! They might indeed be dubbed "metabolic categories."

If we look however infinite regress face to face and we do not care about uniqueness, we could continue our construction above forever, in the spirit of Soto-Andrade and Varela (1984) under a mild hypothesis of existence of our homomorphisms  $f_1$ , in the framework of a *concrete category*  $\mathcal{C}$ , i.e. a category of structured sets and structure preserving maps (the only ones that we will consider in this article).

### Hypothesis 1. (Existence of "replacing homomorphisms")

We assume that given any homomorphism  $f : A \rightarrow B$  in our concrete category  $\mathcal{C}$ , we can choose  $a \in A$  such that the following hold:

- there exists a homomorphism  $f_1 : B \rightarrow H(A, B)$ , such that  $f_1(f(a)) = f$  (we say then that  $a \in A$  is an  $f$ -generic element),
- there exists a homomorphism  $f_2 : H(A, B) \rightarrow H(B, H(A, B))$ , such that  $f_2(f_1(f(a))) = f_1$  (i.e.  $f(a)$  is  $f_1$ -generic), and so on...

Notice that this hypothesis requires implicitly that,  $A$  and  $B$  being any objects in  $\mathcal{C}$ , the set of homomorphisms  $H(A, B)$  should also be an object in  $\mathcal{C}$ , i.e. it can be endowed with the same structure as  $A$  and  $B$ . Also, simple examples (see below) show that it is not to be expected that every  $a \in A$  be  $f$ -generic for a given  $f : A \rightarrow B$ .

**Example 1.** In the category of (finite dimensional) vector spaces and linear mappings, our hypothesis is clearly fulfilled. Indeed, if  $f$  is the null mapping 0, we just take  $a = 0$  and  $f_1, f_2, \dots$  to be 0 all the way. If  $f \neq 0$ , take  $a$  to be any non zero vector in  $A$ , such that  $f(a) \neq 0$  and then  $f_1$  to be any linear mapping from  $B$  to  $H(A, B)$  sending  $f(a)$  to  $f$ ,  $f_2$  to be any linear mapping sending  $f$  to  $f_1$ , and so on. These (non zero!) linear maps exist recursively by the well known elementary "linear extension property" for finite

dimensional vector spaces, saying that you can always construct linear mappings from one vector space  $V$  to another that take a prescribed value at a given non zero vector in  $V$ .

**Example 2.** In the category of additive groups and addition preserving maps, we take  $A = B = \mathbb{Z}_3^+$ , the set of integers  $0, 1, 2 \bmod 3$  endowed with the operation  $+$  of addition mod 3. Notice that  $1 + 1 + 1 = 0 \bmod 3$ . Then  $H(A, A) = \{h_a | a \in A\} \simeq A$ , where  $h_a$  is the "scaling map" with ratio  $a$ , that sends  $b$  to  $ab$  ( $b \in A$ ), which we identify with  $a \in A$ , writing  $h_a = a$ . So we identify the mapping  $h_a$  with its value  $a$  at 1. The set  $H(A, A)$  endowed with the operation of addition of mappings is also an additive group, isomorphic to  $A$ , and  $h_a + h_b = h_{a+b}$  ( $a, b \in A$ ).

If we take now  $f$  to be the null mapping  $h_0 = 0$ , we see that for any  $a \in A$ , every  $f_1 : A \rightarrow H(A, A)$ , satisfies  $f_1(f(a)) = f$ , since  $f_1(f(a)) = f_1(0) = 0 = h_0 = f$ . Hence any  $a \in A$  is  $h_0$ -generic and we may take  $f_1$  to be  $h_0, h_1$  or  $h_2$  (i.e. such that  $f_1(1) = h_0, h_1$  or  $h_2$ ). The choice of  $f_1$  becomes relevant when we go one step further, asking now for a homomorphism  $f_2 : H(A, A) \rightarrow H(A, H(A, A))$  such that  $f_2(f) = f_1$ . In a diagram:

$$\begin{array}{ccccc} A & \xrightarrow{f} & A & \xrightarrow{f_1} & H(A, A) & \xrightarrow{f_2} & H(A, H(A, A)) \\ a \mapsto f(a) & \mapsto & f & \mapsto & f_1 \end{array}$$

Indeed, since  $f = h_0$ , we have that necessarily  $f_2(f) = f(0) = 0 = h_0$ , so  $f$  is  $f_1$ -generic only for  $f_1 = h_0$ , but not for  $h_1$  or  $h_2$ . On the other hand, if we begin with  $f = h_2$  instead of  $h_0$ , then for any non zero  $a \in A$ , we find a *unique*  $f_1 : A \rightarrow H(A, A)$  such that  $f_1(f(a)) = f$ , since the equation amounts to  $f_1(2a) = 2$ , i.e.  $x2a = 2$ , i.e.  $x = a^{-1}$ , if we write  $f_1 = h_x$ . So every non zero  $a \in A$  is  $f$ -generic in this case but 0 is not, since  $f_1(f(0)) = h_0$ .

Applying now our hypothesis recursively, we can construct the following infinite sequence of homomorphisms (and objects) in our concrete category  $\mathcal{C}$ , issued from any homomorphism  $C_0 \xrightarrow{\Phi_0} C_1$  in  $\mathcal{C}$ :

$$\begin{array}{ccccccccccc} C_0 & \xrightarrow{\Phi_0} & C_1 & \xrightarrow{\Phi_1} & C_2 & \xrightarrow{\Phi_2} & C_3 & \xrightarrow{\Phi_3} & \dots & \xrightarrow{\Phi_{n-1}} & C_n & \xrightarrow{\Phi_n} & C_{n+1} & \xrightarrow{\Phi_{n+1}} & \dots \\ c_0 & \rightarrow & c_1 & \rightarrow & c_2 & \rightarrow & c_3 & \rightarrow & \dots & \rightarrow & c_n & \rightarrow & c_{n+1} & \rightarrow & \dots \end{array}$$

satisfying the following:

$$C_2 = H(C_0, C_1), \dots, C_{n+1} = H(C_{n-1}, C_n)$$

so that  $\Phi_n \in H(C_n, C_{n+1}) = C_{n+2}$ ,

$$\Phi_1(\Phi_0(c_0)) = \Phi_0 \quad \text{for a suitable } c_0 \in C_0,$$

$$\Phi_n(c_n) = c_{n+1} \in C_{n+1} \quad (n \geq 0) \quad \text{and}$$

$$\Phi_{n+1}(\Phi_n(c_n)) = \Phi_n \quad \text{for all } n \geq 1;$$

Notice that to have consistent notations, we have renamed  $A$  to  $C_0, B$  to  $C_1, C$  to  $C_2; f$  to  $\Phi_0, f_1$  to  $\Phi_1$ .

Moreover, since  $\Phi_0(c_0) = c_1$  we have  $\Phi_0 = \Phi_1(c_1) = c_2$ , and inductively,

$$\Phi_n = \Phi_{n+1}(\Phi_n(c_n)) = \Phi_{n+1}(c_{n+1}) = c_{n+2} \quad (n \geq 0),$$

in other words,  $c_n = \Phi_{n-2}$  for all  $n \geq 2$ , so that

$$\Phi_{n+1}(\Phi_n(c_n)) = \Phi_{n+1}(c_{n+1}) = \Phi_{n+1}(\Phi_{n-1}) = \Phi_n,$$

showing how the homomorphisms  $\Phi_n$  play here alternatively the role of argument, function and value...

We have then three different but equivalent ways to state the recursive relationship between the  $\Phi_n$ 's:

1.  $\Phi_{n+1}(\Phi_n(c_n)) = \Phi_n$
2.  $\Phi_{n+1}(\Phi_{n-1}) = \Phi_n$
3.  $\Phi_{n+1}(c_{n+1}) = \Phi_n$

Remark now that the last one may be written

$$ev_{c_{n+1}}(\Phi_{n+1}) = \Phi_n$$

in terms of the “evaluation at  $x$ ” mappings  $ev_x : f \mapsto f(x)$ . So the following “reverse” sequence of mappings and elements emerges, where each  $C_n$  “projects” onto  $C_{n-1}$ :

$$\begin{array}{ccccccc} C_1 & \xleftarrow{ev_{c_0}} & C_2 & \xleftarrow{ev_{c_1}} & C_3 & \xleftarrow{ev_{c_2}} & \dots \xleftarrow{ev_{c_{n-2}}} C_n \xleftarrow{ev_{c_{n-1}}} \dots \\ c_1 & \xleftarrow{ev_{c_0}} & \Phi_0 & \xleftarrow{ev_{c_1}} & \Phi_1 & \xleftarrow{ev_{c_2}} & \dots \xleftarrow{ev_{c_{n-2}}} \Phi_{n-2} \xleftarrow{ev_{c_{n-1}}} \dots \end{array}$$

This sequence of evaluation maps  $ev_{c_n}$  forms what mathematicians call a *projective (or inverse) system of mappings*. In the category of sets and mappings, every such system of mappings, call it

$$C_1 \xleftarrow{p_1} C_2 \xleftarrow{p_2} C_3 \xleftarrow{p_3} \dots \xleftarrow{p_{n-1}} C_n \xleftarrow{p_n} C_{n+1} \xleftarrow{p_{n+1}} \dots$$

has a (projective) “limit”, which is rigorously characterized as the set  $C^\infty$  consisting of all sequences  $(c_1, c_2, \dots, c_n, \dots)$  of “coherent” choices of elements  $c_n \in C_n$  (“coherent” meaning here that each  $c_n$  “projects” onto  $c_{n-1}$ , i.e.  $p_{n-1}(c_n) = c_{n-1}$ ). This projective limit set  $C^\infty$  “projects” also in a natural way onto each  $C_n$ , sending each sequence to its  $n$ -th term  $c_n$ . Intuitively, this construction allows us to get hold as elements in the limit set  $C^\infty$ , of “mythical” or “ideal” objects” that cast a series of approximating down to earth “shadows” (the  $c_n$ 's). In concrete categories we may expect moreover that the structure we have on all  $C_n$ 's will carry over to the limit set  $C_\infty$ , which will become then a bona fide object in our category, projecting itself by homomorphisms onto each  $C_n$ .

**Digression: A baby projective limit.** To convey a better insight into projective limits, we recall here a baby example from Soto-Andrade and Varela (1984), that highlights their elementary set theoretical nature.

Consider the increasing nested sequence of finite sets

$$C_n = \{1, 2, \dots, n\} \quad (n = 1, 2, 3, \dots),$$

whose union is the set  $\mathbb{N}$  of all natural numbers. This sequence of sets becomes a projective system if we “project downwards”, or “contract inwards” each  $C_{n+1}$  onto the smaller  $C_n$  by sending every  $m \leq n$  to itself and  $n+1$  to  $n$ . Call these projections (or contractions)  $p_n$ . So on  $C_{n+1}$  we have  $p_n(n) = n = p_n(n+1)$ . The projective limit  $C^\infty$  can be intuited now as the set of all numbers in  $\mathbb{N}$  plus an extra “mythical boundary point”  $+\infty$ , situated at the far right of all natural numbers.

Indeed, going back to the precise definition of  $C^\infty$ , we see that the points  $m \in \mathbb{N}$  appear as “limits” of the sequences of coherent choices  $(1, 2, \dots, m-1, m, \dots, m, \dots)$  that after a while “stutter” indefinitely or become “constant”. But we also have the coherent chain of choices given by  $1 \in C_1$ ,  $2 \in C_2$ ,  $3 \in C_3$ , and so on. Notice that each  $m \in C_n$  is the “ancestor” of the preceding  $m-1 \in C_{m-1}$ .

This sequence of choices represents then our “mythical far right boundary point”  $+\infty$ , whose  $n$ -th projection is  $n$ . Analogously, we may obtain  $\{-\infty\} \cup \mathbb{Z} \cup \{+\infty\}$  as a projective limit. This shows concretely how the projective limit allows us to get hold of “mythical” or “ideal” objects that cast a series of approximating down to earth “shadows”.

Recall that also fractals, a paradigmatic example of “mythical shapes”, may be looked upon in this way, as projective limits of everyday shapes (*loc. cit.*).

**Properties of the limit objects  $C^\infty$  and  $\Phi_\infty$ .** The coherent sequence  $\Phi_n$  in the system of evaluation maps  $ev_{c_n}$  is an element of the projective limit  $C^\infty$ . We call it  $\Phi_\infty$  and we write  $\Phi_\infty = \lim_{n \rightarrow \infty} \Phi_n$  to convey the intuition that  $\Phi_\infty$  is a kind of “limit” of the  $\Phi_n$ 's as  $n$  tends to  $\infty$ . Notice that this quite analogous to the way in which a “rational” person constructs  $\sqrt{2}$  with the help of Cauchy sequences of rational numbers. Now, intuitively, by passing to the limit as  $n$  tends to  $\infty$  in the recursive relation  $\Phi_{n+1}(\Phi_{n-1}) = \Phi_n$  we obtain the stunning self referential equation

$$\Phi_\infty(\Phi_\infty) = \Phi_\infty,$$

saying that  $\Phi_\infty$  is a *solution to Ouroboros equation!*

Analogously, making  $n$  tend to  $\infty$  in the equation  $C_{n+1} = H(C_{n-1}, C_n)$ , we get

$$C_\infty = H(C_\infty, C_\infty),$$

so that  $C_\infty$  is a reflexive domain, as in Soto-Andrade and Varela (1984). We will not go here into the rigorous justification of this passage to the limit, since it involves a more precise description of  $\Phi_\infty$  as a mapping in  $H(C_\infty, C_\infty)$ , taking into account the double system of mappings  $\Phi_n : C_n \rightarrow C_{n+1}$  and  $ev_{c_n} : C_n \leftarrow C_{n+1}$ , as in Scott (1972).

Apparently no mathematician imagined this recursive procedure to construct solutions of Ouroboros equation before Rosen introduced his  $A \xrightarrow{f} B \xrightarrow{\Phi} H(A, B)$  setup as a formal description of metabolism (Rosen, 1958; Letelier et al., 2005). Notice that this construction is quite different although formally analogous to Scott's (Scott, 1972, 1973).

**An arithmetical avatar of Ouroboros.** Generalizing example 2 above, we put  $C_0 = C_1 = A = \mathbb{Z}_m^+$ , the set of integers  $0, 1, 2, \dots, m-1 \bmod m$ , endowed with the operation  $+$  of addition mod  $m$ . Then  $C_2 = H(A, A) = \{h_a | a \in A\} \simeq A$ , where  $h_a : b \mapsto ab$  for all  $b \in A$  and we identify as before each  $h_a$  with  $a$ . We endow  $H(A, A)$  with the operation of addition of mappings.

Now, since recursively  $H(A, A) \simeq A$ ,

$$H(A, H(A, A)) \simeq H(A, A) \simeq A,$$

$$H(H(A, A), H(A, H(A, A))) \simeq H(A, A) \simeq A$$

and so on, we have that all  $C_n$  are isomorphic to  $A$ .

To identify the mappings  $\Phi_n$  we need then only to solve multiplicative equations  $ax = b \bmod m$  in  $A$ . If  $m = 3$ , as in example 2 we choose  $c_0 = 1 \bmod 3$  and  $\Phi_0 = h_2 = 2$ . Then  $c_1 = 2$  and  $\Phi_1 = h_1 = 1$ , and our coherent sequence begins  $1 \xleftarrow{h_2} 2 \xleftarrow{h_1} 2$ . Next, we must look for  $\Phi_2$  such that

$\Phi_2(2) = h_1$ , i.e. for  $a \in A$  such that  $a \cdot 2 = 1$ , so  $a = 2$ .

It follows recursively that our sequence will look like

$$1 \xrightarrow{h_2} 2 \xleftarrow{h_1} 2 \xrightarrow{h_2} 1 \xleftarrow{h_2} 2 \xrightarrow{h_1} 2 \xleftarrow{h_2} 1 \xrightarrow{h_2} 2 \xleftarrow{h_1} 2 \xrightarrow{h_2} \dots$$

so, intuitively,  $\Phi_\infty$  is the “limit” of this “wave like” oscillating sequence, although formally  $\Phi_\infty$  is this sequence.

Notice also that our sequence  $\Phi_\infty$  is a multiplicative analogue mod 3 of the ubiquitous Fibonacci sequence: Instead of  $c_{n+1} = c_n + c_{n-1}$  we have  $c_{n+1} = c_n \cdot c_{n-1} \bmod 3$ .

If we take now  $m = 10$ , for instance, and we put  $c_0 = 3$  and  $\Phi_0 = h_9$ , so that  $c_1 = 7$ , we find recursively that  $\Phi_\infty$  is embodied in the projective sequence

$$3 \xleftarrow{h_9} 7 \xleftarrow{h_3} 9 \xleftarrow{h_7} 7 \xleftarrow{h_9} 3 \xleftarrow{h_7} 9 \xleftarrow{h_3} 3 \xleftarrow{h_9} 7 \xleftarrow{h_3} 9 \xleftarrow{h_7} 7 \xleftarrow{h_9} 3 \dots$$

Translating back into Rosen’s original terminology, we have here  $a = 3$ ,  $b = 7$ ,  $f = 9$ ,  $\Phi = 7$ , but  $\beta = (ev_b)^{-1} = 3$ , the inverse of  $b$ . So  $\beta$  may be reasonably identified with  $b^{-1}$  but not with  $b$ , as pointed out in Cárdenas et al. (2010).

**A linear avatar of Ouroboros.** We sketch here a linear example where sets of “metabolites” are vector spaces instead of integers modulo  $m$ , so that structure preserving mappings are linear. We denote by  $M_{m,n}$  the set of all real matrices with  $m$  rows and  $n$  columns, identified as usual with linear mappings from  $\mathbb{R}^n$  to  $\mathbb{R}^m$ . We put

$C_0 = \mathbb{R}^2 = M_{2,1}$ ,  $c_0 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ ,  $C_1 = \mathbb{R} = M_{1,1}$  and  $\Phi_0 = \begin{pmatrix} 1 & 0 \end{pmatrix}$  (the first projection of  $\mathbb{R}^2$  onto  $\mathbb{R}^1$ ). Then we find recursively

$c_1 = 1$ ;  $C_2 = H(C_0, C_1) = M_{1,2} \simeq \mathbb{R}^2$ ;  $c_2 = \Phi_0 = \begin{pmatrix} 1 & 0 \end{pmatrix}$ ;  $\Phi_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ , since  $\Phi_1(c_1) = \Phi_0$ ;

$C_3 = H(C_1, C_2) = M_{2,1} \simeq \mathbb{R}^2$ ;  $c_3 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ ;  $\Phi_2 = Id_2 \in M_{2,2}$  or any matrix with first column  $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ ;

$C_4 = H(C_2, C_3) = M_{2,2} \simeq \mathbb{R}^4$ ;  $c_4 = \Phi_2$ ,  $\Phi_3$  being any matrix with first column  $\begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \end{pmatrix}$  if  $\Phi_2 = Id_2$ ;

$C_5 = H(C_3, C_4) = M_{4,2} \simeq \mathbb{R}^8$ , and so on, where we identify matrices with row or column vectors reading their coefficients as usual text. Notice the recursive multiplicative Fibonacci rule  $d_{n+1} = d_n \cdot d_{n-1}$  for  $d_n = \dim C_n$ .

Notice that Rosen’s demanding assumption on the invertibility of the evaluation at  $b (= c_1)$  is satisfied in the arithmetical realization above, where in fact *all* evaluation maps are invertible. In the linear example, the map  $ev_{c_1}$  is still invertible, although the subsequent evaluation maps are not. In particular, any  $2 \times 2$  matrix with first column  $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$  would do as  $\Phi_2$ .

## Ouroboros in Autocatalytic Sets

Here we will approach Ouroboros equation in the spirit of Jaramillo et al. (2010), where attempting to relate the theories of  $(M,R)$  systems and Replicative Autocatalytic Sets (Hordijk and Steel, 2004), a framework for treating molecules as operators was proposed. We will use here the term “metabolism” as synonym of “metabolic network”.

We look upon a metabolism as a directed graph  $\mathcal{M}$  whose set of nodes  $P(X)$  is the collection of all subsets of the set  $X$  of all metabolites and catalysts involved in the metabolism and whose set of arrows  $R$  is given by the reactions  $A \rightarrow B$  in the metabolism ( $A, B \subset X$ ). Molecules  $x$  in  $X$  not produced by the metabolism are coded as reactions of the form  $\emptyset \rightarrow x$ , where the empty set symbol  $\emptyset$  stands for the environment seen as a virtual molecule. We assume further that every metabolite  $x \in X$  appears in the target of some arrow in  $\mathcal{M}$ . Catalysts are defined by a map  $C : R \rightarrow X$  that assigns a molecular identity to the catalyst of each reaction in  $R$ . Of course, we assign the empty catalyst  $\emptyset$  to any arrow (reaction) with source  $\emptyset$ .

A *premetabolism*  $\mathcal{M}'$  of the metabolism  $\mathcal{M}$  is generated by a subset  $X' \subset X$ , by taking  $P(X')$  as the set of nodes of  $\mathcal{M}'$  and all arrows in  $\mathcal{M}$  whose source lies in  $P(X')$ , as its set of arrows.

There is now a natural sense in which a premetabolism  $\mathcal{M}'$  may be applied to itself, giving raise to a new premetabolism noted  $\mathcal{M}' \circ \mathcal{M}'$ : look at  $\mathcal{M}'$  and just carry out every possible reaction indicated by  $\mathcal{M}'$ ; then collect all the resulting metabolites together to form the metabolite set  $X''$  of the premetabolism  $\mathcal{M}' \circ \mathcal{M}'$ .

Ouroboros avatar in this context reads then

$$\mathcal{M}' \circ \mathcal{M}' = \mathcal{M}'$$

To illustrate this formalism let us introduce a simple molecular system which is an  $(M,R)$  system and a Replicative Autocatalytic Set, taken from Letelier et al. (2006):

This defines a metabolism  $\mathcal{M}$  based on  $X = \{S, T, U, ST, SU, STU\}$ , with  $R$  and  $C$  given by the three reactions above together with  $\emptyset \xrightarrow{\emptyset} S$ ,  $\emptyset \xrightarrow{\emptyset} T$ ,  $\emptyset \xrightarrow{\emptyset} U$ . Now, writing just  $X'$  for a premetabolism  $\mathcal{M}'$ , we can calculate for instance:

$$\{S, T, SU, STU\} \circ \{S, T, SU, STU\} = \{S, T, ST\},$$

$$\{S, T, ST\} \circ \{S, T, ST\} = \{S, T\},$$

$$\{S, T\} \circ \{S, T\} = \{S, T\},$$

so this premetabolism dies out to a trivial solution of Ouroboros equation (i.e. one whose associated reactions are all of the form  $\emptyset \xrightarrow{\emptyset} x$ ). On the contrary, we have  $\{S, T, U, SU, ST, STU\} \circ \{S, T, U, SU, ST, STU\} = \{S, T, U, SU, ST, STU\}$ ,

i.e.  $\{S, T, SU, ST, STU\}$  defines a non trivial solution to Ouroboros equation!

## Ouroboros in Autopoietic systems

Before concluding we would like to bring in the theory of Autopoiesis, as it has deep connections to the idea of

Figure 1: Original cover of the book introducing autopoietic systems (Maturana and Varela, 1973). Although the notion of self-reference is not explicitly mentioned in the book, the authors chose an Ouroboros to illustrate its cover.

self-reference. In fact one of its creators, Varela spent almost a decade looking for a suitable framework to formalize the notions behind this connection (Varela, 1975; Varela and Goguen, 1978; Varela, 1981; Soto-Andrade and Varela, 1984). We won't attempt to reproduce his results, but instead show why self-reference arises from the conceptualization of Autopoiesis theory.

First, we should introduce the perspective of Maturana and Varela for defining a system. A system (or machine) is defined as a unity distinguishable from its surroundings, characterized by two concepts: *organization* and *structure*. The former relates to all processes (or relations) that define the system as a unit and that determine the dynamics of transformations and interactions that the system may undergo as such a unit. The latter are all actual relations that hold between the components of the system in a given space and time (Maturana and Varela (1980), pages 77-84). Now we can define an Autopoietic system (*loc. cit.*) as a network of processes of production, such that its components satisfy the following:

- i) through their interactions and transformations regenerate and realize the network of processes that produced them;
- ii) constitute the system as a concrete unity in the space in which the components exist by specifying the topological domain of its realization.

The first property of Autopoietic systems can be interpreted as a description of a closed network of production or *metabolic closure*, where the elements needed for the occurrence of each step of the network (such as catalysts) are produced by the network itself. From a dynamical perspective, can also be viewed as non trivial fixed-points of the network dynamics. The notion of *metabolic closure* is com-

mon and comparable between several theories of living systems (see Cárdenas et al. (2010) for references). However, Autopoiesis demands more than self-production. What is maintained and reconstituted through the system's dynamics is its *organization*, i.e. what makes it distinguishable as a unit. This is secured in time by the first property and in space by the second. Therefore, if we were to define an autopoietic system we would be tempted to say something like "a unit that regenerates what distinguishes itself as a unit...".

As the last idea suggests, *organizational invariance* can be understood as an ultimate case of recursion or self-reference. In the previous sections we have discussed how to find consistent and non trivial cases where self-reference is possible; future challenges would involve bringing both properties of autopoietic systems into our framework.

## Conclusion and final remarks

As we have surveyed here,  $f(f) = f$  is an intriguing equation that abstracts phenomena from many fields. It must be underlined that our interest in this topic arose from a very basic (and unsolved) question in theoretical biology: "What is a correct theoretical framework to formalize systems that construct themselves?". Metabolism is an outstanding example, as the action of metabolism results in the reconstitution of the components that were responsible for its occurrence in the first place.

We are of the opinion that, in order to construct a formalism that captures Metabolism from the perspective of Autopoiesis and  $(M,R)$ -systems, self-reference is an unavoidable point to consider - not to be confused with simulations of Metabolism, which we regard as complementary efforts. As presented in this paper, dealing with self-reference mathematically, even if it seems to challenge our classical conceptions, is certainly feasible.

Nevertheless, we are aware that the methods exposed are still halfway towards a definitive theory. In particular we should be able to move beyond hypothetical examples into a framework closer to concrete biological systems. Towards this goal there are several avenues for improvement. For instance, so far we have interpreted Metabolism as a network of reactions and catalysis, leaving for later other dimensions of Metabolism, such as time. Self-reference could be regarded as identity conservation under the Metabolic dynamics (Varela, 1975; Varela and Goguen, 1978), and we expect that adding the temporal dimension should allow us to ask more complex questions, closer to molecular systems. Also, we haven't looked closely at the physicochemical properties of Metabolism, which may provide a grounding as well as a guide for our mathematical models.

In another avenue, one of the main lessons is the vanishing dichotomy between operand and operator, implicit in  $f(f)$ . This suggest that the phenomena of interaction more than application (in the old functional sense), or concurrency more than sequentiality, may constitute a more appropriate

metaphor. As it is well known, life phenomena are intrinsically concurrent, and as such, it appears natural that the emerging formalisms for concurrency are beginning to be applied to this field (Milner, 2009; Cardelli, 2005). We wonder whether there may be avatars of Ouroboros lurking in the concurrent world, an interesting question to explore in future work.

## Acknowledgments

We would like to dedicate this paper to the memory and work of Francisco Varela, friend and mentor.

# Recruitment, Selection and Alignment of Spatial Language Strategies

Michael Spranger<sup>1</sup>

<sup>1</sup>Sony CSL Paris, 6 rue Amyot, 75005 Paris, France  
spranger@csl.sony.fr

## Abstract

All languages of the world have a way to talk about space and spatial relations of objects. Cross-culturally, immense variation in how people conceptualize space for language has been attested. Different spatial conceptualization strategies such as *proximal*, *projective* and *absolute* have been identified to underlie peoples conception of spatial reality. This paper argues that spatial conceptualization strategies are negotiated in a cultural process of linguistic selection. Conceptualization strategies originate in the cognitive capabilities of agents. The ecological conditions and the structure of the environment influence the conceptualization strategy agents invent and which corresponding system of lexicon and ontology of spatial relations is selected for. The validity of these claims is explored using populations of humanoid robots.

## Introduction

Human language is a complex adaptive system (Beckner et al., 2009), which is shaped by its users in a process of cultural evolution in order to achieve communicative goals such as drawing the attention to an object in the environment using spatial language. Language evolves constrained by factors such as communicative success, expressivity, learnability and ecological significance. This paper argues that these claims are also true for spatial language and that they are at the heart of explanations for the diversity of spatial language attested across different cultures.

Spatial language exhibits enormous amount of cross-cultural variation on two levels.

**Spatial language systems** Spatial language is typically a conglomerate of different systems. English for instance has a *proximal* system consisting of the two spatial relations “near” and “far”, a *projective* system including relations such as “left” and “front”. Moreover, English features an *absolute* system of spatial relations, e.g. “north” and “east”. Languages differ with respect to the particular organization of language systems. Spanish, for instance, features three proximal relations (Kemmerer, 1999).

**Spatial language strategies** Languages differ qualitatively in the kind of systems they support. For instance, some

languages such as the Mayan language Tenejapan do not have projective terms but only absolute spatial relations (Levinson, 2003). Speakers of this language conventionally refer to objects in the immediate vicinity as *uphill* or *downhill*. Tenejapan speakers, therefore, habitually conceptualize reality differently than speakers of English.

There are two questions immediately following from this observation: (1) how do language systems form, (2) what are the origins of strategies. If one wants to study the evolution of spatial language, answers to the origins and development of both layers of language change have to be identified. Previous work has shown how language strategies can form language systems, e.g. for color and actions (see Steels, 2011 for an overview). In these experiments, agents are a priori endowed with a particular language strategy which includes a way of construing reality plus a battery of language change operators. The experiments then show that given these prerequisites autonomous agents can negotiate a particular system of categories (ontology) and words (lexicon).

Recently the origins of language strategies themselves have come under investigation. Bleys (2010) proposes that color strategies are under selective pressure driven by communicative success and cognitive effort (see also van Trijp, 2010 for a similar argument). This paper broadens this approach by extending it to spatial language and, most importantly, by proposing a concrete account of the origins of language strategies. Three important concepts guide our discussion (Steels, 2011).

**Recruitment** Language strategies are grounded in general cognitive capabilities and operations (Steels, 2007). For instance, the absolute strategy in English requires that agents are able to categorize objects using spatial categories that relate to particular geocentric features of the environment. In English absolute system this is related to compass readings and map use (Tenbrink, 2007). In other languages such features can include geocentric landmarks such as mountains which are always visible, or other global features such as the aforementioned uphill-downhill distinctions (Levinson, 2003). The categorization of these objects themselves is a cognitive ability that

needs to be present before a linguistic absolute spatial system can form. Cognitive operations are recruited and assembled to form spatial conceptualization strategies.

**Selection** Once a strategy has formed it is used to build a concrete system of spatial categories and linguistic means to express them. For instance, in the simplest case a strategy is expressed lexically by naming the spatial relations. The system and the strategy are both subject to selective pressures. Other strategies might compete in terms of success, expressivity and ecological significance. To organize competition and selection, the overall success of a strategy and the associated ontology and lexicons are tracked.

**Alignment** Language is a phenomenon that occurs in the interactions of individuals of a group of language users. Language strategies or any linguistic material are invented in local interactions in which typically few members of a population participate. Different parts of the population might invent other strategies. This poses a problem as for language to be usable it needs to be conventionally used and known to the complete population. Alignment is the process by which a strategy and the corresponding language systems spread in the population. We organize alignment of strategies using the scoring of strategies used for orchestrating selection and competition.

This paper gives a mechanistic account of the origins and evolution of spatial language strategies by identifying concrete cognitive operations, selection and alignment mechanisms. We defend the main claim using artificial language evolution experiments which have been a key technique to identify, explore and validate ideas about cultural language evolution (Steels, 1995; Kirby, 2002; Smith et al., 2003).

## Adaptive Spatial Language Games

For researching the basic claims of this work, we setup experiments in which robotic agents (Sony humanoid robots, see Fujita et al., 2003) encounter objects in spatial scenes. Such setups are called *spatial language games* and they package a specific intention – talking about objects in the environment – with a specific interaction script.

Figure 1 shows the environment in which two robots interact. Both robots are equipped with a vision system that singles out and tracks objects (Spranger, 2008). The environment contains four types of objects: *blocks*, *boxes*, *robots* and *geocentric markers*. The vision system extracts the objects from the environment and computes a number of raw, continuous-valued features such as *x*, *y*, *width*, and *height*, but also color values in the YCrCb color space.

Always two agents randomly drawn from a population interact, one acts as the speaker, the other as the hearer. The spatial language game uses the following game script assum-

Figure 1: Spatial setup. To the left the world model extracted by the left robot is shown. To the right the same for the other robot is depicted.

ing a population  $P$  of agents, and a world consisting of a set of individual objects.

1. The speaker selects an object out of the context, further called the topic  $T$ .
2. The speaker tries to find a meaning comprised of a particular spatial relation and a particular way of conceptualizing reality for describing the topic.
3. The speaker looks up the word associated with the spatial relation in his memory and produces the word.
4. The hearer looks up which relation is associated with this word in his memory and examines the context to find a unique object which satisfies the relation.
5. The hearer points to this object.
6. The speaker checks whether the hearer selected the same object as the one he had originally chosen. If they are the same, the game is a *success* and the speaker signals this outcome to the hearer.
7. If the game is a *failure*, the speaker points to the topic  $T$  he had originally chosen.

Such an interaction can fail for different reasons. For instance, the speaker might be unable to discriminate the topic object because he is missing a spatial relation or a conceptualization strategy. Both success and failure of communication provide opportunities agents to adapt their linguistic knowledge, ontologies and repertoires of conceptualization strategies.

## Grounded Spatial Conceptualization Strategies

We use a computational formalism called *Incremental Recruitment Language* (IRL) that was specifically developed for representing adaptive conceptualization strategies (Spranger et al., 2010) and spatial semantics. To make this more concrete let us consider the semantics underlying a specific spatial phrase. Figure 2 shows the representation of the spatial semantics of a phrase like “near the box” which consists of a spatial relation (near) plus additional information about the landmark (the box).

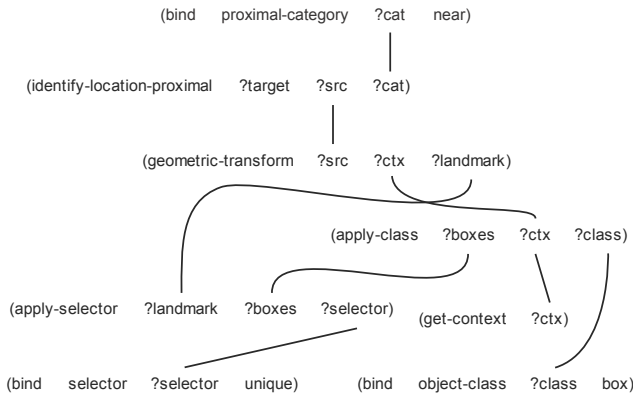

Figure 2: IRL-program representing the semantic structure of the phrase “near the box”.

The main idea behind IRL is that semantic structure is procedural (Johnson-Laird, 1977) and can be represented using programs (IRL-programs). Consequently, we represent the semantics of the phrase as a set of cognitive operations such as applying a categorization (`identify-location-proximal`), and transform the viewpoint on the scene to a specific object (`geometric-transform`) that are linked in a certain way. For instance, the output of the operation `geometric-transform` linked by the variable `?src` (all variables start with a `?`) is connected to the input of the categorization operation. In other words, once the set of objects from the context (introduced by `get-context`) is transformed to a particular viewpoint then the spatial category is applied.

The following operations (excerpt) are used as building blocks for spatial conceptualization strategies.

**geometric-transform** transforms the environment to a particular landmark object (in the example this is the box).

**identify-location-proximal** applies the spatial category given as argument to the input source set. The operation returns the single object which has the highest similarity with the spatial category. This operation applies proximal relations.

**identify-location-projective** works similar to the previous operation but is special to projective relations. We use the intrinsic notion of projective relations (Levinson, 2003). Landmarks such as the box and the robots can have an inherent orientation which highlights one of their sides as being the front.

**identify-object-absolute** encodes an absolute strategy. Absolute strategies compute rotation based on the direction towards a geocentric wall marker available in some spatial scenes.

Besides cognitive operations (algorithms), semantic structure also contains data. So called `bind`-statements introduce pointers to agent internal representations of concepts, prototypes and spatial relations. For example, `(bind proximal-category ?cat near)` introduces the spatial category `near`. Spatial relations are implemented using insights from cognitive semantics (Herskovits, 1986) and prototype theory (Rosch, 1975). There are two types of categories, distance-based (proximal) and angle-based (projective and absolute).

**Angular relations** Angular categories (projective and absolute relations) have a focal region around a specified axis. Similarity of some location to an angular category depends on the distance of angles. For instance, the front category has a high degree of applicability along the frontal axis. The following equations defines the degree of applicability, i.e. similarity,  $\text{sim}_a \in [0, 1]$  given an object  $o$  and an angular category  $c$  and a parameter  $\sigma$  which steers the steepness of the function.

$$\begin{aligned}\text{sim}_a(o, c) &:= e^{-\frac{1}{2\sigma c} d_a(o, c)} \\ d_a(o, c) &:= |a_o - a_c|\end{aligned}$$

$a_o$  denotes the angle of the position of  $o$  to the coordinate center and  $a_c$  is the prototypical angle of  $c$ .

**Proximal relations** Proximal relations are represented using prototypical distances.

$$\begin{aligned}\text{sim}_d(o, c) &:= e^{-\frac{1}{2\sigma c} d_d(o, c)} \\ d_d(o, c) &:= |d_o - d_c|\end{aligned}$$

$d_o$  denotes the distance of the object  $o$  to the coordinate center and  $d_c$  is the prototypical distance of the proximal category  $c$ .

**Spatial conceptualization strategies** The IRL-program Figure 2 shows a specific semantic structure that is part of a specific conceptualization strategy, namely the proximal spatial strategy. If we remove the spatial relation from the IRL-program in that figure, we are left with a conceptualization strategy which involves a landmark (the box) and a (unspecified) proximal spatial relations. We call such partial structures *chunks* (Spranger et al., 2010). Chunks are reified conceptualization strategies. They have a score which represents how much the agent prefers the strategy over others (e.g., see Mainwaring et al., 2003 for preferences in perspective choice).

Spatial conceptualization strategies involve more than just a choice of spatial relations. Landmarks, perspective, frames of reference (Tenbrink, 2007) are all important aspects of the construal of spatial relations and researchers are still mapping out the taxonomies and unifying theories for the vast

amount of spatial conceptualization strategies found in natural language (Levinson, 2003). For instance, which landmarks can be used with a particular spatial relation – just people, animals or also inanimate objects – is part of the choices manifest in a particular strategy. We can represent all these different factors using distinct cognitive operations and IRL-programs.

**Production and interpretation** When agents communicate they face the problem which language strategy to choose: proximal, projective or absolute. Within each strategy there are additional choices which spatial relation the agent wants to use, and which landmark to employ. Finally, agents have to name the category and retrieve a name for it in order to make themselves understood<sup>1</sup>. Production – the process of finding an utterance for discriminating an object – and interpretation – the process of finding the topic given an utterance – are heuristics guided, automated search processes that try to find good semantic structure (IRL-programs).

**Production** In production, agents choose the spatial conceptualization strategy and the spatial relation which is most *discriminating* the topic T with respect to all other objects in the context. A strategy and the chosen category are discriminating if they maximize the similarity of the topic but minimize the similarity of all other objects (Herskovits, 1986). Once the category is chosen, agents will verbalize the category by retrieving the term associated with the category.

**Interpretation** In parsing, this process is reversed and agents use their lexicon to find the category linked to the spatial term in the utterance. The category is used to find back the conceptualization strategy which is in turn applied together with the spatial relation to single out the topic.

We use *Fluid Construction Grammar* (FCG) (Steels and De Beule, 2006) for verbalization. FCG is a formalism developed for language evolution in which linguistic knowledge is represented using form-meaning associations, so called *constructions*. Constructions are scored and can be freely and deleted from an agent's memory which allows to model the change of linguistic knowledge of that agent.

Constructions are not the only items that are scored. Production and interpretation are heavily influenced by the score of the different linguistic items. Spatial relations, conceptualization strategies (chunks) and lexical items all have individual scores associated with them which are used to weight the results. The scores reflect individual preferences.

<sup>1</sup>In this paper, agents are confined to uttering single words in spatial language games.

## Co-Evolution of Spatial Relations

Conceptualization strategies are necessary prerequisites for building ontologies and lexicons. This section shows that given a chunk and a set of invention, adoption and alignment operators concrete systems of spatial relations can be negotiated in populations. Due to space constraints this section only exercises this for the projective strategy. Similar propositions hold for absolute and proximal strategies (Spranger, 2011b). The following paragraphs detail the operators.

**Invention:** *Speaker cannot find a discriminating spatial category in production*

- **Diagnostic:** When the speaker cannot conceptualize a meaning (step 2 of the spatial language game fails).
- **Repair:** The speaker constructs a spatial relation  $R$  based on the relevant strategy (projective) and the topic pointed at. The new category is necessary based on the distance or angle observed for the topic object (the initial sigma is small 0.1). Additionally, the speaker invents a new construction associating  $R$  with  $s$ .

**Adoption:** *Hearer encounters unknown spatial term  $s$*

- **Diagnostic:** When the hearer does not know a term (step 3 fails).
- **Repair:** The hearer signals failure and the speaker points to the topic T. The hearer then constructs a spatial relation  $R$  based on the relevant strategy and the topic pointed at. Additionally, the speaker invents a new construction associating  $R$  with  $s$ .

**Category alignment** Projective categories are represented by prototypical angles. After each interaction agents update the prototypical angle to better reflect the new observation by averaging the angles of objects in the sample set  $S$ . The new prototypical angle  $a_c$  of the category is computed using the following formula for averaging angles.

$$a_c = \text{atan2} \left( \frac{1}{|S|} \sum_{s \in S} \sin a_s, \frac{1}{|S|} \sum_{s \in S} \cos a_s \right) \quad (1)$$

The new  $\sigma$  value  $\sigma'$  which describes the shape of the similarity function of the category is adapted using the following formula.

$$\sigma'_c = \sigma_c + \alpha_\sigma \cdot \left( \sigma_c - \sqrt{\frac{1}{|S| - 1} \sum_{s \in S} (a_c - a_s)^2} \right) \quad (2)$$

This formula describes how much the new  $\sigma_c$  of the category  $c$  is pushed in the direction of the angle standard deviation of the sample set by a factor<sup>2</sup> of  $\alpha_\sigma \in [0, \infty]$ .

<sup>2</sup> $\alpha$  is given by the experimenter and in all experiments described here  $\alpha = 0.5$

Figure 3: Results for a formation experiment in which agents develop a projective category system.

**Lexicon alignment** The invention and adoption repairs introduce a particular problem – the problem of *synonymy*. Synonymy occurs when an agent explicitly represents that a spatial category can be named using different spatial terms. Each of these different names is represented using a separate construction each of which links the synonymously used category to a different string. Allowing agents to track synonymy in their lexicons can be beneficial for overall lexicon size, but only if agents also have additional mechanisms for managing synonymy. Such a mechanism, called *lateral inhibition*, was introduced in Steels (1995):

- In case the interaction was a success both speaker and hearer reward the winning construction – the one used in production and interpretation – by a score of  $\delta_{\text{success}}$ . Competing constructions are punished by  $\delta_{\text{inhibit}}$ . There are two types of competing constructions. First, there are those constructions which associate the same spatial relation but with a different word. Second, there are constructions that link the same word to different spatial relations.
- After a failed game, both speaker and hearer decrease the score of the used association with  $\delta_{\text{fail}}$ .

**Measures** To be sure that our approach to formation works reliably, we test it by running multiple trials of the same experiment. In each trial agents start with an empty ontology and lexicon. Success, performance and language development of the population are tracked using the following measures.

**Communicative Success** Communicative success is the most important measure as it reflects the overall performance of the population. Every interaction is either a success or a failure. Success is counted with 1.0 and failure is counted as 0.0.

### Number of Categories and number of constructions

This measure simply counts the average number of categories and constructions known to the agent.

**Interpretation Similarity** This is a measure tracking how similar the interpretation of each word known to each agent is. For this the categories attached to the word in each agent is compared. Since projective categories are described by a direction and a similarity function width parameter  $\sigma$ , two categories are most similar (1.0) when both angle and  $\sigma$  are equal.

**Results** Figure 3 shows the dynamics of experiments in which 10 agents start without any categories and constructions and gradually have to solve their communicative problems by invention and adoption of linguistic and semantic material (25 trials). In each trial 10000 spatial language games are played, with two agents randomly drawn from the population, interacting, and inventing, adopting and aligning linguistic knowledge.

The graph shows that agents are able to form successful language systems that gradually become more and more similar in the population as the linguistic knowledge spreads from agent to agent. After 10000 interactions agents are communicating successfully in over 95% of the interactions. In all trials, the population agrees on using a total of three spatial relations and corresponding names.

## Selection and Alignment of Spatial Conceptualization Strategies

The previous section demonstrated that given a conceptualization strategy and strategies for invention, adoption and alignment agents can co-evolve successful systems for referring to objects in their environment. The important claim in this section is that conceptualization strategies are negotiated in a cultural process, similar to how the lexicon is negotiated, through local interactions by agents in a community. The idea is that a particular strategy survives when it is relevant to an agent because it is efficient and useful in discriminating objects and it contributes to the communicative success of an agent at least in a few spatial contexts.

**Selection and Alignment** Selection of a strategy is intricately linked to the success of the ontology and lexicon, i.e. spatial category system, it builds. For instance, if an agent is building a language system with an absolute strategy this entails that the absolute relations and the strategy itself are subject to the same selective pressure. It is the success of the overall system, i.e. the spatial relations together with the performance of the strategy, that drives the organization of the syntactic and semantic repository of the agent.

The previous section talked about the invention and alignment of words and categories. The same operators are used for building different language systems. Additionally, the

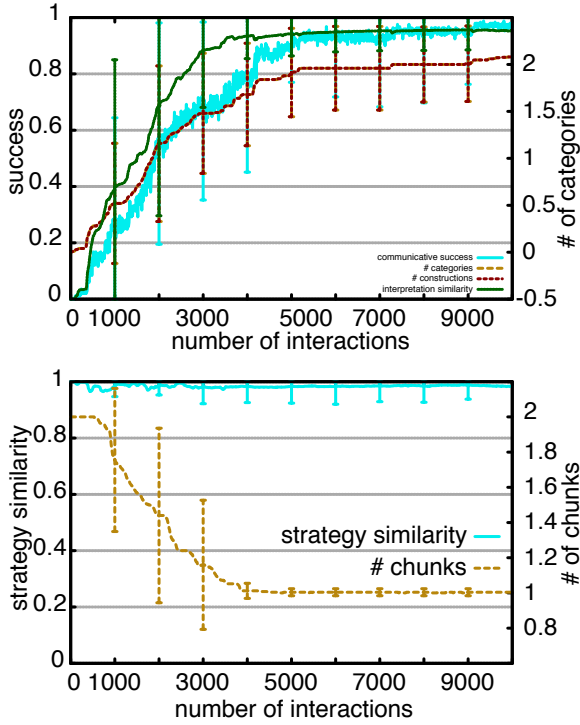

Figure 4: Dynamics of a category formation experiment in which 10 agents align the conceptualization strategy used at the same time.

success of a strategy, i.e. chunk, is tracked after every interaction by updating its score. If the conceptualization strategy was used successfully its score is increased by a factor  $\delta_{\text{success}}$  otherwise it is punished by  $\delta_{\text{failure}}$ . All other conceptualization strategies not used are punished by the score  $\delta_{\text{competitor}}$ . The value of these deltas is typically by a magnitude lower than the deltas for updating categories and words.

**Measures** We test our approach by running experiments in which agents are given different conceptualization strategies. To monitor the alignment of conceptualization strategies we use an additional measure.

**Number of chunks** This measure averages the number of conceptualization strategies with a score bigger than 0 over every agent.

**Conceptualization strategy similarity** The *css* is defined for a population  $P$  as the average *acss* for every two agents. Since *acss* is symmetric, all combinations of two agents are considered.

**Agent conceptualization strategy similarity** The *acss* is computed by comparing the score of each strategy. Since strategies are never removed but merely reduced to a score of 0.0 we can compute a distance of scores between the

chunks in each agent and envelope the result using an exponential decay function which results in the following formula.

$$\text{acss}(a_1, a_2, S) := e^{(-1 \cdot \sum_{s \in S} |\text{score}(s, a_1) - \text{score}(s, a_2)|)}$$

In this formula  $a_1, a_2$  are the agents whose similarity score is computed,  $S$  is the set of strategies given to agents and  $\text{score}(s, a_1)$  is the score agent  $a_1$  gives to strategy  $s$ .

**Experimental Setup and Results** We test the power of strategy alignment using contexts which can be manipulated to feature absolute and intrinsic properties. More specifically, we manipulate the distribution of intrinsic and absolute properties in the environment. Figure 4 shows the dynamics of an experiment where agents start equipped with two strategies: an absolute and an intrinsic one. The environment is such that it favors absolute systems. In 50% of the scenes both intrinsic and absolute features are present. In the remaining 50% of the contexts only absolute features are present and no intrinsic ones.

The environmental conditions have a strong effect on the development of the system. All 25 populations agree on using an absolute strategy. What is important is that the contexts where only absolute features are present reward the absolute strategy and punish the intrinsic conceptualization strategy. Consequently, even in a context where intrinsic and absolute features are present, the absolute strategy is preferred. The development of such a preference has important effects on the invention of categories. Because of the preference for the absolute strategy, invention of categories shifts to producing only absolute categories. The successful use of these categories enforces the absolute strategy and leads to further punishment of the intrinsic strategy. The effect is that only the absolute strategy survives. Additionally, the graph shows that roughly together with the category system, agents align their conceptualization strategy.

## Recruitment of Conceptualization Strategies

Conceptualization strategies are networks of cognitive operations encoding a particular way of construing reality. Consequently, they originate in a process of *recruitment* which assembles cognitive operations into strategies, i.e. chunks. Recruitment is a necessary pre-requisite for the usage of conceptualization strategies and their alignment in a population. Once a chunk is invented it immediately extends the conceptualization capabilities of the inventing agent.

**Recruitment** Strategy invention is deeply integrated into the processing of agents. Agents unable to conceptualize or unable to conceptualize with sufficient confidence diagnose a problem which is fixed by a repair that starts the search for new conceptualization strategies. The reason for this integration specifically with other invention mechanisms such as

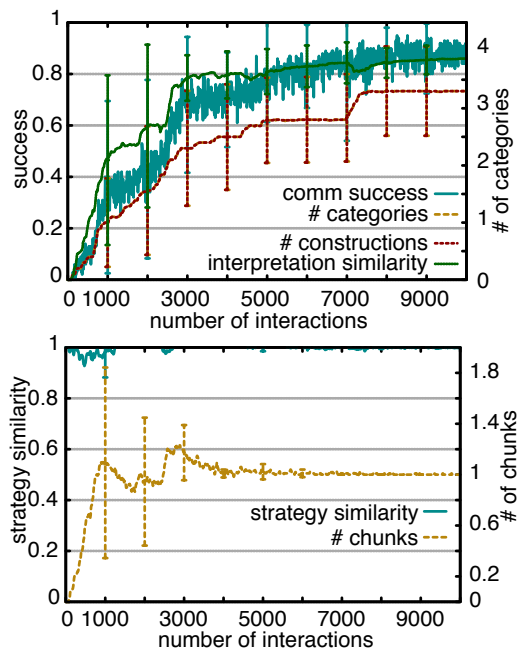

Figure 5: Results for strategy invention, alignment and category development. A population of 10 agents develops both conceptualization strategies as well as lexical systems for spatial strategies corresponding to these strategies.

category invention is that agents when inventing new strategies also immediately have to invent new categories with these strategies because a strategy itself is not verbalized but the name of the spatial relation. This sort of dual invention is especially important in the beginning of experiments, when agents have neither developed strategies nor categories.

But there is a second reason for deep integration of strategy invention. When an agent already has developed a strategy then he might also solve a particular communicative problem by inventing new categories for established strategies. Such decisions whether to use a new category with an existing strategy or a new strategy with an existing category, or even to use a newly invented strategy with a newly invented category are made based on the discriminative power of each these different possibilities in the particular context. So for instance if an existing strategy has a low score the probability of inventing a new strategy increases, whereas if the current topic can be sufficiently discriminated using an existing strategy no invention occurs.

We need two more operators besides the operators discussed in previous sections.

**Invention:** *Speaker cannot find a meaning for referring to the topic*

- **Diagnostic:** When the speaker cannot conceptualize a meaning (step 2 of the spatial language game fails).

- **Repair:** The speaker invents new conceptualization strategies by assembling cognitive operations such as identify-proximal, geometric-transform into chunks which is immediately followed by the invention of categories for each new chunk (see section on co-evolution of categories and terms). At this point the speaker might have a number of new solutions to his conceptualization problem consisting of new strategies and new corresponding spatial relations. Subsequently, the speaker selects the strategy and category which is *most discriminating*. Once selected, he invents a new word and construction for expressing the new strategy.

**Adoption:** *Hearer encounters unknown spatial term  $s$*

- **Diagnostic:** When the hearer does not know a term (step 3 fails).
- **Repair:** The hearer signals failure and the speaker points to the topic  $T$ . The hearer then constructs new strategies, i.e. chunks, and for each of them he invents a new spatial relation  $R_i$  based on the the topic pointed at. The hearer then decides on which of the strategies is most discriminating. This is the one selected for storing. Additionally, the hearer invents a new construction linking  $R_i$  with  $s$ .

These two invention and alignment operators are specific to the invention of chunks. Moreover, agents are equipped with the selection and alignment operators for chunks, spatial relations and words discussed earlier.

**Results** Figure 5 shows the dynamics of invention and alignment of conceptualization strategies in a population of 10 agents (25 trials). Agents have a repository of 10 basic cognitive operations from which they can draw new building blocks whenever there are problems in communication. They can choose different landmarks: the robot, or the box, and different category systems absolute and intrinsic projective, as well as proximal. The agents manage to agree on one particular strategy while at the same time developing a category system and a lexicon from scratch.

However, the process does not show the same overall success as previously discussed experiments. The reason is that conceptual alignment is a difficult process which is complicated by the number of choices in strategies, population size and the variety of different contexts and discriminative situations which might all favor different strategies. In some contexts proximal is the best strategy, some allow absolute and/or projective categories to be invented. Nevertheless, agents do come to an agreement. Here, they agree on average on a single conceptualization strategy.

For space reasons, we can only discuss one particular experiment with trials all equal in environmental condition. But, of course once the system is setup one can study the effect of varying conditions. The systems discussed here

are very flexible and find solutions to different environmental conditions featuring additional landmarks, intrinsic and absolute features. Additionally, agents react flexibly to different object distributions that favor distance-based or angle-based strategies.

## Discussion

This paper has argued for selection, recruitment and alignment as the basic mechanisms explaining the evolution of language strategies together with corresponding language systems. We have shown (1) how strategies can be represented, (2) how strategies build language systems, (3) how selection works on strategies and (4) how strategies are built by recruiting cognitive operations. We provided mechanistic explanations and validated them in robotic experiments.

The basic claim validated is that we can understand the evolution of strategies as a process of cultural negotiation fueled by the cognitive capabilities of agents, i.e. the cognitive operations available. The process is constrained by environmental factors such as the availability of geocentric landmarks. While cognition and ecology influence the selection process, the negotiation takes place within a single static population via linguistic interactions. This is also the main difference to other models of cultural evolution which claim that intergenerational turnover is the main cause of language change (Kirby, 2002; Smith et al., 2003).

We have only considered a simple lexical verbalization strategy. Certainly, spatial language shows much more variation in the kinds of syntactic material that is employed to convey distinct spatial semantics. A discussion can be found in Levinson and Wilkins (2006) and Tenbrink (2007) and evolutionary models in Spranger (2011a). Moreover, spatial language can feature other conceptualization strategies involving toponyms, directional categories or body-centered spatial relations. Given a suitable implementation of cognitive operations, we claim that the same approach can be used to study the evolution of such strategies.

## Acknowledgements

I am greatly indebted to Masahiro Fujita, Hideki Shimomura, and their team for creating the Sony humanoid robots and for making them available for this research. I thank Luc Steels and Martin Loetzsch for help with the robotic setup, and I thank Kateryna Gerasymova for help with writing the paper. This research was funded by the Sony CSL Paris with additional funding from the EU FP7 ALEAR project.

## Abstract

The minimal cell (MC) project aims at understanding the emergence of cellular life by constructing experimental models of cells, according to a synthetic (constructive) biology approach. Our strategy – also known as the semi-synthetic one – is based on the encapsulation of the minimal number of biomolecular components inside lipid vesicles (liposomes). Being interested in studying the key step for constructing semi-synthetic cells, namely the physical entrapment of the solutes, we have recently reported that the mechanism of vesicle formation can lead to a spontaneous local increase in concentration of proteins inside vesicles (Luisi et al., ChemBioChem 2010, 11, 1989-1992). In particular, it was shown that the protein ferritin can reach intravesicle concentration of at least one order of magnitude higher when compared to the bulk (external) concentration. This self-organization phenomenon might give a rational account for the formation of functional cells from diluted solutions, and therefore help to understand the origin of metabolism. The effective encapsulation of solutes, however, is only one of the ways for achieving functional cells. The second route is fusion of vesicles or the exchange of solutes among vesicles (Caschera et al., J. Coll. Inter. Sci. 2010, 345, 561-565). Both processes allow the combination of different solutes to give compartments that can exhibit improved reactivity. Aiming at developing a realistic model for cooperative interactions among vesicles, we have recently developed a cell colony model. This is based on the formation of lipid vesicles clusters adherent to a solid substrate, representing a minimal model of cell communities. Here we summarize the most significant aspects of our recent activities.

## The physics of solute encapsulation

Looking at the physico-chemical mechanisms that have lead to the origin of cellular life, a still open question is whether functional cells have been originated from the encapsulation of an already developed metabolism (metabolism- or replicator-first scenarios), or whether the cell metabolism was entirely (or almost entirely) developed inside compartments (compartment-first scenario). In both cases, there are some aspects that need clarification, as the low probability of co-entrapping all required molecules in the same compartment in the first hypothesis, or the lack of permeability control in the second hypothesis (Luisi et al., 2010).

In particular, although the encapsulation of solutes into liposomes is a well-established field, especially due to the

large amount of work done in the field of drug delivery, we still miss a complete view of the physics underlying this important mechanism. In fact, with a few exceptions (Sun and Chiu, 2005; Dominak and Keating, 2007; Lohse et al., 2008), all experimental studies deal with the *average* entrapment yield, and no attention has been given to the entrapment behavior at the level of single vesicles, also due to technical difficulties.

We have recently started a systematic study on the encapsulation of biopolymers into lipid vesicles. This study was inspired by our report on the protein expression inside 200 nm (diameter) vesicles, that suggested the possible deviation from the expected intravesicle solute distribution (Souza et al., 2009).

As a model system, we have used the protein ferritin, an iron-storage protein, consisting of a nucleus of electron dense ferrihydrite-like iron salts surrounded by 24 protein subunits. Ferritin can be directly visualized as single molecule by electronmicroscopy, so that it becomes possible to directly count the number of ferritin molecules inside vesicles imaged via cryo-transmission electron microscopy.

After analyzing about 7,700 submicrometric vesicles (Fig. 1a), prepared by varying the concentration of ferritin, the preparation method and the membrane lipid composition, we have concluded that the encapsulation of this solute inside lipid vesicles does not follow the expected behavior. In our experimental conditions, this is given by the Poisson distribution of  $N$  solutes inside vesicles that are expected to entrap, on average,  $\mu$  solutes:

$$f(N) = e^{-\mu} \frac{\mu^N}{N!}$$

where  $f(N)$  represents the fraction of vesicles containing  $N$  ferritins, and  $\mu$  is the average expected number of ferritin molecules. The  $\mu$  value can be calculated from the vesicle volume  $V$ , and the ferritin concentration  $C$ :

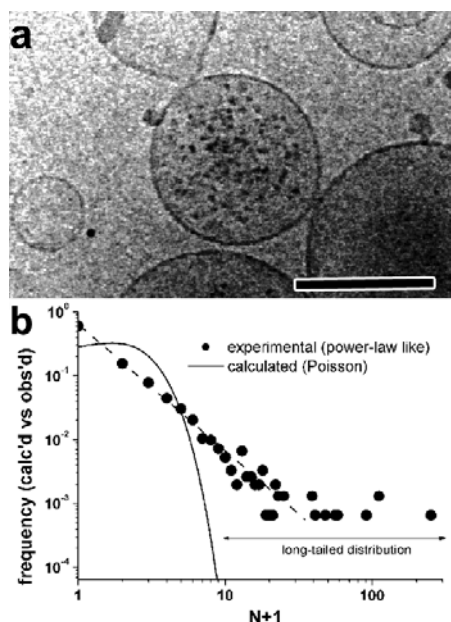

$$\mu = N_A C \cdot V$$

( $N_A$  being the Avogadro's number).

In particular, we have found that the distribution of ferritin-containing vesicles follows a power-law-like shape, characterized by an abnormally high amount of empty vesicles ( $N = 0$ ), a decreasing pattern at intermediate  $N$ , and – significantly – a non-zero long tail (Fig. 1b), which represents

the non negligible probability of co-entrapping a relatively high number of ferritins (up to hundreds), whereas the average expected value is of few units.

**Figure 1.** Entrapment of ferritin inside lipid vesicles. (a) Cryo-TEM electronmicrograph of a ferritin containing vesicle (size bar 200 nm). (b) Comparison between calculated Poisson ( $C = 4 \mu\text{M}$ , diam. 100 nm) distribution and experimental data profile. Redrawn after Luisi et al. (2010). The “long tail” feature has been highlighted. Note the logarithmic axes and the abscissa values shift ( $N+1$ ).

According to these results it appears that the co-encapsulation of several molecules in the same compartments is a physically possible process, and we believe that these observations contribute significantly for understanding the emergence of complex primitive cells from separated components. In fact, our results demonstrate that it is possible to form a solute-rich compartment even starting from diluted solution. This also implies that sluggishly reacting (diluted) systems might become reactive thanks to the spontaneous concentration increase inside lipid vesicles. Further studies about the mechanism will clarify our work hypothesis, based on weak and cooperative solute/membrane interactions, which affect the mechanism of vesicle closure (i.e., a process under kinetic control).

## Experimental models of cell communities

As we have anticipated, the co-entrapping of diverse solutes in the same compartment is not the unique process that can lead to solute-rich compartments starting from simpler ones. A complementary way is represented by all those mechanisms that have as a result the sharing of solutes among several compartments, in particular fusion and solute exchange. We have recently reported a study on the fusion between cationic and anionic vesicles as a way for reaching higher complexity, and loosely resembling the idea of symbiogenesis. In

particular, it was shown that oppositely charged vesicles can react (up to  $\sim 20\%$  yield) to neutralize their net charge and give rise to neutral species derived from the fusion of the vesicles (Caschera et al., 2010). As a consequence, the internal solutes, initially present in two vesicle populations, become co-encapsulated in the resulting new vesicles. We have reasoned that such fusion process, as well as the possibility of exchanging solutes among vesicles, could occur not only in suspended vesicles, but also in the case of vesicles forming small solid-supported communities. Here, the physical proximity of vesicles could not only favor such dynamical transformation, but simultaneously stabilize the community thanks to multiple physical interactions. Research is currently going on in our laboratory aimed at characterizing vesicle colonies with respect to their reproducible formation, physico-chemical stability, fusion, solute exchange as well as solute capture from the environment, and stability against flow (Carrara, 2010).

Thanks to this new experimental model we aim at studying the new “dimension” of *cell communities*, which is generally missing in the discussion on the origin of cellular life. Moreover, the model will allow a more direct investigation of communication between synthetic cells through the synthesis, release, uptake, and processing of diffusible species. This represents a concrete example of chemical communication, with possible implication in chemically-based information and communication technologies (ICTs).

A first attempt to use lipid vesicles for establishing a communication between synthetic and natural cells has been reported by Gardner et al. (2009).

# Reflecting on Open-Ended Evolution

Susan Stepney<sup>1</sup> and Tim Hovord<sup>1</sup>

<sup>1</sup>YCCSA, University of York, YO10 5DD, UK

susan@cs.york.ac.uk

## Abstract

We describe a computationally reflective object-oriented architecture suitable for incorporating open-ended innovation and emergent entities into simulations. This allows emergent properties to be reified into objects. This requires modifying the model, and the metamodel, by incorporating novel classes and metaclasses dynamically. The classes and metaclasses are modified by including them in the model through reflection. We argue that such computationally reflective introduction of novelty is necessary for true open-ended simulations.

## Introduction

Open-ended dynamics, supporting constant novelty generation, is a goal of ALife simulation.

Open-ended evolution has been defined as “a process in which there is the possibility for an indefinite increase in complexity” ([20], which also contains a comprehensive review of the concept in biology). Bedau [2] talks in terms of systems that exhibit “supple adaptation”, which involves them “responding appropriately in an indefinite variety of ways to an unpredictable variety of contingencies”. Open-ended novelty generation and evolution are features of biological life, but are proving hard to achieve in silico.

Classical evolutionary algorithms, with their fixed genome representations, can produce new things only within that limited representation. Evo-devo algorithms break out of this limitation, by allowing a genome to develop into a phenotype, but they are still confined to a single (albeit much richer) representation.

The desired continual increase in complexity is not merely a constant supply of new things (variations of a theme), or even of new kinds of things (speciation), but of new kinds of new kinds of things (major transitions, radical novelty, novel concepts). In computational terms, we might say we need a constant supply of new objects (the new things), new classes (new kinds of things, new representations), and new metaclasses (new kinds of kinds of things, new kinds of representations).

Here we take a computational modelling view of the problem, and describe what we believe are minimal requirements

for true open-ended dynamics in simulations: simulations that can modify their own model and metamodel as they execute. This implies that they can modify how they modify themselves. One key step on this route is the need to reify (“make concrete, or real”) emergent properties, as these are a rich source of novel concepts outside the language of the pre-existing system.

The structure of the rest of the paper is as follows. First we discuss the process of reifying emergent properties, both at the class and metaclass levels. Then we describe how a computational system can modify its own model and metamodel at runtime. Finally we specify a bootstrap architecture for such a self-modifying system.

## Extension, Intension, and Emergence

Consider an agent-based flocking simulation, implemented in some object-oriented (OO) programming language. A collection of boid objects exhibits various behaviours, and potentially forms flocks.

Assume the individual boid objects have names, eg Tweety, Cheeky, Polly, and ages, eg juvenile, adult, old. We can define particular sets of boids in two ways. An *extensional* definition explicitly enumerates the members:  $A = \{\text{Tweety}, \text{Polly}\}$ . An *intensional* definition is an implicit definition of membership in terms of properties of the members:  $B = \{b : \text{Boid} \mid b \text{ is juvenile}\}$ .

In an atemporal world of pure logic, a property is eternally either true or false, so extensionally defined set  $A$  and intensionally defined set  $B$  are either equal or not equal (have precisely the same members, or do not), and the difference in definitional approach is logically unimportant<sup>1</sup>. However, when properties are a function of time (as with stateful objects), an intensionally defined membership need not be static (for example, the membership of  $B$  may change as boids age). Hence  $A$  may equal  $B$  at one time, but not at another. In such a case, we need to be clear about whether the

<sup>1</sup>Except for such paradoxical definitions as “the set of all sets that are not members of themselves”, and other issues underpinning the foundations of mathematics, but we are not addressing these issues.

extent or the intent is the relevant defining property of our set of interest (for example, are we interested in Tweety and Polly, and “juvenile” is just a convenient shorthand for denoting them at this moment; or are we interested in juveniles, who just happen to be Tweety and Polly at this moment).

In general, we are interested in intensional property-based definitions, in potentially-changing collections of things that have certain properties in common (such as “all the blue birds more than a year old”), rather than in explicit but arbitrary collections (such as  $\{\text{Tweety}, (\emptyset, \text{Rover}), 42\}$ ). And we are more interested in generic intensionally-defined concepts (“flock”), than in specific one-off extensional collections (“those birds over there”).

In an OO program, nevertheless, collection objects (instances of Dictionaries, Sets, Lists, etc) are almost always extensional: they are static collections of the actual objects. The intent of such sets is only implicit (not captured in the code, except maybe through invariants or contracts), and much coding effort goes into maintaining this intent (explicitly adding and removing objects from the otherwise-static collection). This intent-implementing code, with its property-checking component, can be encapsulated inside a class. For example, consider the set of “all instances of class X”. This is an intensional definition: the set will contain different elements at different times, as instances of class X are created and destroyed. So in Smalltalk-80 [7] the (class) method `allInstances` returns an extensional set of all the instances of the class at the time of the message-send. The set itself does not change as objects are created and destroyed: a new message needs to be sent to the class to find the current value. The implementation hides the details of how this set is constructed each time; logically it is equivalent to constructing the set by examining every object and testing for the defining property.

## Emergence as implicit intension

Now consider the OO boid simulation. We point to an area of the screen, and say, “the flock is those boids”. So at any given moment, a flock appears to be an extensionally-defined set of boids:  $flock = \{\text{Tweety}, \text{Cheeky}, \dots, \text{Polly}\}$ . However, unlike a true extensional definition, the membership of the flock set can and does change, as boids leave and enter. This demonstrates that the flock is ‘really’ intensionally defined:  $flock = \{b : \text{Boid} \mid b \text{ has property } f\}$ . We just do not know what the intensional property  $f$  is, in advance<sup>2</sup>. The flocking property is emergent.

In some sense a flock is a ‘thing’, but it is not an object in our simulation, and there is no Flock class with which to capture and hide the intent-preserving code that tracks this

<sup>2</sup>Additionally, the property is probably somewhat fuzzy. For example, consider what might be the minimum size of the set *flock*. One boid, even two boids, do not make a flock. It has no well-defined answer; a flock is a fuzzy concept. (See, for example, the description of the Sorites Paradox in [11].)

set as boids enter and leave the flock. (Of course, we could have defined such a class, but that would require us to know beforehand the emergent properties; we assume here that we have not.)

We need some way to add this class and its intensional definition to the model and simulation *as and when the property emerges*. First we discuss different degrees of intensionalisation, and then a method and architecture for modifying the simulation with novel emergent properties.

## Intensionalising Emergence

We reify a specific flock by capturing it as an extensional object in the simulation, for example, as an instance of some generic Collection class (*theFlock* = `collectionInstance( $b_1, \dots, b_n$ )`). We can define the concept of flock in a new class Flock that explicitly captures the emergent intensional property, and so intensionalise the flock: *theFlock* = `flockInstance( $b_1, \dots, b_n$ )`. We can intensionalise an emergent property in a simulation in the following three ways, yielding different dynamics in the resulting system.

### External Instrumentation

Ordinary agents might remain blind to the existence of the emergent: it has no direct effect on them. For example, boids in a simple flocking simulation react to other boids independent of whether they are in a flock. (That is, their behavioural *rules* are unchanged, although of course their resulting *behaviour* is sensitive to the existence of the flock.)

In a simulation, we might add a FlockRecogniser subsystem, including a class FlockTag whose instances tag the detected flocks, and merely provide statistics on the simulation’s behaviour. Such instances would have no effect on the individual boids’ behaviour, whether within or outside a flock.

### Internal Detection

External instrumentation is the least interesting kind of reification, as the emergent is explicitly visible only to external observers. Crutchfield [5] talks about “intrinsic emergence”, where there are internal observer processes that can “take advantage of the emergent patterns”.

The next level of reification includes internal detection, whereby ordinary agents notice the existence of the emergent, and change their behaviour based on it. For example, a more sophisticated flocking simulation could have boids modified to be able to sense and interact directly with flock objects, preferring to move closer to a flock than to boids not in a flock, say. The flock object exists in the simulation, but is merely a derived consequence of the boids’ behaviours: it has no active behaviour of its own, it merely influences the behaviour of other objects.

## Reification

With full reification of the emergent, ordinary agents notice the existence of the emergent, change their behaviour, and are also directly affected by it. The emergent becomes an intensional entity in its own right. Being a component of the emergent then stops being defined merely as an extensional property (happening to being in the correct location to be in the extension, say), and becomes something that is granted by the emergent entity (membership rules, say).

For example, a reified flock object in a simulation might actively prevent boids from entering or leaving the flock. It would then be acting as a kind of ‘membrane’ around the flock. (We are *not* suggesting this happens in real flocks. Here we are simply exploring the kinds of things that a simulation might react to the presence of an agent: we are interested in getting complex open-ended dynamics in the simulation, not in faithfully replicating such processes occur in the real world.) The reified emergent becomes available in the simulation to be a firm component in further (higher-level) emergent behaviour.

The effect of the reified emergent on its constituents could be considered to be a form of downward causation [3, 22]. Although such a concept is anathema to reductionists, it is an everyday notion to sociologists. Reification of some societal constructs changes membership properties (for example, citizenship) from extensional (happening to be located in the country) to intensional (having the conceptual property of being a citizen) in exactly this way.

## Intensionalising Emergence internal

We have discussed modifications to the simulation to achieve several kinds of intensionalisation, to capture emergent properties as explicit entities within the simulation. In this section we propose how to achieve this *dynamically within the simulation*, through the use of computational reflection [16].

## Models

When writing a program, it is good software engineering practice to write a model of the program. For an OO program, that model is often written in an OO modelling language such as UML, identifying the classes, associations, interactions, behaviours, and so on. This model provides the abstract language of the concepts to be implemented in code. Even if no such model is written explicitly, it is implicit in the structure and dynamics of the written and executing code.

For example a (very simplified) class model of an agent-based boid simulation might look like figure 1. This is a model of the implemented code. Emergent (unimplemented) properties do not appear in this kind of model.

Figure 1: A (very simplified) UML class model of a boid simulation. There is a single Boid class, listing the attributes and methods.

Figure 2: Model of Boids and emergent Flocks

## Emergent classes

Although the model of the simulation code does not include emergent concepts, we can build a (different) model that does. In this new model, the emergent is captured as an extensional object; it can then be intensionalised (its defining property captured in a class definition).

So we augment our model with an emergent class (which we draw as a dashed class box)<sup>3</sup>. This class captures the emergent property, and its instances. Figure 2 shows two levels: a model level with a normal class Boid and an emergent class Flock. We also show an object level view (a snapshot of the objects present during execution). The boid objects are instances of the Boid class. Some boid objects are members of flocks. We say that these emergent flock objects are instances of the emergent class Flock.

The emergent class might be a subclass of an existing ‘ordinary’ class in the model. For example, in an evolutionary system, a new kind of mutation operator might emerge ([8] discusses an example of an emergent macromutation, figure 3). In such a case we assume that the superclass is *abstract*, with neither intensional nor extensional instances of its own. On the other hand, the emergent class might be

<sup>3</sup>This is not part of UML, and so is an extension of the modelling language.

Figure 3: An example of an abstract superclass with many predefined subclasses

Figure 4: A (very simplified) metamodel of agent-based models. There is an Agent Type (an instance of which is the Boid class), and a Behaviour Type (instances include the boids' avoid and align behaviours). This metamodel has been augmented by an emergent Aggregate Type (an instance is the emergent Flock class).

a genuinely new kind of concept in the model, with no pre-existing superclass.

Once we have augmented our model with emergent objects and classes, we could build a new simulation with them as coded classes. But for an open-ended simulation, we need a system that can itself recognise such entities, and change its own model, *at run-time*, to include such intensionalised emergent classes dynamically.

## Metamodels

Changing the model (to allow for new kinds of executing objects), although necessary, is not sufficient for full open-endedness. We also need to change the metamodel, to allow new kinds of things in the model.

In an analogous way to how a model provides the language for writing the code, a metamodel provides the language for writing a *model*: it defines the kinds of things that can occur in the model (it is the model of the model). UML's metamodel includes concepts such as class and association. An agent-based modelling language metamodel would include concepts such as agent and behaviour. In the same way that models need to be augmented to include emergents, so do metamodels (figure 4).

Models and instances form a two-level modelling architecture. The Object Management Group (OMG) uses a four level modelling architecture [12, ch.8]: M0 = base instance (the objects in the simulation); M1 = model (defining the kinds of things in the simulation, such as Boid, Ant; written

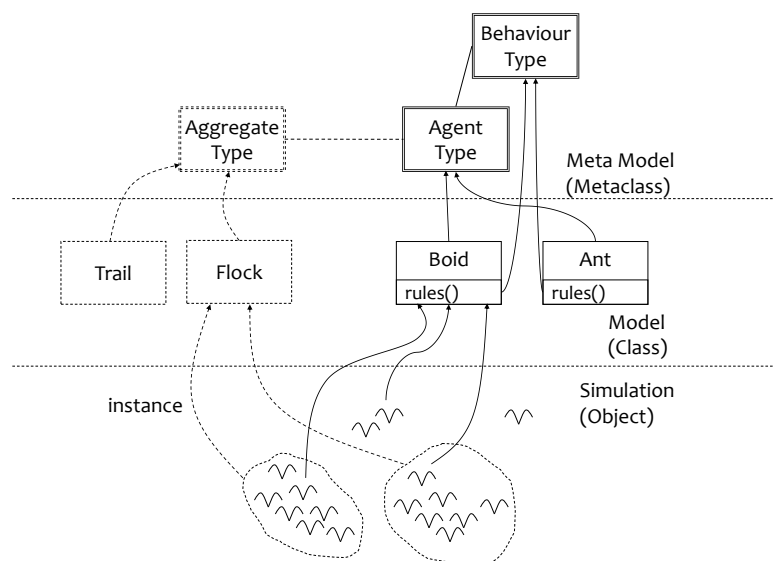

Figure 5: Metamodel and Model of an agent-based simulation

in, for example, UML); M2 = metamodel (defining an ontology, the kinds of thing in the model, eg Class and Association for UML models, AgentType for agent-based models (ABMs); also written in for example UML); and finally M3 = meta-metamodel (defining the kinds of thing in the meta-model, written in, for example, OMG's Meta Object Facility (MOF) language). Infinite regress is avoided by allowing the meta-metamodel to be written in MOF. Here we consider only the bottom three layers, M0-2.

Another example of this four level architecture is: M0 = executing program; M1 = a Python program; M2 = the Python programming language; M3 = BNF and denotational semantics. Changing the model is analogous to changing the *program*; changing the metamodel is analogous to changing the *programming language*.

## Emergent Metamodels

The metamodel of an ABM (figure 5) describes the kinds of things in an agent-based simulation: it has a metaclass AgentType. The emergent class like Flock in the model also needs a metaclass: it is an emergent AggregateType. So there can be emergent metaclasses too (where an emergent class is not an instance of some existing metaclass).

## Speciation and major transitions

We have seen three main kinds of reification:

1. Reifying an emergent subclass (for example, the macro-mutation class in figure 3). The concept already exists in the model (the superclass); the reified subclass is a variant of that concept.

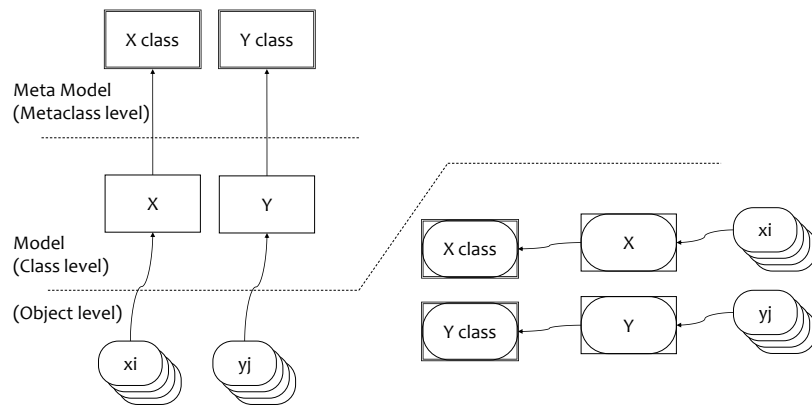

Figure 6: (left) the Smalltalk-80 Metaclass/Class/Object model as a three-layer model; (right) the implementation, all in the Object layer

2. Reifying an emergent class (for example, the Trail class in figure 5). The concept did not exist in the model (there is no relevant superclass), but does in the metamodel (once AggregateType is reified). The reified class is a new instance of that concept: the trail is a new kind of aggregate object, a new kind of thing with new kinds of behaviours, roughly analogous to a new species or genus in biology.
3. Reifying an emergent metaclass (for example, the aggregate type in figure 4). The concept did not exist in the metamodel: the aggregate type is a new kind of meta-object, a new concept in the language, roughly analogous to a major transition in evolutionary biology [17] (for example, the move from unicellular to multicellular organisms).

Such reification provides the requisite novelty generating power, when implemented in a computational system.

### Dynamic Models and Metamodels

The process of changing the model and metamodel needs to be dynamic, so that we can add reified emergent classes and metaclasses as they emerge and are recognised at run-time. Smalltalk-80 [7] provides an approach to this. Two fundamental concepts in Smalltalk-80 are: everything is an object; an object is an instance of some class. Since everything is an object, a class is an object, and so is an instance of some class, called its metaclass. So object *x* is an instance of class *X*, and class *X* is the (singleton) instance of its metaclass, referred to<sup>4</sup> as *X class*. Since everything is an object,

<sup>4</sup>In Smalltalk-80, metaclasses are not explicitly named. A metaclass can be referred to by sending the message `class` to the class's single instance. The value of this message expression is the metaclass. So the metaclass of class *X* can be referred to as *X class*. (Since there is also a class called `Class`, this terminology can lead to awkward constructions, such as "the class `Class class`".)

a metaclass is an object, and so is an instance of some class, the class `Metaclass`<sup>5</sup>.

So Smalltalk-80 has the objects, the classes (model) and metaclasses (metamodel) *all available as objects at runtime* (figure 6). All can be instantiated, deleted, and modified at runtime, via this *computational reflection* ("a reflective system is a computational system which is about itself in a causally connected way" [16]). Although Smalltalk-80 is not a pure reflective language, it does have reflective capabilities, and many others can be added programatically [6].

Other computationally reflective languages (ones that can modify themselves at run-time, to a greater or lesser extent) include Lisp, Prolog, Python, Ruby, and JavaScript.

### Examples of self-modifying and reflective systems

Suber [23] discusses self-amendment in the context of law making, and describes Nomic [10][23, appx.3], a (non-computer-based) law-based game where changing the rules (including the rule that players must obey the rules) is a move. Suber asks if it is possible either to make some rules unchangeable whilst preserving the power to amend others, or to irrevocably repeal the power to amend the rules.

Reflection is key in the branch of Artificial Intelligence concerned with "learning to learn", metamemory and metacognition [4, 14, 15, 18, 21, 24]. Learning changes the model; learning how to learn, learning a better learning algorithm, is changing the metamodel. Note that our concern here is not in high-level *cognition*, however, but in the role of reflection in open-ended *evolution*.

Biology is the ultimate self-modifying system. Hick-innbotham et al [9] describe a self-modifying computational

<sup>5</sup>Of course, since `Metaclass` is a class, it is the singleton instance of its metaclass, `Metaclass class`. And `Metaclass class` is a metaclass, so like all metaclasses, it is an instance of `Metaclass`. This circularity stops the potential infinite regress of needing metaclasses, etc. See [7, pp268-72] for details.

architecture inspired by biological DNA, RNA and protein machines. Tomita et al [25] use graph-rewriting automata with five kinds of rewriting rules, to implement self-replication. They discuss the possibility of embedding the graph rewriting program as a graph itself within the system, allowing for execution to modify which rules are applied. This is analogous to modifying the model at run-time; an analogy to modifying the metamodel would be to introduce new kinds of rewriting rules.

Reflection is proposed as the route to self-adaptive software systems [1, 16]. The architectural requirements specified in [1] differ from our own here, however, because the application domain is very different. For example, [1] is concerned with reflection on programming language concepts, subject to real world domain constraints; we are concerned with reflection on novelty generating mechanisms, and need to impose constraints in terms of some energy model (next). They are concerned with software engineering structuring, clear separation of model and metamodel layers and their respective concerns, and with performance; we are concerned with open ended novelty generation, and embrace the biologically-inspired ‘messiness’ of deliberately mixing layers of abstraction. Consequently, they carefully separate domain and reflective aspects, and keep the computation to do with reflection in the metamodel level only; our architecture of computation is orthogonal to the model and metamodel layers (next), to enable reflection at all levels, not only the metamodel reflecting on the model.

### An open-ended architecture

As discussed above, computational reflection provides a route to open-ended novelty. As Maes [16] says: “A language with reflective facilities is **open-ended**: reflection makes it possible to make (local) specialised interpreters of the language, from within the language itself.”

Reflection provides the computational mechanism, but we also need an architecture within which to generate and run the open-ended code. Here we describe an architecture for such a system. We use OO terminology; this specific paradigm, although well-suited, is not necessary for the architecture, just some analogue of the underlying concepts in a reflective programming language.

We define only a bootstrap architecture. The whole point of computational open-ended novelty generation is for the system to modify this architecture at run-time.

The key feature is that the three levels – instance, class, and metaclass – all exist as executing and modifiable objects in the system at run-time. For the bootstrap, we separate the system into three subsystems: an initial seed application, the observer-reifier-modifier (ORM) intentionaliser, and the virtual machine (VM). The seed application, for example, some agent-based simulation, acts as the raw material from which the open ended novelty grows. The other two subsystems are described below. See figure 7.

### ORM Intentionaliser: modifying the models

Our framework for intensionalising emergent structures has three components:

1. emergence **observers**, that observe novel emergent structures and behaviours
2. emergence **reifiers**, that intensionalise the recognised types, and add the relevant classes or metaclasses into the run-time, thereby changing the model or metamodel
3. model **modifiers**, that modify the simulation (instances, classes, or metaclasses) to exploit the reified structures

In [1], a distinction is made between structural reflection (reification of structural aspects such as data types) and behavioural reflection (reification of computations and their behaviours). It is crucial that emergence recognisers capture patterns both of structure and of behaviour: at different levels of emergence features can appear to be either ‘particles’ or ‘processes’ [22].

The ORM subsystem therefore includes *ObserverType*, *ReifierType*, and *ModifierType* metaclasses, and bootstrap class instances of these, to provide the meta-functionality. For example, we might have the class *Eye* as a bootstrap instance of *ObserverType*, whose own instances observe the simulation for particular spatial and temporal patterns that indicate emergence. An *Eye* instance might detect a flock- or trail-like emergent. It notifies a suitable *Reifier* instance, which can appropriately intensionalise the emergent, for example, as an internally detectable object. A suitable *Modifier* instance then modifies other classes in the simulation so that their instances can detect the new objects. It might also modify their behaviours to use the detected information, or, in an evolutionary simulation, allow these modified behaviours to evolve.

Key to the overall architecture is the fact that the simulator is reflective, not just at the core agent level, but throughout. Hence a bootstrap observer (for example) can observe not only novel agent patterns, but also novel observation, reification, and modification patterns, which can then be reified and modified appropriately. We bootstrap with *Hammer* and *Eye* classes; later *Spanner* and *Ear* classes can emerge and be reified. Eventually new *ModifierType* metaclasses could be reified. Hence the simulation can not only change itself, it can change the way it changes itself (this does imply requirements on the representation of modifier rules [14]).

Being able to modify the modifier, being able to produce new kinds of ways of recognising, reifying and modifying the simulation, closes the self-referential loop, and produces a truly open-ended system.

### Virtual machine: constraints

The virtual machine provides whatever run-time support is needed for the ORM architecture, in the usual manner (at

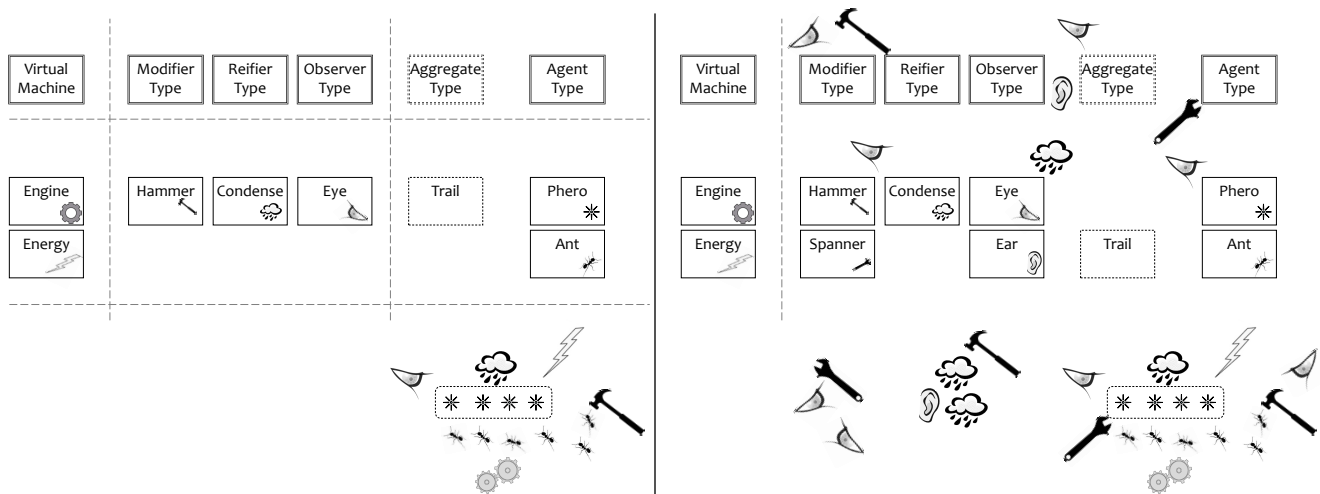

Figure 7: The architecture, showing metamodel, model (class boxes show an instance icon), and instance layers (horizontal dashed lines), and VM, ORM, and ABM subsystems (vertical dashed lines). (left) Minimal self-modification: the layers and subsystems are well-defined, the bootstrap ORM objects observe and reify the emergent trail class and modify the ABM objects, the ORM model and metamodel are fixed. (right) Constrained self-modification: the ORM components observe and modify the ABM and ORM objects, model, and metamodel (but not the VM), reifying emergent ORM components, and potentially modifying the kind of modifiers.

a minimum, compilation, dynamic object communication, and error handling). In addition, it provides some form of constraint on the modification processes. The research challenge is to achieve framework behaviour that allows a simulation to exploit emergent novelty without dissolving into chaos. A completely unconstrained framework could well modify itself out of existence. Some form of constraint, for example an analogue of conservation of energy, might be needed to allow the system to develop in interesting directions without devolving into a mess of object soup.

However, a completely constrained system, that allows no modification, no intensionalisation, is static and cannot achieve open-ended dynamics. This is the state of most classic ABM simulations.

It seems plausible that some degree of constraint between a totally static mode and meta model, and total freedom, is required; this is possibly some “edge of chaos” [13] requirement. Hence the role of the constraint is to help the system self-organise to maximally complex patterns of structure and behaviour.

## Modifying the VM

If the virtual machine is implemented in the same language and at the same level as ORM, it could potentially also be a target of the self-modification process. Here we assume that the constraint part is to be unmodifiable, for the reasons given above, but the interpreter or message handler part is a valid target of modification.

Consider a Smalltalk-80 implementation. The simulation and modifier objects are Smalltalk-80 objects, and are im-

plemented (given their execution semantics) in a Smalltalk-80 VM. A suitably defined physics engine could be included at the object level, and be subject to the same modification processes as the objects themselves.

## Discussion

Consideration of a metamodel of emergence has led to the insight that emergent properties are emergent intensional definitions. The difference exhibits itself in simulations, where the emergent properties are observed via instrumentation, rather than reified directly. If the emergent properties are reified and intensionalised, with their own definitions and behaviours, they can become the kind of agents that result in (further) emergent properties.

In order for these kinds of emergent innovation to be included in a simulation, the simulation needs to be able to modify its own model, and metamodel, dynamically (at run time). We contend that **for a simulation to exhibit open ended dynamics, it must include a form of computational reflection** that allows it to modify its own model and metamodel as the simulation is running.

We have specified the design of an open-ended architecture. (The next stage of work is to develop a prototype implementation.) This architecture has the instances, model, and metamodel all available for modification at run-time. It has three subsystems: a virtual machine providing run-time support and modification constraints, an observer-reifier-modifier intensionalizer, and a seed application. This is a *bootstrap* architecture: successful self-modification will modify this architecture.

Rosen [19, §10a] argues that the difference between an organism and a mechanism is that an organism “is closed to efficient causation”, and that a mechanism cannot be so closed. He uses Aristotle’s term “efficient cause” as the cause that brings something about. He argues that life is self-defining, self-causing, autopoietic; but that simulations cannot be, that simulations require something outside the system to define them. We claim that the reflective approach and bootstrap architecture described above *can* allow simulations to be similarly self-defining, self-generating, self-causal, and hence to exhibit some of the properties Rosen requires for life.

## Acknowledgments

## Abstract

In this paper, we study self-organized flocking in a swarm of behaviorally heterogeneous mobile robots: aligning and non-aligning robots. Aligning robots are capable of agreeing on a common heading direction with other neighboring aligning robots. Conversely, non-aligning robots lack this capability. Studying this type of heterogeneity in self-organized flocking is important as it can support the design of a swarm with minimal hardware requirements. Through systematic simulations, we show that a heterogeneous group of aligning and non-aligning robots can achieve good performance in flocking behavior. We further show that the performance is affected not only by the proportion of aligning robots, but also by the way they integrate information about their neighbors as well as the motion control employed by the robots.

## INTRODUCTION

Flocking is the cohesive and aligned motion of a group of individuals along a common direction. All studies about flocking within computer science and robotics root back to the seminal work of Reynolds (1987). He was the first to simulate flocking of birds based on three behaviors: *separation* — individuals try to keep a minimum distance between their neighbors, *cohesion* — individuals try to stay together with their neighbors, and *alignment* — individuals try to match their velocities to the average speed of their neighbors. The vast majority of the studies about flocking assume that all the robots in the swarm are behaviorally identical and exploit the three behaviors described above.

In this paper, we consider flocking in a behaviorally heterogeneous swarm of robots. All robots in the swarm use the separation and the cohesion behavioral rule. However, only a fraction of the robots, which we call the *aligning* robots, uses the alignment behavior. The rest of the robots, which we call the *non-aligning* robots, do not use the alignment behavior.

We believe that studying heterogeneity in alignment in self-organized flocking is very important from the practical point of view. The alignment behavior is more demanding in terms of robotics hardware requirements than the separation and cohesion behaviors. In fact, it requires either an elaborate sensing device, through which robots can detect the

orientation of neighboring robots or, as explained in this paper, a communication device. Therefore, understanding if a swarm can achieve flocking with only a few aligning robots can support the design of swarms with minimal hardware requirements.

We conduct simulation-based experiments and we measure self-organized flocking performance in terms of the degree of group order, group cohesiveness and average group speed. With respect to these criteria, we found that the swarm achieves good flocking performance when the proportion of aligning robots is high. Conversely, this performance decreases as the proportion gets lower. To tackle this problem, we propose a new model of robot motion. In the new model, non-aligning robots modulate their forward speed, instead of moving at a fixed forward speed as the other robots.

The rest of the paper is organized as follows. In the next section, we present the related works in flocking, starting from studies in biology and then in robotics. We then introduce our heterogeneous flocking model, the robots and we explain how we implement flocking on the robots. Subsequently, we describe the experimental setup, the metrics and the results. Finally, we conclude the paper and propose future directions of research.

## RELATED WORK

Flocking is a widely observed phenomenon in social animals (Camazine et al., 2001) such as locusts (Buhl et al., 2006), birds (Ballerini et al., 2007) or human beings (Dyer et al., 2008). Animal groups show a great diversity in their population due to the differences in age, morphology (Krause et al., 1998), nutritional state (Krause, 1993), personality (Michelena et al., 2010), and leadership status (Reebs, 2000) of the individuals. This diversity mainly results in behavioral differences among the individuals. Couzin et al. (2002) showed that behavioral differences between the individuals in a group change both the dynamics and the organization of the group. Subsequently, Couzin et al. (2005) conducted a seminal study about leadership in animal groups. They modeled a heterogeneous group of in-

dividuals of which only a few are aware of a target direction. They showed that the few informed individuals are able to move the whole group along the target direction. In Janson et al. (2005), the authors propose a model to explain how scout bees are able to direct large swarms of uninformed bees towards a new nesting site. Even when the proportion of scout bees is low, they are able to lead the swarm by flying through it at a slightly faster speed. Sayama (2009) presented the preliminary results obtained in simulation using the Swarm Chemistry framework. They studied the movement of a swarm consisting of two different chemical species, and found that a chaser-escaper relationship between the two different populations of agents is established. More recently, Diwold et al. (2011) showed how a swarm can still fly towards a common direction even when the agents are not all aligned, and when the location of the nesting site is not known with precision.

In robotics, most of the studies about flocking assume a homogeneous set of behaviorally equivalent individuals. One of the earliest studies in robotics was performed by Mataric (1994). She devised a set of “basis behaviors” to implement flocking in a group of robots: safe-wandering, aggregation, dispersion and homing. With the proposed set of behaviors, robots are able to move cohesively towards a homing direction. Kelly and Keating (1996), following a behavior-based approach, designed a leader-following behavior to realize flocking. Hayes and Dormiani-Tabatabaei (2002) proposed a flocking behavior having collision avoidance and alignment behaviors based on local range and bearing measurements. Spears et al. (2004) proposed a framework based on artificial physics. The robots were able to form a regular lattice structure using attraction/repulsion virtual forces and move along a direction indicated by a light source in the environment. Holland et al. (2005) proposed a flocking behavior for unmanned ground vehicles based on separation, cohesion and alignment behaviors. Turgut et al. (2008) proposed a flocking behavior based on separation/cohesion and alignment behaviors. They implemented this behavior in robots with limited sensing capabilities and conducted a systematic study on the effect of sensing noise in heading measurement on flocking. In a recent study, Moslinger et al. (2009) proposed a flocking behavior for robots with limited sensing capabilities. It is based on only attraction and repulsion behaviors. By adjusting the sizes of attraction and repulsion zones, they achieved flocking for a small group in a constrained environment.

Other works in robotics considered a group of behaviorally heterogeneous robots. Momen et al. (2007) studied flocking with a heterogeneous robotic swarm inspired by mixed-species foraging flocks of birds (Graves and Gotelli, 1993). Using simulations, they showed some aspects of mixed-species flocking, such as behavioral differences in their attraction and repulsion rules. Çelikkanat and Şahin (2010), inspired by Couzin et al. (2005) extended the flock-

ing behavior proposed by Turgut et al. (2008) and created a heterogeneous robot swarm by informing some of the robots about a target direction. Recently, in another follow-up study, Ferrante et al. (2010) introduced a new communication strategy to improve flocking performance in case of both static and changing target directions.

To the best of our knowledge, most of the studies in swarm robotics about self-organized flocking have not considered diversity in alignment capabilities.

## METHOD

We follow a design method based on the artificial physics framework introduced by Spears et al. (2004). According to this method, robots exert virtual forces on each other. The swarm consists of aligning and non-aligning robots. Aligning robots are subject to the following virtual forces

$$\mathbf{f} = \alpha_1 \mathbf{p} + \beta_1 \mathbf{h},$$

whereas for the non-aligning robots the virtual force is computed as

$$\mathbf{f} = \alpha_2 \mathbf{p}.$$

We define  $\mathbf{p}$  as the *proximal control vector* and  $\mathbf{h}$  as the *alignment control vector*. The proximal control vector  $\mathbf{p}$  accounts for attraction and repulsion rules for keeping the robot together with its neighbors and to avoid collisions.

The alignment control vector  $\mathbf{h}$  is used to make the aligning robots match the average heading direction of its neighboring aligning robots. The parameters  $\alpha_1$ ,  $\beta_1$  and  $\alpha_2$  are used to adjust the contribution of the corresponding vectors.

### Proximal control

Let  $m_p$  denote the number of neighbors of a robot within a range  $D_p$ . Let also  $d_i$  and  $\phi_i$  denote the relative range and bearing of the  $i^{th}$  neighbor, respectively. The proximal control vector  $\mathbf{p}$  is given by:

$$\mathbf{p} = \sum_{i=1}^{m_p} p_i(d_i) e^{j\phi_i}.$$

$p_i$  is calculated as a function of  $d_i$  using a force function derived from the Lennard-Jones potential function, which results in the formation of regular structures as shown in Hettiarachchi and Spears (2009):

$$p_i(d_i) = 12\epsilon \left[ \frac{d_{des}^{12}}{d_i^{13}} - \frac{d_{des}^6}{d_i^7} \right].$$

The parameter  $\epsilon$  determines the strength of the attractive and repulsive force, and  $d_{des}$  is the desired distance between the robots.

## Alignment control

Let  $\theta_0$  denote the orientation of a given robot. Furthermore, let  $m_a$  denote the number of aligning robots within the range  $D_a$  of this robot, and  $\theta_i, i \in \{1, \dots, m_a\}$  their orientation. All orientations are expressed in the body-fixed reference frame of the robot under consideration<sup>1</sup>. The robot calculates the alignment control vector, that is, the average orientation of the  $m_a$  robots, including its own:

$$\mathbf{h} = \frac{\sum_{i=0}^{m_a} e^{j\theta_i}}{\|\sum_{i=0}^{m_a} e^{j\theta_i}\|},$$

where  $\|\cdot\|$  denotes the norm of a vector.

## Motion control

We present two motion control rules. The two rules differ in the way the forward speed  $u$  and the angular speed  $\omega$  are determined. The first rule is denoted as *constant forward speed motion control* (henceforth CMC). In CMC, robots are always moving at a constant forward speed, but can change their angular speed. According to the second rule, denoted as *variable forward speed motion control* (henceforth VMC), robots move not only at a variable angular speed but also at a variable forward speed.

**CMC:** The forward speed is kept constant at

$$u = U.$$

The angular speed is proportional to the angular component of the total force  $\mathbf{f}$ . Hence, it ignores the magnitude  $\|\mathbf{f}\|$  of the force:

$$\omega = K\angle\mathbf{f}.$$

**VMC:** First, let  $\mathbf{f}_x = \|\mathbf{f}\| \cos(\angle\mathbf{f})$  and  $\mathbf{f}_y = \|\mathbf{f}\| \sin(\angle\mathbf{f})$  denote the projection of the total force  $\mathbf{f}$  on the  $x$ -axis and  $y$ -axis of the robot body-fixed reference frame respectively. Accordingly, the forward speed  $u$  is directly proportional to the  $x$  component of the total force and the angular speed  $\omega$  is directly proportional to the  $y$  component of the force. Hence:

$$\begin{aligned} u &= K_1 \mathbf{f}_x \\ \omega &= K_2 \mathbf{f}_y. \end{aligned}$$

$K, K_1, K_2$  are constants, whose values are given in Table 1.

In this work, we consider and study two different cases in which we vary the motion control rule applied to the non-aligning robots. In the first case, referred as the *CMC-CMC*

<sup>1</sup>In our study, we define two reference frames, both of which use the right-hand convention. One is the reference frame common to all of the robots, which is available due to the light source. The other is the body-fixed reference frame specific to each robot. The body-fixed reference frame is fixed to the center of a robot: its  $x$ -axis points to the front of the robot and its  $y$ -axis is coincident with the rotation axis of the wheels.

case, all robots share the same motion control rule, that is, CMC. In the second case, referred as the *CMC-VMC* case, aligning robots use CMC, whereas non-aligning robots use VMC.

## FLOCKING WITH ROBOTS

In this study, the swarm is composed of simulated versions of the foot-bot robot developed by Bonani et al. (2010). The foot-bot is a differentially-driven mobile robot with the following sensors and actuators: i) A light sensor used to measure the orientation of robot ( $\theta_0$ ) with respect to a light source present in the environment perceived by all robots. ii) A range and bearing sensing and communication device (henceforth called RAB), with which a robot can communicate with its neighbors and perceive their range and bearing measurements (Roberts et al., 2009). iii) Two wheels actuators, that are used to control independently the left and right wheels speed of the robot.

To achieve proximal control with the foot-bot the RAB is used for measuring the relative range and bearing  $d_i$  and  $\phi_i$  of the  $i_{th}$  neighbor. For achieving alignment control, we use communication to simulate orientation sensing as in Turgut et al. (2008). In particular, each aligning robot sends its orientation, expressed in the global reference frame, using the communication unit present in the RAB. At the same time, it receives the orientation  $\theta_i$  of its  $i_{th}$  neighboring aligning robot. It transforms this angle into its body-fixed reference frame. In this way, we are able to simulate a robot sensing the orientation of its neighboring aligning robots.

To achieve motion control, we first limit the forward speed within  $[0, U_{max}]$ , and the angular speed within  $[-\Omega_{max}, \Omega_{max}]$ . We then use the differential drive model used in Turgut et al. (2008) to convert the forward speed  $u$  and the angular speed  $\omega$  into the linear speeds of the left ( $N_L$ ) and right ( $N_R$ ) wheel:

$$N_L = \left(u + \frac{\omega}{2}l\right),$$

$$N_R = \left(u - \frac{\omega}{2}l\right),$$

where  $l$  is the distance between the wheels.

The values of the constants that we used in our experiments are given in Table 1.

## EXPERIMENTS

We execute simulation-based experiments with a swarm of foot-bots using the ARGOS simulator (Pinciroli et al., 2011), an open-source<sup>2</sup>, plug-in based, multi-physics engine simulator.

<sup>2</sup><http://iridia.ulb.ac.be/argos/>

Variable	Description	Value(s) / Range
$N$	Number of robots	$\{25, 100\}$
$\rho$	Prop. of aligning robots	$\{0.4, 0.8\}$
$\beta_1/\alpha_1$	Align. robots parameters	$\{1, 2, 4, 6, 8, 10\}$
$\alpha_2$	Non align. robots parameter	$\{1, 2, 4, 6, 8, 10\}$
$U$	Maximum forward speed	1.5 cm/s
$K$	CMC angular gain	0.5 1/s
$K_1$	VMC linear gain	0.25 s/kg
$K_2$	VMC angular gain	0.1 s/(kg · m)
$l$	Inter-wheel distance	0.1 m
$U_{max}$	VMC max forward speed	20 cm/s
$\Omega_{max}$	VMC max angular speed	$\pi/2$ rad/s
$\epsilon$	Strength of pot. function	0.5
$d_{des}$	Inter-robot distance	0.6 m
$\sigma$	Amount of noise	0.1
$T$	Experiment duration	600 secs

Table 1: Experimental values or range of values for all constants and variables

## Experimental setup

At the beginning of each experiment,  $N$  mobile robots are randomly placed (position and orientation-wise) with a proportion  $\rho \in [0, 1]$  of aligning robots. The density of robots is kept fixed and equal to 6 robots per square meter on a square shaped area. A light source is placed at a fixed position in the environment, far away from the swarm, to provide the common reference frame.

In the experiments, noise is added to the orientation measurement and the angle of the proximal control vector. Noise is modeled as a uniformly distributed random variable within the range  $[-\sigma\pi, \sigma\pi]$ .

We conduct experiments considering the two different cases of motion control.

**CMC-CMC** In this case, all robots use CMC. Here, we study the effect of the ratio  $\frac{\beta_1}{\alpha_1}$ , and we do not change  $\alpha_1$  and  $\beta_1$  independently, since CMC does not utilize the magnitude of  $\mathbf{f}$ , but only its angular component. As such, multiplying both  $\alpha_1$  and  $\beta_1$  with the same constant value will produce no difference in the robot motion. For the same reason,  $\alpha_2$  does not effect the robot motion.

**CMC-VMC** In this case, aligning robots use CMC whereas non-aligning robots are using VMC. For the non-aligning robots, the magnitude of  $\mathbf{f}$  plays a role in their motion. Thus, additionally to the effect of changing  $\frac{\beta_1}{\alpha_1}$  of the aligning robots, we study the effect of changing  $\alpha_2$  of the non-aligning robots.

We show the results in heterogeneous self-organized flocking with medium ( $N = 25$ ) and large ( $N = 100$ ) swarm sizes and with low ( $\rho = 0.4$ ) and high ( $\rho = 0.8$ ) proportions

of aligning robots. We study the effect of changing the ratio  $\frac{\beta_1}{\alpha_1} \in \{1, 2, 4, 6, 8, 10\}$  and, for the heterogeneous case, we also study the effect of changing  $\alpha_2 \in \{1, 2, 4, 6, 8, 10\}$ , but we report here only the results obtained with the best case, that is,  $\alpha_2 = 10$  (refer to Stranieri et al. (2011) for the complete set of results ). In our supplementary page (Stranieri et al., 2011), we also report the flocking performance as a function of  $\rho \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$ .

For each experimental setting, we execute  $R$  runs and report median and interquartile range of the results. The duration of one run is  $T$  simulated seconds.

We study how the heterogeneous flocking performance is influenced by: i) the way robots implement their motion (CMC-CMC motion versus CMC-VMC motion), ii) the parameters that affect the strength of the proximal control vector and of the alignment control vector, that is,  $\frac{\beta_1}{\alpha_1}$  and  $\alpha_2$ , and iii) the ratio of aligning robots  $\rho$ .

We also experiments in the VMC-VMC case, but we didn't obtain any positive results, even with  $\rho = 1$ .

## Metrics

In this study, we are interested in having a swarm of robots that move cohesively as a single group. Furthermore, the swarm should be aligned towards the same direction and move towards it as fast as possible. We use three metrics to measure the degree of attainment of these objectives: order, group cohesion and rescaled group speed.

**Order:** The order metric  $\psi$  measures the angular order of the robots (Vicsek et al., 1995),  $\psi \approx 1$  when the group shares a common heading and  $\psi \ll 1$  when each robot is pointing in a different direction. The order is defined as:

$$\psi = \frac{1}{N} \left\| \sum_{i=1}^N e^{j\theta_i} \right\|.$$

**Group cohesion:** To measure group cohesion  $\xi$ , we determine the number of groups  $g$  present at the end of each experiment (Couzin et al., 2005). Group cohesion is computed as:

$$\xi = 2 - \min(2, g).$$

and therefore takes values in  $\{0, 1\}$ .

**Rescaled Group speed:** We calculate the average group speed as:

$$s = \left\| \frac{\mathbf{c}_T - \mathbf{c}_0}{T} \right\|,$$

where  $\mathbf{c}_T$  and  $\mathbf{c}_0$  are the position of the center of mass of the swarm at the end and at the beginning of the experiment, respectively. We then rescale the average group speed:

$$s_r = \frac{s}{U},$$

where  $U$  is the maximum forward speed of CMC.

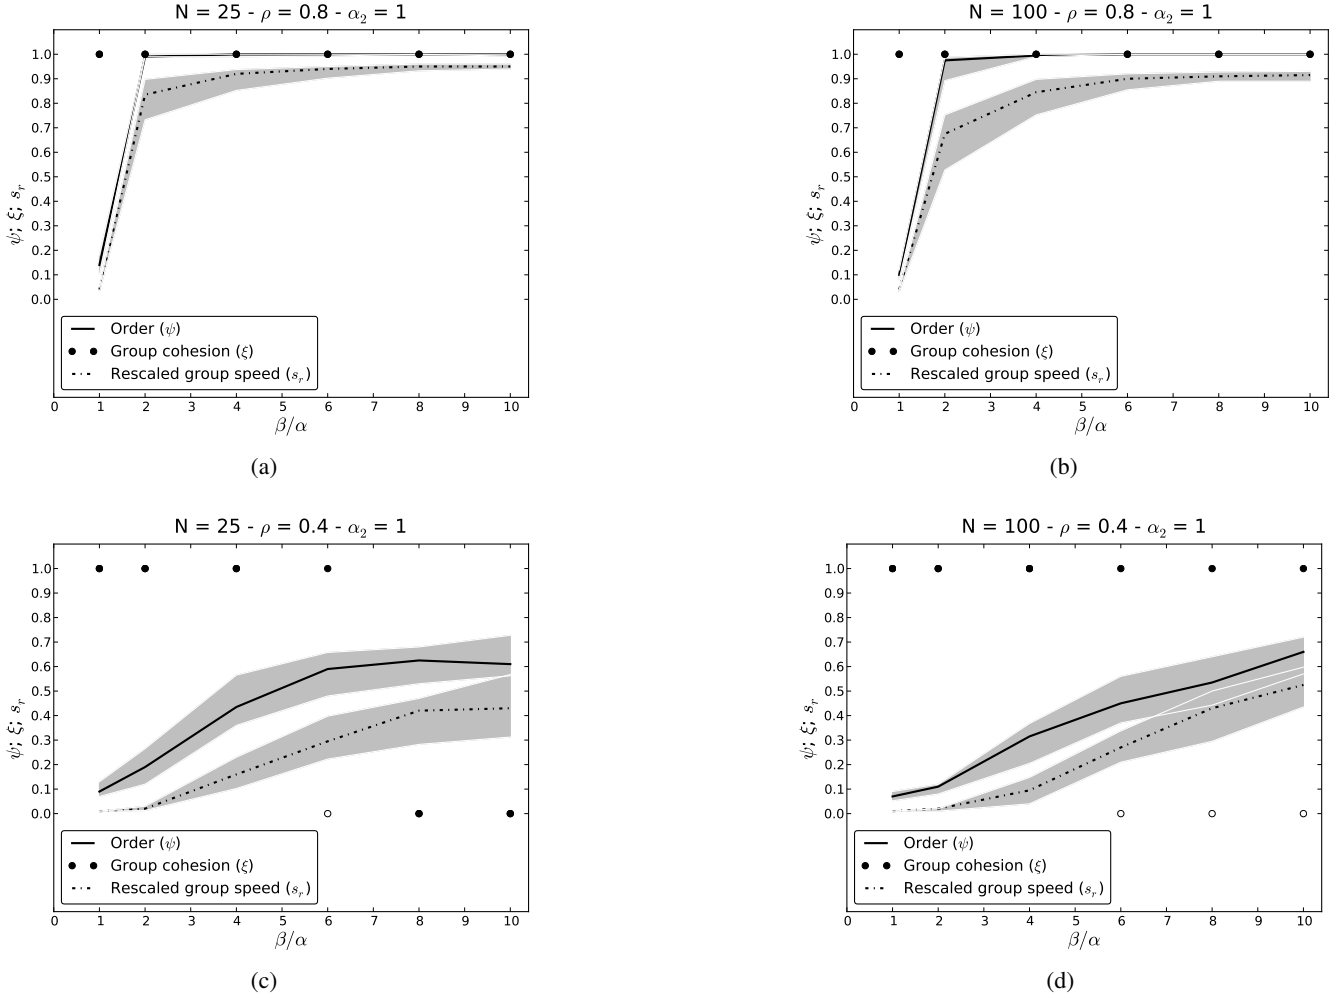

Figure 1: CMC-CMC case experiments for varying swarm size ( $N \in \{25, 100\}$ ) and ratio of aligning robots ( $\rho \in \{0.4, 0.8\}$ ). Thick lines show the median values, whereas the gray areas show the 25% and the 75% interquartile range of the data. For group cohesion, filled circles correspond to median values and empty circles to the 25% percentile score of the data.

## Results in the CMC-CMC case

The experimental results for CMC-CMC case are depicted in Figure 1. We first focus on the  $\rho = 0.8$  case, for both  $N = 25$  (Figure 1a) and  $N = 100$  (Figure 1b). Results show that the swarm is cohesive in most runs. However, order and speed are high only when  $\frac{\beta_1}{\alpha_1} \geq 2$ . Furthermore, while order is high at different values of the ratio  $\frac{\beta_1}{\alpha_1}$ , speed increases with increasing values of  $\frac{\beta_1}{\alpha_1}$ , until it saturates at around  $\frac{\beta_1}{\alpha_1} = 6$ . This shows that, when the alignment control vector is higher, robots tend to move faster. This is explained by the fact that the alignment control vector is more stable, over time, than the proximal control vector. Thus, the higher the weight of the alignment control vector, the more the robots tends to move forward rather than to turn. This allows the swarm to move faster, until speed saturates at the

maximum forward speed  $U$ .

When the proportion of aligning robots is  $\rho = 0.4$ , performance gets sensibly worse (Figures 1c and 1d). In both cases ( $N = 25$  and  $N = 100$ ), we observe two possible outcomes: for small values of the ratio  $\frac{\beta_1}{\alpha_1}$ , the swarm remains cohesive, but does not move. This happens because the relative contribution of the alignment control vector is not enough for the aligning robots to pull the entire swarm towards the agreed goal direction. For larger values of the ratio  $\frac{\beta_1}{\alpha_1}$ , group speed and order get higher. However, in at least 25% of the runs, the swarm splits. This happens because, in those runs, clusters of non-aligning robots are present. Since the motion of these robots is governed only by the proximal control vector, they are not able to match the higher speed of the aligning robots since they tend to turn more rather than to move forward, thus they remain disconnected from the group.

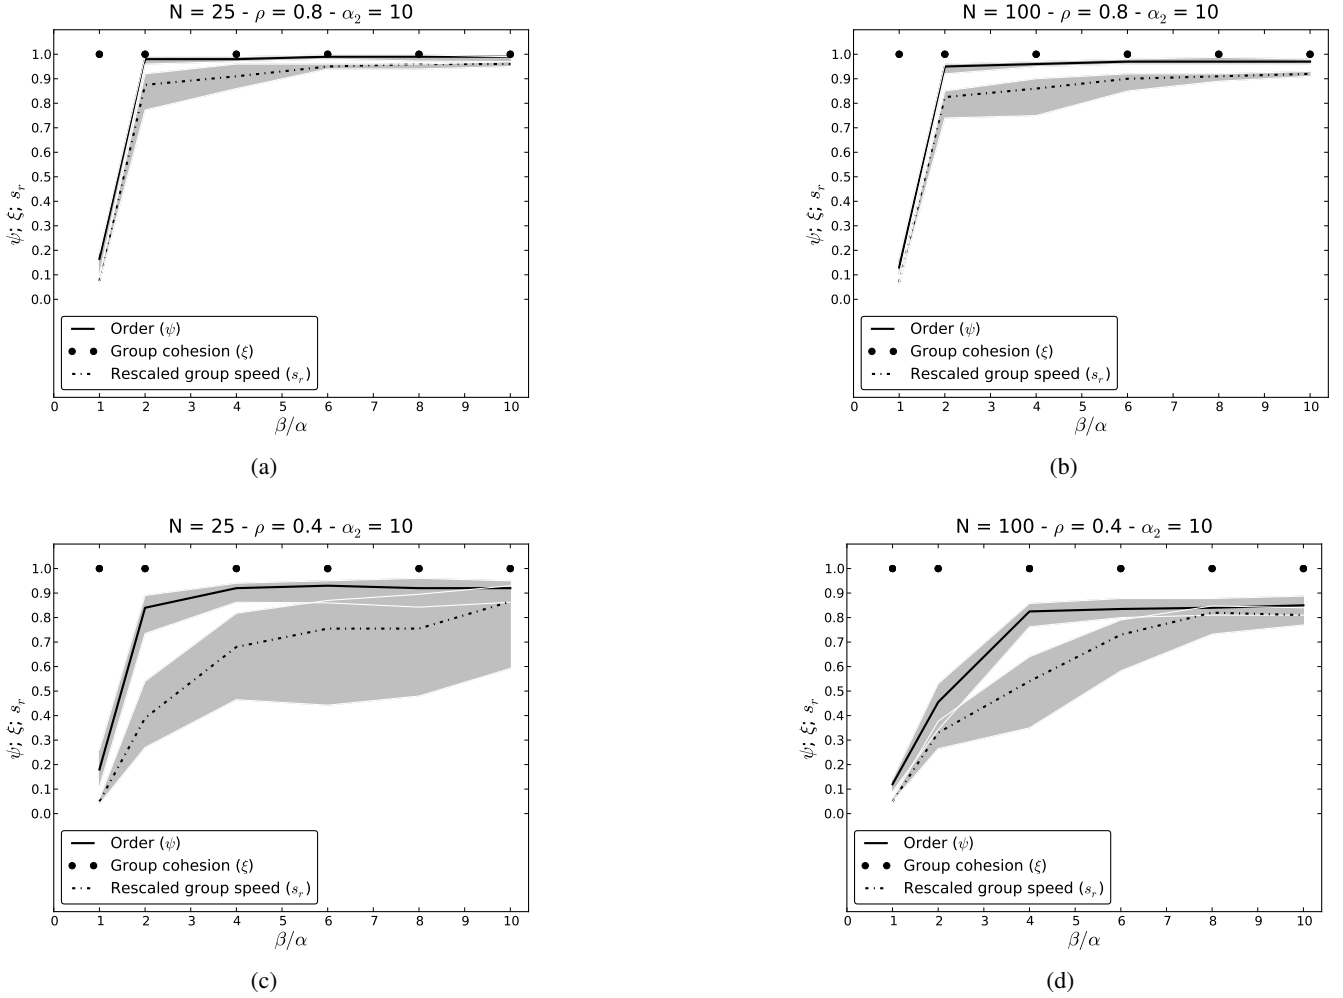

Figure 2: CMC-VMC case experiments for varying swarm size ( $N \in \{25, 100\}$ ) and ratio of aligning robots ( $\rho \in \{0.4, 0.8\}$ ). Thick lines show the median values, whereas the gray areas show the 25% and the 75% interquartile range of the data. For group cohesion, filled circles correspond to median values and empty circles to the 25% percentile score of the data.

In Stranieri et al. (2011), we also report the performance as function of  $\rho$ . We consider the case  $\frac{\beta_1}{\alpha_1} = 10$ , as it generally provides the best overall results. As shown in Stranieri et al. (2011), the flocking performance is acceptable in terms of the metrics used for  $\rho \geq 0.6$  in both cases  $N = 25$  and  $N = 100$ .

### Results in the CMC-VMC case

In the CMC-VMC case, results with  $\rho = 0.8$  (Figures 2a and 2b), are similar to the results obtained, with the same ratio, in the CMC-CMC case. The results with  $\rho = 0.4$  are much better in the CMC-VMC case (Figures 2c and 2d) with respect to the CMC-CMC case (Figures 1c and 1d). With both swarm sizes we have that, when  $\frac{\beta_1}{\alpha_1} > 2$ , the swarm is able to effectively flock together at the cost of a reduced speed.

In Stranieri et al. (2011), we also report the flocking performance as a function of  $\rho$  for  $\frac{\beta_1}{\alpha_1} = 10$  and  $\alpha_2 = 10$ . Differently from the CMC-CMC case, in the CMC-VMC case the performance of flocking degrades more gracefully as the proportion of non-aligning robots decreases.

The improved capability of the swarm to stay together is due to the advantage of using VMC in the non-aligning robots. In fact, non-aligning robots are able to respond to the high variations in the proximal control vector much more when they can also change their forward speed. As such, they are also able to stay together with the aligning robots, both when they are alone and when they are in small or big clusters. Finally, the reduced speed and the high variation of speed among runs is due to the following fact. In presence of a low proportion of aligning robots, we observed that the group heading direction is stable over short periods

of time but changes over long periods of time due to the disturbances caused by the non-aligning robots. This results in a non-linear trajectory executed by the entire swarm, which is different for each run. Since the rescaled group speed is computed assuming a linear trajectory, this measurement has large variation in the total displacement changes from run to run.

## CONCLUSIONS AND FUTURE WORKS

In this paper, we studied self-organized flocking in a swarm composed of behaviorally heterogeneous mobile robots. The swarm is composed of aligning robots, which are able to agree on a common heading direction, and non-aligning robots which lack this capability. We furthermore propose a new model for achieving motion in self-organized flocking. According to this model, aligning robots only change their angular speed, whereas non-aligning robots change both their forward and their angular speed.

We study the performance in terms of group alignment order, cohesiveness and speed. Results show that self-organized flocking is also possible when some individuals in the swarm lack the capability to agree on a common direction. More in particular, we showed that: i) a higher proportion of aligning robots always corresponds to a better performance; ii) performance is affected by the relative contribution of alignment and proximal control, and iii) for smaller proportions of aligning robots, flocking is possible only when the non-aligning robots also change their forward speeds.

Possible directions for future work are the following: First, we plan to study energy efficiency within the same framework of study. In particular, the use of a heterogeneous group of aligning and non-aligning robots poses a trade-off between efficiency of the motion and energy utilized. In fact, we observed that, in order for the swarm to hold cohesiveness, the non-aligning robots spend a lot of energy to vary their speed more reactively. Second, we would like to study the correlation between spatial aspects of the swarm composition. In particular, we would like to study whether particular configurations (i.e., topology, connectivity, ...) have different effects on the flocking performance. Third, we plan to perform experiments involving two different types of real robots.

# An improved transfer entropy method for establishing causal effects in synchronizing oscillators

James Thorniley

Center for Computational Neuroscience and Robotics  
University of Sussex, Brighton, UK  
jt241@sussex.ac.uk

## Abstract

A number of authors have proposed that the analysis of spatio-temporal information transfer may help to understand cognitive behavior in biological and artificial agents. A specific case of interest is the study of synchronization of central pattern generators (CPGs) in embodied systems. Pitti et al. used simulated biped walkers to demonstrate a correlation between task success and measured transfer entropy from the body to the neural oscillator. This suggests it may be possible to use transfer entropy to help understand, control and improve the behavior of limbed robots.

This paper presents a novel method of analyzing synchronizing oscillators with transfer entropy, which it is hoped will lead to advances in controlling such systems. The necessary discretization of continuous time oscillator observations is performed via a stroboscopic analysis that preserves the information of interest and allows a natural interpretation of the results. Unlike some CPG studies, the current work addresses the tendency of naive transfer entropy calculations to overestimate causal relationships in a significant and non-trivial way. Transfer entropy may also underestimate causal links when used on purely observational data, so it is important to determine the limits of the method. It is found that in weak (rather than rigid) synchronization transfer entropy can be measured and interpreted as a causal information flow.

## Introduction

Recent work has developed information theoretic understandings of embodied cognition (Lungarella and Sporns, 2006; Pfeifer et al., 2007). In learning and adaptation, information theoretic feedback mechanisms can guide system development in the absence of explicit goal directed feedback (Klyubin et al., 2005). By studying the information flow in an evolved artificial agent's neural network, Williams and Beer (2010) are able to explain how the neural dynamics perform a computational role. In evolutionary robotics, the use of information theoretic goal functions has been shown to generate interesting behaviors (Der et al., 2008).

Central pattern generator (CPG) synchronization is thought to underlie animal gaits (Collins and Stewart, 1993) and potentially therefore has applications in robotics. However, in a complex synchronizing system it is often difficult

to determine the nature of the interactions between oscillators. Ceguerra et al. (2011) approached this problem by using a form of transfer entropy to analyze the synchronization process in networks of coupled oscillators, which was shown to be more effective than other methods.

The current work investigates information transfer between oscillators coupled by non-trivial physical mechanisms. This is similar to the study by Pitti et al. (2009), in which simulated biped walkers were coupled to oscillators. It was shown that at optimal values of the coupling (where the best walking behavior is achieved) there is an increase in information transfer from the body to the oscillator. Thus the information transfer is thought to correlate to the successful entrainment of the body and controller dynamics.

Transfer entropy (Schreiber, 2000) is the information gained from conditioning the entropy rate of a time dependent variable on a secondary historical variable as well as its own past. It is a directional measure, and is often interpreted as signifying causal links (Pitti et al., 2009; Lungarella and Sporns, 2006), however when used to analyze finite experimental time series data there is a strong risk of overestimating such causal influence, a problem that is known from the literature (Marschinski and Kantz, 2002; Lizier and Prokopenko, 2010). Furthermore, because transfer entropy is applied here to purely observational data, this method is only claimed to be a reasonable guide for detecting causal influences, as outside intervention would be needed to expose all causal links (Ay and Polani, 2008). A complete scientific approach to building causal models is well beyond the scope of this paper (see Pearl, 2009).

The method of calculating transfer entropy presented here uses a novel time discretization approach, inspired by the stroboscopic analysis of Schäfer et al. (1998). Other than that, the method follows Marschinski and Kantz (2002) by conditioning on the longest practicable history of the target variable (a requirement that is sometimes neglected).

The effect of oscillator coupling on transfer entropy is investigated in a continuous time system composed of either a single oscillator and passive body model, or a pair of two such systems (see Figure 1). The following sections will first

Figure 1: Simplified system under study. An electronic oscillator is attached to a mass-spring-damper system, providing force actuation and incorporating the resultant extension of the spring into the feedback path of the oscillator circuit. The model is extended by duplicating the system (dashed box) and coupling via the mechanical component.

introduce the models studied, and later develop the transfer entropy calculation based on time series data from simulations of these models. The relationship between transfer entropy and the dynamical process of synchronization is discussed. It is argued that a state of synchronization will not always lead to increased transfer entropy, but during an ongoing process of weak synchronization transfer entropy will be found, and in such cases will show causal relationships. It appears that measured transfer entropy may be useful in predicting the effects of making changes in a system, such as varying coupling parameters, which implies that it may be possible to develop control techniques based on information transfer.

## Model construction

The model developed here is intended to be a minimal first approximation to a physically realizable modular active dynamic walker. That is, though it is intended that further work will develop this system as a real robot, the current model is not fully realistic, but contains the fundamental components: a chaotic oscillator that can be implemented as an electronic circuit, and a simple mass-spring-damper system analogous to a passive compliant robot body. This structure makes it comparable to the architecture of Pitti et al. (2009), except that the neural controller here is a continuous time analog circuit, rather than a discrete time map, and the physical component does not include a full environment.

### Chaotic oscillator

The oscillator design developed by Sprott (2000) and improved on in Kiers et al. (2004) was chosen. It is extremely simple to implement using widely available electronic components, and can easily be tuned to produce chaotic or periodic behavior. The Sprott system has the further advantage of having relatively stable dynamics, in that it tends to reach its only periodic or chaotic attractor quickly after being biased at a sensible voltage and does not tend to drift or diverge away from the desired dynamics.

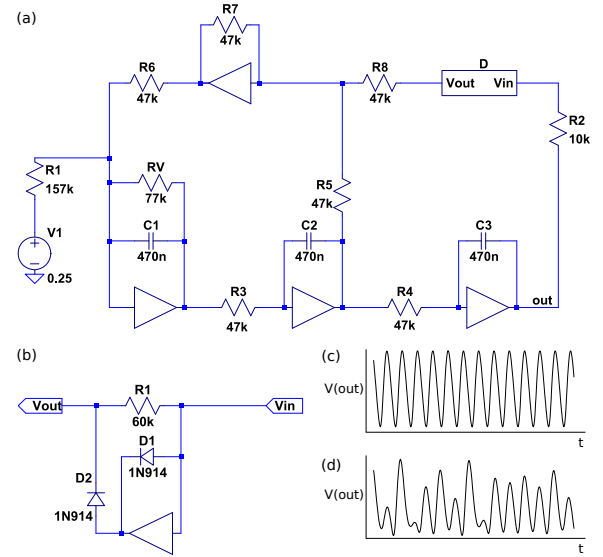

Figure 2: Chaotic oscillator based on Kiers et al. (2004). (a) Positive feedback based circuit design. (b) Nonlinear sub-circuit component  $D$ . (c) Typical steady state periodic output simulated using LTSpice, with resistor  $R_v$  set to 50 kΩ (periodic solution) and (d) 77 kΩ (chaotic solution).

The dynamics of the oscillator in isolation are well documented by Kiers et al. (2004), but it is useful to recap them here. The circuit diagram is given in Figure 2. The circuit consists of three op-amp integrators producing anti-derivative signals in a chain, with the output of the final integrator being fed back through a nonlinear amplifier and a combined with the output of the other integrators with a summing amplifier. The circuit effectively implements the following third-order “jerk” function in which  $D(x) = -6 \min(x, 0)$  and  $Q$  and  $\alpha$  are constants.

$$\ddot{x} = -Q\ddot{x} - \dot{x} + D(x) - \alpha \quad (1)$$

The constant bias  $\alpha$  is provided by the voltage source, and for a range of small positive values (e.g.  $\alpha = 0.1$  works well) it will allow oscillatory behavior. Tuning  $R_v$  in the circuit will vary the  $Q$  parameter, which will result in chaotic and periodic solutions at different values, as shown in Figures 2c and d, generated by simulating the circuit with LTSpice<sup>1</sup>. The fundamental frequency of the oscillations is related to the time constants of the integrators, that is  $\frac{1}{\omega_0} = \tau_0 = RC = 47 \text{ k}\Omega \times 470 \text{ nF} \approx 0.022 \text{ s}$  in the example circuit of Figure 2. Equation 1 is a non-dimensionalized description of the circuit attained by taking the derivatives with respect to  $\omega_0 t$  (so if  $t$  is in seconds, equation 1 will effectively have a natural frequency of  $\omega_0 = 1 \text{ rad s}^{-1}$ ). Thus control of the fundamental frequency in the numerical solution of equation 1 is achieved, when required, by rescaling

<sup>1</sup><http://www.linear.com/designtools/software/#LTspice>

Figure 3: Maxima of the oscillator variable  $x_1$  at different values of  $Q$ . The fixed parameters are  $\alpha = 0.1$ ,  $\zeta = 0.3$  and the coupling is (a)  $\gamma = 0$  (no coupling), (b)  $\gamma = 0.1$ , (c)  $\gamma = 0.3$

the time variable by the desired value of  $\omega_0$ .

Figure 3a shows the effect of  $Q$  on the dynamics of the system, by showing the maxima of  $x_1$  over time at different values of  $Q$ . The diagram can be obtained by numerically integrating equation 1 with a computer library such as LSODE (Hindmarsh, 1983), as was used here, or by using a SPICE simulation of the circuit in Figure 2. The system follows a period doubling route to chaos as  $Q$  decreases, with a notable periodic island around  $Q \approx 0.58$  and returns to periodicity via a further bifurcation near  $Q \approx 0.47$ .

### Coupled mass-spring-damper

The dynamics of an ideal mass-spring-damper (MSD for brevity) can be expressed in terms of the time dependent extension of the spring  $x$  using the second order differential equation 2 with  $m$  being the mass,  $k$  the spring constant and  $c$  the damping coefficient.

$$\ddot{x} + \frac{c}{m}\dot{x} + \frac{k}{m}x = 0 \quad (2)$$

Alternatively define the angular velocity  $\omega_0 = \sqrt{\frac{k}{m}}$  and the damping ratio  $\zeta = \frac{c}{2\sqrt{mk}}$ , take derivatives with respect to  $\omega_0 t$  as in equation 1 (see above) and rearrange to get:

$$\ddot{x} + 2\zeta\dot{x} + x = 0 \quad (3)$$

To couple the two systems together, the oscillator variable is added to the acceleration of the spring system after subtracting 0.5 (to make the influence of the oscillator approximately symmetric around zero, as it normally oscillates between around 0 and 1), and the spring extension is added to the feedback path of the oscillator after multiplying by a coupling parameter  $\gamma$ . Thus the complete system is given by equations 4 and 5, with  $x_1$  and  $x_2$  being the time varying oscillator variable and spring extension respectively.

$$\ddot{x}_1 = -Q\ddot{x}_1 - \dot{x}_1 + D(x_1 + \gamma x_2) - \alpha \quad (4)$$

$$\ddot{x}_2 = -2\zeta\dot{x}_2 - x_2 + (x_1 - 0.5) \quad (5)$$

Note that the derivatives in both equations are taken with respect to the same time variable  $\omega_0 t$  and thus the oscillator and MSD systems always have identical natural angular velocities. This implies  $RC = \sqrt{\frac{m}{k}}$ , clearly in a real system this would be unlikely, so the following assumes that small discrepancies in the spring and oscillator natural frequencies are of little consequence.

The coupling could be achieved electronically by adding a voltage signal into the input of the nonlinear feedback amplifier in the circuit in Figure 2 via a series variable resistor such that when the diodes are switched off the op-amp in the nonlinear sub-circuit  $D$  acts as a summing amplifier and the variable resistor allows control of the coupling strength.

With no coupling ( $\gamma = 0$ ) clearly the oscillator drives the MSD but will not be influenced by it, thus the bifurcations of the oscillator dynamic will remain as in Figure 3a. With  $\gamma > 0$  the bifurcation structure changes dramatically, as shown in Figures 3b and 3c.

### Synchronization vs. resonance

Is the change of the dynamics as coupling is increased shown in Figure 3 a form of synchronization? When coupling (here meaning the feedback coefficient  $\gamma$ ) is zero an engineer might call the MSD system a passive resonant filter – remember that is it still driven by the electronic oscillator, so the frequency spectrum of the spring extension will appear to be a filtered version of the oscillator output. With feedback however, the oscillator changes its behavior noticeably as we have seen, so perhaps there is something more than simple resonance happening – a form of synchronization.

This appears to be the view taken by Pitti et al. (see Figure 3 in Pitti et al., 2009), who suggest that resonance is the forward process (from oscillator to dissipative system) and synchronization occurs along the feedback path. However this seems to contradict the view of Pikovsky et al. (2001, pp. 14–17) and Ceguerra et al. (2011), who require that synchronization only applies to synchronous variation of systems that are capable of oscillating independently.

Pikovsky et al. give the example of an ecological sys-

tem such as hare-lynx populations, where both variables (the populations of the two species) oscillate in a phase locked manner, but the system cannot be decomposed into isolated subsystems. Assuming the lynxes eat only hares, then an isolated lynx population with no access to hares would simply die out, not oscillate at some natural frequency. Likewise an isolated mass-spring-damper not stimulated by an appropriate oscillator will die down as its energy dissipates.

Of course some mechanical systems can oscillate independently – think of a passive dynamic walker (McGeer, 1990), a biped structure that walks down a hill, obtaining its energy purely from gravitational potential. As long as the slope is present, the passive dynamic walker could be considered to have its own natural oscillation. If this were the system being coupled to a neural oscillator, then it would seem that true synchronization could be discussed. However current scenario of an isolated mass-spring-damper is unambiguous – there is decomposition that leaves two oscillators and hence no synchronization as a “complex dynamical process, not a state” (Pikovsky et al., 2001). In the later experiments of Pitti et al. (2009) there are multiple neural oscillators in a single system, so the notion of synchronization becomes more applicable. This scenario will also be investigated later in this paper.

## Transfer entropy

This section will develop a measure of transfer entropy that can be meaningfully applied to continuous time oscillators.

Initially, assume we have two discrete time series  $X$  and  $Y$  of finite length. The value of  $X$  at time  $n \in \{1, 2, \dots, N\}$  is  $X_n$ , discretized such that  $X_n \in \mathbf{X}$ , a finite set of symbols. Apply the same notation to  $Y$ .

The  $k$ -history of  $X$  at  $n$ , i.e.  $\{X_n, X_{n-1}, \dots, X_{n-k+1}\}$  is written  $X_n^{(k)}$ , and likewise the  $l$ -history of  $Y$  is  $Y_n^{(l)}$ . The transfer entropy from series  $Y$  to series  $X$ , written  $T_{Y \rightarrow X}$ , is the information gained about  $X_{n+1}$  in moving from prior knowledge of  $X_n^{(k)}$  alone to also having  $Y_n^{(l)}$ . This is given by the Kullback-Leibler divergence, or equivalently the conditional mutual information, calculated using the summation in equation 6.

$$\begin{aligned} T_{Y \rightarrow X} &= I(X_{n+1}; Y_n^{(l)} | X_n^{(k)}) \\ &= D_{KL}(P(X_{n+1} | X_n^{(k)}, Y_n^{(l)}) || P(X_{n+1} | X_n^{(k)})) \\ &= \sum_{x'} P(X_{n+1}, X_n^{(k)}, Y_n^{(l)}) \log \frac{P(X_{n+1} | X_n^{(k)}, Y_n^{(l)})}{P(X_{n+1} | X_n^{(k)})} \end{aligned} \quad (6)$$

The probabilities are estimated from observations of a single instance over a long time series. This is similar to the methods of Pitti et al. (2009) and Marschinski and Kantz (2002). It is very important therefore that the time series is statistically stationary over the period of interest, which can be a practical problem with transfer entropy calculations.

It is also possible to calculate similar information transfer statistics from ensembles of non-stationary systems by calculating probabilities from the ensemble at each point in time (e.g. Ceguerra et al., 2011; Williams and Beer, 2010). The time average approach was chosen here because there is at least potential applicability to complex real systems (e.g. a real robot) where experiments cannot be repeated in such a way that the entropy calculation would be possible and valid.

The following sections consider further practical issues regarding the application of this measure to the simulated time series in these experiments. Since these time series are continuous, sensible discretizations must be established. Further, appropriate values of  $k$  and  $l$  need to be chosen.

## Stroboscopic discretization

The time series are first analyzed using a stroboscopic method similar to that of Schäfer et al. (1998). Consider again the continuous time series generated by the coupled oscillator-MSD system in equations 4 and 5:  $x_1(t)$  and  $x_2(t)$ . The series of maxima of the oscillator voltage are  $\hat{x}_1$  and the time of the  $n$ th maximum of  $x_1$  is  $\hat{t}(n; x_1)$ . Figure 4 shows the phase of  $x_2$  plotted at each maximum of  $x_1$ .

Figure 4: Stroboscopic visualization of the spring extension at each maximum of the oscillator in the coupled oscillator-MSD system. Top: The solid blue line is the oscillator voltage  $x_1$ , and the dashed green line is the spring extension  $x_2$ . Bottom: The points represent the phase of  $x_2$  taken at each maximum of  $x_1$ . The oscillator is set to a chaotic mode with  $Q = 0.67$ , the remaining system parameters are  $\alpha = 0.1$ ,  $\omega_0 = 1 \text{ rad s}^{-1}$ ,  $\zeta = 0.3$  and  $\gamma = 0.01$ .

The phase of the spring extension is calculated here on a “peak-to-peak” basis. That is, the phase of the spring at the  $n$ th maximum of the oscillator  $x_1$  is taken to be the (linear) proportion of the time between the last and the next maximum of the spring extension  $x_2$  that has already elapsed, written  $\phi(n; x_2, x_1)$ . Alternative methods of calculating the phase were considered, such as using the Hilbert transform as per Schäfer et al. (1998). This was found to be problematic due to the chaotic nature of the signals here, hence the

simpler peak-to-peak method was chosen, but in other applications the Hilbert transform might well provide useful phase values to use with this transfer entropy method.

For each phase angle of  $x_2$ ,  $\phi(n; x_2, x_1)$  with  $n > 1$ , the time period of the most recent oscillation of  $x_1$  can also be calculated by:

$$\Delta\hat{t}(n; x_1) = \hat{t}(n; x_1) - \hat{t}(n-1; x_1) \quad (7)$$

Thus the two continuous time series  $x_1$  and  $x_2$  can be converted to “stroboscopic” discrete time representation:  $\Delta\hat{t}(n; x_1)$  and  $\phi(n; x_2, x_1)$ , usually defined for all  $n \in \{2, 3, \dots, N\}$  (with the proviso that  $\phi$  is only defined when the nearest maxima of  $x_2$  are known).

It would of course have been possible to simply discretize  $x_1$  and  $x_2$  by choosing arbitrary time intervals. The advantage of the stroboscopic method is that the time intervals are determined naturally by the dynamics of the system. Furthermore, the time series being compared here have a natural interpretation in terms of synchronization, which is well documented in the literature. In what follows the “stroboscopic” transfer entropy is effectively the influence of the phase difference on the future frequency of oscillation. This will be denoted  $ST_{A \rightarrow B}$  as shorthand for transfer entropy after the stroboscopic conversion has been applied, i.e.  $T_{\phi(\cdot; A, B) \rightarrow \Delta\hat{t}(\cdot; B)}$ . so this measure is similar to that of Ceguerra et al. (2011), except that here the timing of the samples is based on the system’s oscillation rather than arbitrary. In other words, the entropy is measured in bits per oscillation rather than bits per second.

## Simulation method

The “stroboscopic” time series defined above can easily be obtained from numerical simulation of the oscillator-MSD system. First LSODE was used to obtain a solution to the initial value problem given by equations 4 and 5 via numerical integration, with the starting values of  $x_1$ ,  $x_2$  and the necessary derivatives ( $\dot{x}_1$  etc) at time  $t_0 = 0$  chosen randomly from the range  $[0, 1)$ . The first part of the time series from  $t_0$  to a chosen cutoff point  $t_{tr}$  was discarded to remove the “transient” dynamic of the system. During the following interval, between  $t_{tr}$  and the end of the simulation at another chose time  $t_1$ , it is assumed that the dynamic reaches an attractor (observation suggests that this is the case). Therefore the observations used should be at least nearly statistically stationary.

Inevitably the numerical solution of the equations will give a discrete-time output series, with intervals chosen here to be one twentieth of a (simulated) second between points. Thus oscillations have a period of around 120 simulation intervals (recall that the effective time constant of the system was  $2\pi$ ). The maximum times ( $\hat{t}$ ) were estimated by finding those values in the simulated time series that were preceded and followed by lower values – a crude method but it is effective in this case.

To estimate the necessary probability distributions, the frequencies of samples in  $p$  bins was used, with the bin sizes adjusted such that each has a similar number of data points in it, following Marschinski and Kantz (2002). More advanced methods could be applied but for the current purposes this appeared to be adequate and should produce reliable results.

## Causality and transfer entropy

Transfer entropy can sometimes be thought of as “causal information”, but care needs to be taken. Transfer entropy is literally, from equation 6, an information gain in moving from conditioning the future of  $X$  on its own history  $X^{(k)}$  alone to conditioning on the joint history of  $X^{(k)}$  and  $Y^{(l)}$ . Suppose that  $k$  and  $l$  (the history lengths) are both 1, as is sometimes the case in the literature (Pitti et al., 2009; Lungarella and Sporns, 2006). The immediate history  $Y^{(1)}$  can contain information about the future states of  $X$  without having any real causal influence if it contains information about past states of  $X$  that have not been conditioned for in the mutual information calculation – i.e.  $X^{(k)}$  is too short a past.

This problem is clearly a possibility in the system under study here. In a single oscillator-MSD system with the feedback coupling  $\gamma$  set to 0, we know from the design of the system that the spring extension has no influence on the oscillator dynamic, but we also know that the MSD system stores mechanical energy and hence contains information about its own past and the past of the oscillator (which stimulated it). Thus the current state of the spring may help to predict the future state of the oscillator when added to just the current state or recent past of the oscillator, but if we control for the entire history of the oscillator, the spring state cannot be useful, as it is itself determined entirely by the history of the oscillator.

Marschinski and Kantz (2002) present a method designed to minimize this overestimation: set  $l$  to 1, then increase  $k$  from 1 until any causal influence of  $X_n^{(k)}$  on the future  $X_{n+1}$  is already accounted for before calculating the information gained by including  $Y_n^{(1)}$ . However, increasing  $k$  will rapidly expand  $\mathcal{X}$  in equation 6, i.e. the support set for which probabilities must be found. In a finite time series this will result in fewer examples of each combination of states from which to calculate the conditional probabilities, and ultimately to sometimes significant overestimation of the transfer entropy. The solution proposed by Marschinski and Kantz is to subtract the transfer entropy obtained when the  $Y$  series is randomly permuted in time, so that any true temporal correlations are lost and any calculated transfer entropy must therefore be due to finite sample error. This measure (which they called effective transfer entropy) will be used in all calculations to follow.

Figure 5a shows how effective transfer entropy overestimates the causal influence of the spring on the oscillator when  $k = 1$  even when no feedback coupling is present so

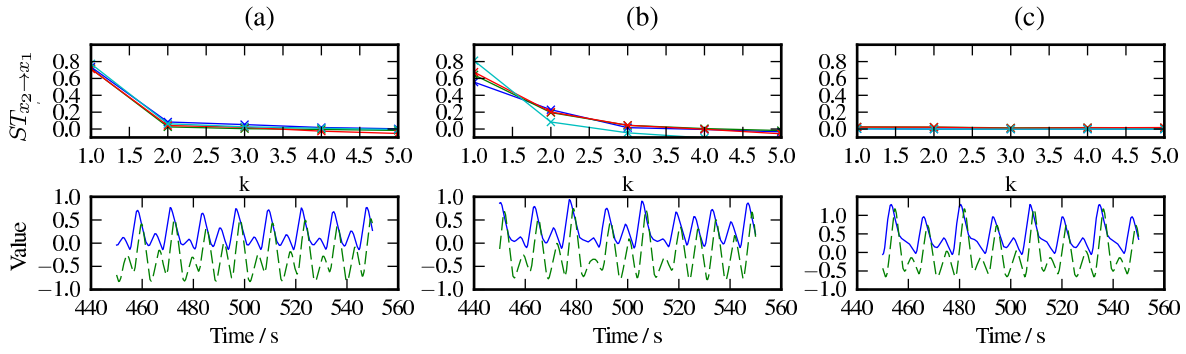

Figure 5: Stroboscopic effective transfer entropy for a single coupled oscillator-MSD system. Coupling was (a)  $\gamma = 0$  (no coupling) (b)  $\gamma = 0.1$  (c)  $\gamma = 0.3$ . Top row:  $ST_{x_2 \rightarrow x_1}$  (from spring phase to the oscillator periods), using four partition sizes  $p \in \{4, 5, 6, 7\}$ . Bottom row: short sections of simulated time series. Other parameters:  $\omega_0 = 1 \text{ rad s}^{-1}$ ,  $\zeta = 0.3$ ,  $Q = 0.67$ ,  $\alpha = 0.1$ . Time series analysed between  $t_{tr} = 400 \text{ s}$  and  $t_1 = 15000 \text{ s}$  with measurement interval  $\Delta t = \frac{1}{20} \text{ s}$ .

the spring cannot possibly have causal influence on the oscillator. Furthermore, it appears that the overestimate at small  $k$  is the only source of apparent transfer entropy even when coupling is added: Figure 5b,  $\gamma = 0.1$ ,  $ST_{x_2 \rightarrow x_1}$  rapidly declines when  $k \geq 2$ . Though the spring does influence the dynamics of the coupled system as we know, this cannot be detected from the time series as the spring can only store information previously generated by the oscillator. When coupling is higher ( $\gamma = 0.3$ , Figure 5c) the system reaches a limit cycle dynamic, and no transfer entropy is detected at any point. The fact that the spring is not an independent oscillator implies both that this is not a true process of synchronization, and further than no transfer entropy can be measured.

### Transfer between two oscillators

The above results show that for transfer entropy to be present with larger values of  $k$  (i.e. to genuinely signify causal dependence), there must be at least two systems capable of producing information. This can be achieved by duplicating the oscillator-MSD system and coupling via the mechanical component (the MSD). There are therefore two  $x_1$  and  $x_2$  variables (one for each system), the coupling is added by updating equation 5 (the dynamics of the MSD) to add the difference between the two springs multiplied by a coupling coefficient  $\gamma_c$  to the acceleration of the local spring. Equation 8 therefore gives the acceleration of the local spring  $\ddot{x}_2$  given the remote spring extension  $x'_2$ .

$$\ddot{x}_2 = -2\zeta\dot{x}_2 - x_2 + (x_1 - 0.5) + \gamma_c(x'_2 - x_2) \quad (8)$$

This system is now a loose analog of a pair of mechanically coupled neural-mechanical systems, call them system  $A$  and system  $B$ . In what follows, system variables and parameters will be superscripted with an  $A$  or  $B$  to signify (where it is ambiguous) which system they are a part of,

e.g.  $x_1^A$  and  $x_1^B$  are the oscillator values for system  $A$  and system  $B$  respectively. Usually the parameters will be identical in both systems, in which case a superscript is not used. The introduced coupling  $\gamma_c$  models the mechanical linkage between the two systems, whereas the existing internal coupling  $\gamma$  can be viewed as a kind of proprioceptive feedback to an oscillator from the limb it directly controls. The following experiments will study the effect of changing  $\gamma$  while keeping  $\gamma_c$  constant, i.e. to ask the question: *given a fixed mechanical coupling (body morphology), how do changes in internal coupling affect overall synchronization, information transfer and causal influences.*

Figure 6 shows how increasing values of internal coupling  $\gamma$  (with the spring coupling fixed at  $\gamma_c = 10$ ) affect the ratio of the mean peak-to-peak frequencies of oscillator  $B$  and oscillator  $A$ , i.e.  $\frac{f_B}{f_A}$  where  $f^S = \langle \Delta t(\cdot; x_1^S) \rangle^{-1}$ . The natural frequency of system  $A$  is fixed at  $\omega_0^A = 1 \text{ rad s}^{-1}$  and  $\omega_0^B$  is varied as shown. Clearly for no coupling the frequencies should vary independently, so the observed frequency difference varies linearly with the natural frequency difference. As coupling is increased, the observed frequencies appear to be pushed further from the natural frequency difference, until at coupling greater than  $\gamma \approx 0.3$ , a synchronization region appears around the central part of the plot where the frequencies tend to lock to a 1:1 ratio (except just around  $\gamma = 0.45$  where there are two peaks representing areas where the frequency ratio, though still synchronized, is 3:2). As  $\gamma$  approaches 0.5 this region starts to shrink again, suggesting an optimal value of  $\gamma$  (in terms of the likelihood of frequency locking) exists in this region.

The effective transfer entropy when the coupling between the oscillators is  $\gamma = 0.35$  is shown in Figure 7. The history length was  $k = 4$  and  $p = 4$  bins were used to discretize each series, the maximum practical values that could be used following the method of Marschinski and Kantz (see above). Mutual information between the instantaneous velocities of

Figure 6: Ratio of peak-to-peak oscillation frequency for  $x_1^A$  and  $x_1^B$  when the natural frequency of the first oscillator is  $\omega_0^A = 1 \text{ rad s}^{-1}$  and the second oscillator is varied near to that, for increasing internal coupling ( $\gamma$ ) in both oscillators. The system parameters were  $Q = 0.67$ ,  $\alpha = 0.1$ ,  $\zeta = 0.3$ ,  $\gamma_c = 10$ ,  $t_{tr} = 400 \text{ s}$  and  $t_1 = 15000 \text{ s}$  with measurement interval  $\Delta t = \frac{1}{20} \text{ s}$ . Inset: mutual information between time series over the same region in parameter space shows the synchronization region more clearly.

the two oscillators (measured by the values of  $\dot{x}_1$  produced by the simulation) is used to measure synchronization, with high values of mutual information implying that the oscillators vary at related speeds and therefore are synchronized. The same binning approach as for transfer entropy is used, but with  $p = 5$  bins. The mutual information is also rendered in the inset plot in Figure 6, which shows that high mutual information corresponds to the frequency locking region.

The relationship between transfer entropy and synchronization is complex. There appears to be a main frequency locking region near  $\omega_0^B = 1 \text{ rad s}^{-1}$  in Figure 7a (where the natural frequencies are most similar) and smaller peaks at larger frequency differences, which are hypothesized to be at points where harmonic resonance along the body allows for greater synchronization between the oscillators. Note that at the mutual information (synchronization) peaks, there is usually a trough in the transfer entropy rate, especially in the approximate range  $1 < \omega_0^B < 1.05$ . Here the synchronization is strongest, and the transfer entropy is not seen because the two systems are coordinated in a highly synergistic manner, such that the coupling appears to be rigid to an outside observer. Because the systems are not generating entropy independently (i.e. the entropy rate  $H(X_{t+1}|X_t^{(k)})$  for either system is 0), no transfer entropy can be measured.

To investigate the notion that the transfer entropy measures directed causal information, the internal coupling  $\gamma$  was set to zero for one of the oscillators (A or B) at a time (with the other retained at  $\gamma = 0.35$ ). Recall that the internal coupling regulates the strength of the signal from the spring extension that is incorporated in the feedback path of the oscillator circuit. Therefore setting the internal coupling to zero for oscillator A will mean that system B cannot have a causal effect on system A, and  $ST_{B \rightarrow A}$  (the transfer entropy from B to A) should be zero, as shown in Figure 7b. Likewise removing the internal coupling from system B results in  $ST_{A \rightarrow B} = 0$  (Figure 7c). In the coupled direction, transfer entropy is generally present. The transfer entropy does not drop to zero in the most synchronized areas of Figures 7b and 7c as it does in the mutually coupled scenario. This suggests that the synchronization is weaker and intermittent, allowing the influence of one oscillator on the other to be measured.

## Conclusions

Transfer entropy from source A to target B is (in a mathematical sense) a Bayesian information gain in moving to posterior knowledge of A from some prior knowledge of B; to infer causality (i.e. “A causes B”) we must be sure that the prior includes *all other causal influences on B that may be correlated with A*, particularly the complete history of B (cf. Lizier and Prokopenko, 2010; Ay and Polani, 2008). Properly measured, transfer entropy will be zero if A does not generate information independently of B.

The above has shown that systems that are weakly synchronizing are capable of this independent information generation, and thus observational transfer entropy can be measured. Furthermore, transfer entropy is *only* found in the case of weak synchrony, and not for systems that are either not truly synchronizing (such as a single mass spring damper coupled to a single driving oscillator), or too rigidly synchronized (as in the case of two very tightly coupled oscillators). Importantly, this means that the observational transfer entropy is not a direct measure of the “strength” of synchrony or causal relationship, because the strongest relationships may show no transfer entropy.

There is a persistent asymmetry in the plots in Figure 7 – in the fully coupled scenario, the transfer entropy appears to be generally higher in the direction leaving the oscillator with higher  $\omega_0$  (remember that  $\omega_0^A$  is always 1, thus in the left hand half of Figure 7a  $\omega_0^A > \omega_0^B$  and notice that generally  $ST_{A \rightarrow B} > ST_{B \rightarrow A}$ ). When feedback coupling is removed in one oscillator, synchronization appears to happen over a larger region when that oscillator has a higher natural frequency, as shown by the asymmetry in the mutual information curves (Figures 7b and 7c). This relation suggests it may be possible to use the transfer entropy to make useful predictions about the consequences of further interventions, with the important caveat noted above that it cannot be a

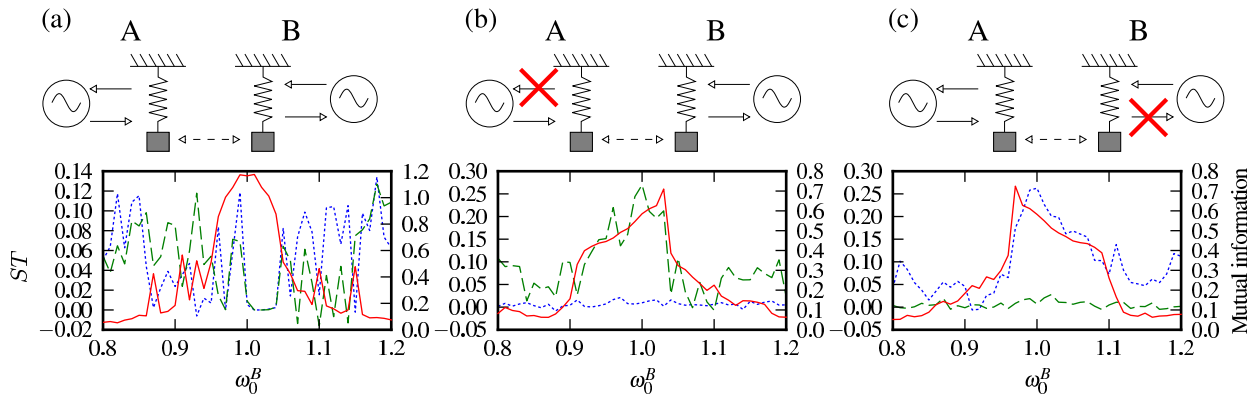

Figure 7: Frequency mutual information (red solid line),  $ST_{B \rightarrow A}$  (blue dotted line) and  $ST_{A \rightarrow B}$  (green dashed line) for double oscillator system, with oscillator  $A$  at  $\omega_0^A = 1 \text{ rad s}^{-1}$  and  $B$  at nearby frequencies as shown. Coupling is: (a) mutual,  $\gamma = 0.35$  in both systems; (b) no feedback in system  $A$  ( $\gamma^A = 0$ ); (c) no feedback in system  $B$  ( $\gamma^B = 0$ ). Other parameters as Figure 6.

perfect method of inferring causality.

Future work will aim to develop a walking robot using analog oscillator controllers in a similar approach to that of Still et al. (2006), but with electrically independent modular limbs that cannot control the mechanical coupling. It is hoped that it may be possible to guide self-organizing synchronization in the limbs via transfer entropy.

## Abstract

Most standard genetic and evolutionary algorithms (GAs) are unable to evolve cooperative solutions to problems where there is a division of labour among genetically different component parts. This is because standard GAs evaluate and select all individuals on the same task which leads to genetic convergence within the population. The goal of evolutionary niching methods is to enforce diversity in the population so that this genetic convergence is avoided. One drawback with some of these niching methods is that they require *a priori* knowledge or assumptions about the specific fitness landscape in order to work. Another issue is that many of these niching methods are not set-up to work on cooperative tasks where fitness is only relevant at the group level. In this paper we present the Group GA which is a group based evolutionary algorithm that can evolve cooperative solutions to problems using emergent niching with minimal *a priori* assumptions. We demonstrate this novel GA on an immune system matching task and explain why we think this type of GA has the potential to effectively solve a wide range of problems that would benefit from being solved cooperatively.

## Introduction

In biology, speciation and niching can be broadly described as the evolutionary process by which a single type of biological organism differentiates into multiple “specialised” organisms, that for instance, take advantage of different resources available in a given environment. In some cases niching produces competing species, but niching can also occur within a single species to produce different specialists that work together to solve a given task. An example of this are bacterial colonies, where within any single colony there are groups of different bacteria doing different jobs, all of which are contributing to the collective well being of the colony. In this case the fitness of the colony depends on the collective symbiotic functionality rather than the fitness of any individual bacteria.

Most standard artificial evolutionary and genetic algorithms (GAs) tend to take a very individual centric view of evolution, where the fittest individuals are selected to produce the next generation of individuals. These types of GAs work well on problems with a single global fitness peak,

where each individual can solve the task on its own; but they are unable to find multiple solutions to multi-peaked problems or solve problems cooperatively, where there is a division of labour between population members which requires different genotypes. For a GA to be able to find cooperative solutions to problems, it must have the following characteristics: (1) It must be able to maintain diversity within the population so that niches can form and (2) it must allow for fitness to be evaluated at the group level.

Evolutionary niching methods solve problem (1) by enforcing diversity in standard GAs so that a single population can be split up into  $n$  different niches. One of the issues with some of the more common niching methods is that they require *a priori* knowledge about the specific fitness landscape to work; in particular whether  $n$  is 2 or 5 or some different number. Most of these evolutionary niching methods use either direct or indirect methods to determine the appropriate number of niches. Direct methods include cooperative coevolution where the number of species is set before evolution begins. Indirect methods include fitness sharing and crowding which rely on a pre-set niching (similarity) radius or some sort of similarity calculation in order to get the population to niche. The other problem with these niching methods is that they are tailored for tasks where each individual in the population can solve the task on its own, not for tasks that are best solved symbiotically where fitness can only be calculated at a group level.

In this paper we present a novel genetic algorithm, the Group GA, which niches based on the evaluation of groups of individuals and therefore can be used to solve tasks that require individuals working together doing different jobs. The Group GA has the added benefit of accomplishing this niching with minimal *a priori* knowledge of the fitness landscape and is able to niche without knowing the optimal number of niches or how the different jobs should be shared out. So unlike the more common niching methods it does not require the number of niches to be set ahead of time nor does it require setting any indirect niching parameter such as a similarity or niching radius.

We demonstrate the emergent niching ability of the Group

GA on an artificial immune system matching task. The goal of this task is to evolve a population of antibodies (protecting agents) to match a set of antigens (harmful invaders). Therefore to solve this task the population of antibodies needs to niche so that it contains different individuals that match different antigens. One reason this task was chosen is because the number of peaks in the fitness landscape can be changed by changing the number of antigens that the population of antibodies needs to match. The other reason for choosing this task is that it makes it very easy to determine when niching has occurred.

In the next section we will briefly review some of the common niching methods as well as a few related evolutionary algorithms that can solve problems symbiotically, where there is a division of labour required. Following our literature review we describe the artificial immune system task and the Group GA in detail. We will then show how the Group GA can be used to evolve a population of antibodies to match a set of four antigens, as well as how it can be used to evolve a population of antibodies that adapts to the addition and removal of antigens during evolution. Finally, we compare the Group GA to other evolutionary methods and discuss the types of tasks we feel the Group GA is best suited to solve.

## Literature Review

We start by reviewing the most common niching methods in artificial evolution. The purpose of these niching methods is to stop the population from genetically converging during evolution as happens when using a conventional GA. All of these niching methods below can be classified as explicit niching methods because they either require the number of niches to be set *a priori* or require an indirect method of enforcing diversity in the population.

We will also briefly discuss SANE and the Binomics GA which are two GAs that are set-up to allow implicit niching to evolve symbiotic solutions to problems. Unlike the explicit niching methods, these algorithms attempt to evolve a diverse, niched population emergently using group evaluation. They also differ from the genetically based niching methods in that these GAs do not require that each individual in the population can solve the task on its own.

## Genetically Based Niching Methods

In this section we briefly describe the common genetically based niching methods. These niching methods function based on the assumption that each individual in the population has its own fitness. For a more in depth summary see Dick (2005) and Mahfoud (1995).

**Fitness Sharing and Clearing** Fitness sharing (Goldberg and Richardson, 1987) is a niching method that relies on some distance metric or similarity measure (either genotypic

or phenotypic) between individuals. By using suitable methods to adjust the fitness of any individual according to how many other similar individuals are within some predetermined niche (similarity) radius, there is a tendency for the population to spread out over multiple peaks or niches in the fitness landscape; thus diversity is maintained. Clearing (Petrovski, 1996) is very similar to fitness sharing but, instead of degrading the fitness of individuals within the same similarity radius or subpopulation, it removes the least-fit individuals within the similarity radius from the population. Horn et al. (1994) show that in Learning Classifier System models where fitness is shared amongst cooperating individuals implicit niching can occur.

**Crowding** Crowding was first introduced by De Jong (1975) as a method of removing similar individuals from a population, with the goal of trying to maintain diversity during evolution. Deterministic Crowding (Mahfoud, 1995) is a specific type of crowding that mates two in the population and then replaces the parent that is most similar to the offspring if the offspring is fitter. It is similar to fitness sharing because there needs to be some similarity calculation done between individual, but unlike fitness sharing there is no requirement to pre-specify a similarity radius.

## Demes and Spatially Structured GAs

An alternative to genetically based niching methods are spatially structured GAs; for a good review see Dick (2005). In these types of GAs, the population is structured within some local geographical distribution (demes) that constrains which members of the population are allowed to be selected or be recombined with one another. By structuring the population into demes more genetic diversity can be maintained across sub-populations.

**Cooperative Coevolution** Cooperative coevolution was first introduced by Potter and De Jong (1994) as a method for function optimisation. In cooperative coevolution the population is pre-divided into different subpopulations, so it can be thought of as a type of spatially structured GA. Each subpopulation represents a subcomponent required to solve the overall task, which means that there needs to be some *a priori* knowledge of the problem so that the appropriate number of subpopulations is chosen. Each subpopulation is evolved separately using a standard GA, but the fitness of the individual members of each subpopulation is based on the performance of the cooperative solutions. In cooperative coevolution speciation is not emergent because the number of subpopulations needs to be determined before evolution begins. For this reason, this class of algorithms has been shown to work well on problems where there is an obvious way of dividing up the population, such as job shop planning and scheduling tasks (Husbands and Mill, 1991; Husbands, 1993; McIlhagga et al., 1996).

## Symbiotic GAs

SANE (Moriarty and Miikkulainen, 1995, 1996), the Binomics GA (Harvey and Tomko, 2010) and simulated ecosystem evolution (Williams and Lenton, 2007) are three examples of GAs that cause implicit niching in the population and attempt to evolve symbiotic solutions to problems. In SANE and the Binomics GA, groups of individuals are evaluated together and then the individuals that are part of the fittest groups are selected to pass on their genes to the next generation. This differs from most standard GAs where individuals are evaluated and then the fittest individuals are selected. These algorithms are relevant to our discussion of speciation/niching because any time a problem is solved symbiotically then implicit niching must be occurring during evolution.

SANE and the Binomics GA have been successfully applied to the evolution of artificial neural networks (ANNs). In both these algorithms the individuals in the population are partial networks that are combined to form fully specified ANNs which are then evaluated. The fitness score of each individual partial network is based on the fitness of the full ANNs that each individual partial network participated in. This means that over time, the individual partial networks that were part of the fittest ANNs will be selected for, while the partial networks that were part of the least fit ANNs will be modified using mutation and recombined with other partial networks. The goal of this method of evolution is to evolve a population of partial networks that symbiotically work together to form high fitness fully specified ANNs.

## The Artificial Immune System Task

We have chosen an artificial immune system matching task to demonstrate the emergent niching abilities of the Group GA. In this section we will describe the details of this task and then in the next section we will describe the Group GA. This task which has previously been used by Forrest et al. (1993) and Potter and De Jong (2000) was chosen because it can be solved cooperatively and clearly illustrates how the Group GA can lead to emergent niching and how it can adapt to a changing fitness landscape, neither of which is possible with a conventional GA. Forrest et al. (1993) used the task to study adaptation in the immune system and Potter and De Jong (2000) solved different variations of this task using cooperative coevolution. We will compare the results of these two papers to the Group GA results later in the paper.

The goal of this task is to evolve a population of antibodies to protect the body from a set of antigens. Very simply speaking, antigens can be thought of as bacteria, viruses or other pathogens and the antibodies can be thought of as the body-guards who mark these antigens for removal. Antibodies in natural immune systems need to be adaptive so that they can combat new and different antigens that enter the body. Therefore this task tries to mimic this challenge of natural immune systems on a very basic level by attempt-

ing to evolve a population of artificial antibodies to match a variable set of antigens.

In this task both the antibodies and antigens are modeled as bit strings. How well an antibody combats a specific antigen is calculated as the number of bit matches between antibody and antigen. For example a [1 0 1 1] antibody matches a [0 0 1 0] antigen at location two and three and therefore the antibody's fitness is equal to two when matched to this antigen. For our purposes the higher the match (fitness) score the better.

Assuming that the length of the antibodies and antigens is the same, when there is more than one antigen in the antigen set the task can be thought of as symbiotic, because it is impossible for a single antibody to match an entire set of antigens on its own. In this case, the population of antibodies needs to evolve in such a way so that it contains specialists to combat each different antigen. Obviously the more antigens there are, the more difficult the task becomes, because the antibody population needs to evolve and maintain a larger number of specialists.

## The Group GA

The Group GA is a novel evolutionary algorithm presented in this paper for the first time. It is based on the Microbial GA (Harvey, 2011) which is a steady-state GA that uses tournament based selection. The Microbial GA is similar to the more familiar GAs, but is minimalist in the sense that it strips away as much as possible, whilst still maintaining the essential components of natural selection which are heredity, variation and selection.

We will first describe the Group GA in general terms and then describe it in terms of the artificial immune system task we present in this paper. What differentiates the Group GA from more conventional GAs is that groups of population members, of some fixed size that is a parameter of the GA (rather than individual population members as in conventional GAs) are evaluated and then selected based on the overall fitness of the group. In other words, the driver of fitness based selection is the relative fitness of an entire group of population members that work together as a unit to solve some task. A single cycle (tournament) of the Group GA can be broken-up into the five following steps:

1. Randomly choose two possibly intersecting groups of population members from the population without regards to fitness.
2. Calculate and assign a fitness score to each group of population members based on the groups' performance on a given task. Fitness is assigned on the group level only; there need not be any way to define or calculate an individual's contribution to the group's fitness score.
3. All members of the group with the lower fitness score are removed from the population and replaced with mutated

copies of the members of the fitter group.

4. The members of the fitter group are put back in the population unchanged.
5. This process is repeated until some pre-defined stopping condition is met.

When we apply the Group GA to the immune system task, the fitness of a group of antibodies is calculated as the average of the best match scores achieved against all the antigens in the set. In other words, to evaluate a group of antibodies, all the antibodies in the group are matched against every antigen in the set and the average of the highest match scores against each antigen is the group fitness. This means that to get a perfect fitness score there has to be at least one antibody that matches each antigen perfectly in the group.

A single cycle (tournament) of the Group GA can be broken-up into the five following steps when applied to the immune system task described in the previous section (see figure 1).

1. Randomly choose two groups of antibodies from the population without regard for fitness
2. Calculate the match scores between all the antigens in the set and each of the antibodies in each group
3. Each group as a whole is assigned a fitness score which is calculated as described above.
4. The group with the lower fitness score is replaced with mutated copies of the antibodies of the more fit group
5. Both groups of antibodies are put back into the population and this process is repeated

We have set up this simulation in such a way that groups of antibodies are randomly chosen from the population and then assigned a fitness based on the ability of this group to match the different antigens in the antigen set. We understand that because an individual antibody can always be assigned its own fitness, some of the genetically based niching methods we reviewed earlier would be able to solve this task without any type of group evaluation. The reason we have used this task to demonstrate the Group GA is because as we will see in the next section it clearly shows how the Group GA causes emergent niching using group evaluation.

The Group GA can be applied more generally to tasks where individual fitness is meaningless because the Group GA randomly selects two groups of population members and uses them to construct two higher level entities that are evaluated and assigned a fitness score. The less fit group of population members is killed off and replaced with a mutated copy of the fitter group. These two groups are then put back into the population and this cycle is repeated. It is important to reiterate that in the Group GA it is the fitness of the group

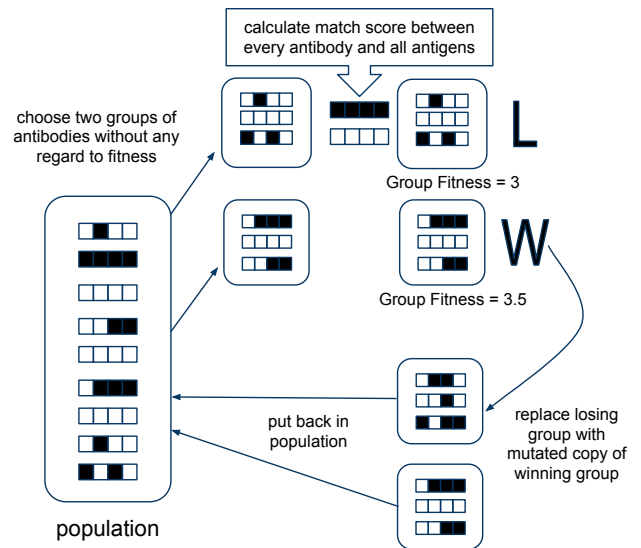

Figure 1: The Group GA as applied to a immune system task with 2, 4-bit antigens

of population members that drives evolution, which is different from most conventional GAs where it is the fitnesses of the individual population members that matters. How fitness is calculated depends on what type of problem is being solved, but regardless it is only the group fitness that matters when determining the tournament winner and loser.

## Evolving Antibodies using the Group GA

In this section we will show how, using the Group GA, a randomly initialised population of antibodies can be evolved to match a set of antigens. In the first experiment we will evolve a population of antibodies to match a fixed set of four different antigens. This is equivalent to the Group GA solving a four-peaked fitness landscape. Then in the second experiment we will evolve a population of antibodies to match a variable set of antigens, where antigens are added and removed during evolution. This second experiment simulates a task where the number of fitness peaks changes during evolution.

In these experiments the antigen and antibodies were 64-bit binary strings. The antibody population size was 100 and the number of antibodies per group was 10. The mutation rate was set to 0.1/64, meaning that at each allele there was a probability of 1/640 of flipping that bit.

Figure 2 shows the antibody population after being evolved for 20,000 tournaments on a four antigen task. The four antigens used in this experiment were: [...0 0 0 0...], [...1 1 1 1...], [1 0 0 0...], and [...1 0 1 0 ...], where these 4-bit patterns are repeated 16 times to make the four full 64-bit antigens. These specific antigens were chosen to try to make the task as difficult as possible. The lower part of figure 2

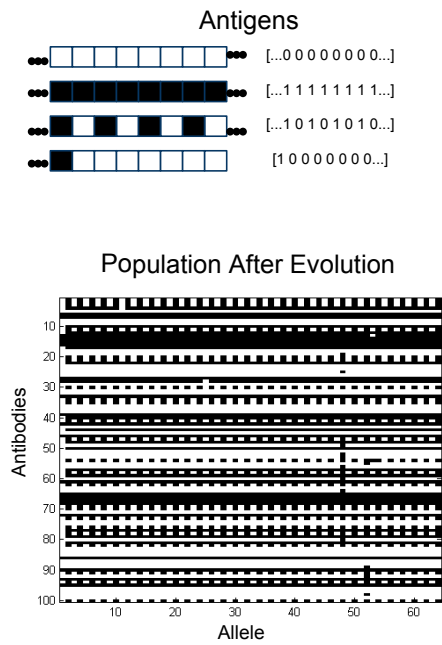

Figure 2: The antibody population after evolution on a 4 antigen task.

(as with the similar plots in later figures) displays each binary genotype in the population horizontally above the next genotype, with white and black representing 0 and 1 alleles respectively. Figure 2 clearly shows how the antibody population has niched during evolution to contains antibodies that perfectly match all four antigens in the set.

Figure 3 is a fitness versus time plot for a single typical run of the four antigen task. The black line shows the group fitness of the tournament winning group of antibodies at each tournament, calculated as described above and the gray line shows the number of antigens covered perfectly by at least one antibody at each tournament. The number of perfect antigens matched perfectly by at least one antibody can range from zero to the total number of antigens in the set. We believe that this is an important measure of performance for this task because if you think of the goal of the antibodies in terms of protecting a body from invasion, then it is important that the population contains at least one antibody to match each antigen. In this figure you can see that throughout evolution the group fitness drops significantly for a tournament or two without decreasing the fitness of the population (number of perfect antibody types). This is because antibody groups are randomly chosen from the population so there is always a chance that a very unfit group is chosen.

Figure 4 shows how the antibody population adapts when antigens are added and removed during evolution. In this experiment, the antigen set initially contained only two antigens [...0 0 0 0...] and [...1 1 1 1...]. At tournament 20K

Figure 3: A plot of group fitness (black line) and number of antigens covered perfectly by at least one antibody (gray line) in the population over time for a single typical run of the 4 antigen task.

a third antigen [...1 0 1 0...] was added and evolution was resumed. At tournament 40K evolution was paused again and the [...1 1 1 1...] antigen was removed from the set before evolution was restarted. This figure clearly shows that when the antibody population is evolved using the Group GA the population can adapt to changes in the antigen set, adding and removing different types of antibodies as appropriate. Figure 5 shows the fitness versus time plot for this a single typical run of this task, where antigens are added and removed during evolution. As this figure shows, when an antigen is added, the fitness of the population drops before quickly recovering as the population adapts to match this new invader <sup>1</sup>.

## Comparison to Other Methods

To get a feel for how well the Group GA is able to solve on this task we compared it to both the Microbial GA (Harvey, 2011) and the Binomics GA (Harvey and Tomko, 2010) on the 4 antigen task described above. Using the Microbial GA to solve this task is equivalent to solving it using any standard GA where the fittest individual antibodies are selected. As expected, when we ran the Microbial GA for 100 runs, each run the antibody population converged to match a single antigen in the antigen set, failing to match the other three.

A more interesting comparison is between the Group GA and the Binomics GA. We chose to compare the Binomics GA as opposed to a genetic based niching method such as fitness sharing or crowding because like the Group GA, the

<sup>1</sup>There are potential similarities between the adaptive mechanism of the Group GA and clonal selection that need to be investigated further.

Figure 5: A plot of group fitness (black line) and number of antigens covered perfectly by at least one antibody (gray line) in the population over time for a single typical run of the task where antigens are added and removed during evolution.

Binomics GA was developed to solve cooperative tasks using emergent niching where group fitness is the driver for selection. As applied to this immune system task, the Binomics GA works as follows:

1. Randomly choose two antibodies from the population and compare their stored fitnesses.
2. The antibody with the lower fitness is genetically changed using mutation and recombination.
3. This modified antibody is combined with a group of randomly chosen antibodies from the population.
4. All the antigens are matched against all the antibodies in the group.
5. The fitness of this group of antibodies is equal to the mean maximum match score in the group.
6. All antibodies in the group have their current fitness updated using some sort of time smoothing that takes into account both their historical and newly calculated fitness.
7. All individuals are put back in the population and this cycle is repeated.

The difference between the Group GA and the Binomics GA is that in the Group GA, groups of antibodies are being both evaluated and selected, while in the Binomics GA groups of antibodies are being evaluated, but it is individual antibodies that are being selected based on this group fitness.

Using the same parameters as in the previous experiments, we compared the performance of the Group GA and

the Binomics GA on the 4 antigen task over 10 runs. We decided to compare the performance of these two algorithms based on the number of evaluations it took to evolve a population that contained antibodies that perfectly matched all antigens in the set. Evolution was stopped at 1600 K evaluations if by that point the population did not contain 4 perfect antibodies. Over 10 runs the Group GA took a median number of 278 K evaluations, while the Binomics GA was unable to solve the task within the maximum number of evaluations allowed in any of the 10 runs. It should be mentioned that if the Binomics GA was allowed to run for more evaluations, it was able to niche to match the four different antigens, but nowhere near as efficiently as the Group GA. In the next section we will discuss why we think the Group GA outperforms the Binomics GA to this extent.

## Discussion

In this paper we have presented a novel evolutionary algorithm that can cooperatively solve problems using emergent niching, where fitness is evaluated at the group level. We demonstrated this by using the Group GA to solve a multi-peaked artificial immune system matching task. Our results show that by evolving a population of antibodies using the Group GA, the population niches to match multiple antigens. We have also shown that when antigens are added and removed during evolution, the Group GA allows the antibody population to adapt to this change matching new antigens that are presented.

In the previous section we compared the performance of the Group GA to the Microbial GA and the Binomics GA. Unsurprisingly, the Microbial GA, where individual antibodies are evaluated and selected was unable to solve the multi-antigen task and ended up converging to match a single antigen every run. The Binomics GA, where groups of antibodies are evaluated and individual antibodies are selected, fared much better and was able to niche to match the different antigens, but took a lot longer as compared to the Group GA. We believe that the reason why the Group GA outperforms the Binomics GA methods on this task is related to the difference between what is being evaluated and what is being selected. Studying the subtle differences between evaluation and selection and how varying what is evaluated and selected affects artificial evolution is not part of the scope of this paper, but will be one of the focuses of our future research.

The two key characteristics of the Group GA that differentiate it from the niching methods described in the literature review are: (1) Niching is accomplished emergently without having to know the appropriate number of niches ahead of time or pre-setting any parameter such as a niche radius and (2) fitness is evaluated at a group level which means that the Group GA can be used to solve symbiotic task where fitness is meaningless at the individual level.

For example, this same immune system task was solved

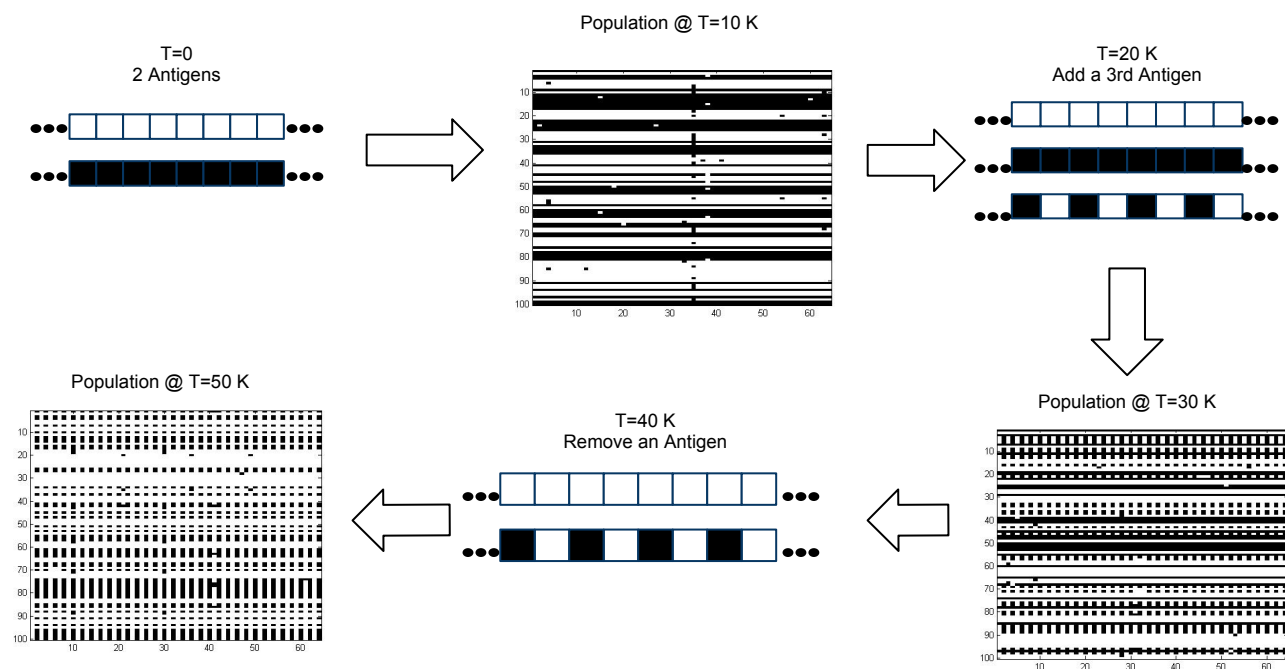

Figure 4: This figure shows how the antibody population adapts during evolution when 64 bit antigens are added and removed (T=10 K corresponds to tournament 10,000).

by Potter and De Jong (2000) using cooperative coevolution where the population was subdivided into  $n$  different species before evolution was started. This method was successful at evolving a population of antibodies to match different antigens as long as the number of different antigens was known *a priori* and the number of antigens remained constant throughout evolution. To overcome these limitations of cooperative coevolution, Potter and De Jong (2000) applied an evolutionary stagnation measure to determine when a new sub-population should be added. This allows antibody species to be added and removed during evolution in response to new antigens, but as Potter and De Jong (2000) state, the level of stagnation at which species should be added or destroyed is task dependent.

This task was also solved by Forrest et al. (1993) using a GA with a best-match fitness scoring scheme. In their algorithm, an antigen is chosen at random and matched against a group of antibodies from the population. Only the antibody in the group with the highest match score gets its fitness increased by its match score, the fitness of all other antibodies remains unchanged. This fitness evaluation step is repeated many times and then the population is evolved using a standard GA. Like the Group GA, this method allows the antibody population to *niche* to match a set of antigens without needing to know *a priori* how many antigens are present. The major difference between this method and the Group GA is that this best match method requires that the fitness

of individual population members can be evaluated on their own. This is possible for this task because each individual antigen can be evaluated on its own by matching it against a single antigen, but tasks where fitness can only be evaluated at the collective, group level will not be able to be solved using this best-match method. In general, the genetically based niching methods described earlier will struggle with this type of symbiotic task where individual fitness is meaningless. An example of this type of task is the evolution of artificial neural networks (ANN) task where the population is made up of partial sub-networks which have no fitness except when they are combined with other sub-networks to form a fully specified networks. Both SANE and the Binomics GA discussed earlier have been used to solve ANN tasks in this way.

For the reasons given above we believe that the Group GA has the potential to be a useful algorithm that can use emergent niching to solve problems where the optimal division of labour is unknown. Going forward, we plan on testing the Group GA on a wide variety of tasks which may benefit from being solved cooperatively in order to find out when it performs well and under what circumstances it performs poorly. We also plan on studying the effect of varying the group size parameter on this immune system task as well as other tasks. Testing the Group GA on an ANN task may be a logical next step, as neural networks can be viewed as a group of neurons symbiotically working together to solve a

problem. We think that the Group GA could be the catalyst for the development of a new class of GAs that specialise in solving tasks cooperatively where there is limited *a priori* knowledge of the fitness landscape.

## Abstract

A new interactive "wall game" is proposed in which two human players alternatively configure a pattern to communicate. A pattern consists of 3x3 sites, on which a player can place one of three symbols. The two major findings in this paper are i) the subjects mainly communicated in two modes. Either the subjects changed the pattern by watching the pattern as it is (dynamical mode) or by having narrative reflection (metaphorical mode). ii) Subjects switched between these two modes. Most of the experiments in evolutionary linguistics are based on "task-oriented communication" and they observe the emergence of lexical items. In contrast, our experiment explores whether "communication without purpose" leads to the emergence of complex rules such as linguistic grammar. We argue that the switching between the two modes observed in our experiment can be seen as a grammatical process in the sense that it is a procedure to take an internal state outside using the media (i.e., patterns in the wall game). Under this hypothesis, the players' exploration of the media becomes a crucial step in the emergence of language and grammar.

## 1. Introduction

Artificial life studies provide a test bed for exploring how symbols and grammars emerge in minimally interacting systems through computer simulation. For the last 10-15 years, artificial life studies have contributed greatly to this direction, and the origin and evolution of language has become a target of many scientific studies (see e.g. Steels, 1996, 2005; Hashimoto and Ikegami, 1996; Rizzolatti and Arbib, 1998; Vogt, 1998; Cangelosi and Harnad, 2000; Sugita and Tani, 2005 etc.). For example, Steels and Kaplan (2001) have developed a platform for studying the interaction between two artificial agents acting as speaker or hearer. In this approach, a population of robots develops a shared vocabulary and a corresponding ontology while playing language games (i.e., ritualized social interactions that follow a specific script).

More recently, there are many researches based on experiments using human subjects (e.g., Steels, 2006; Selten and Warglein, 2007; Scott-Phillips and Kirby, 2010) as a new approach to the origin of language. Subjects communicate through a communication tool and some structured system emerges. Some of these studies testify to a hypothesis that is

raised by computational simulation studies. For example, the "iterated learning model," which is a model of vertical and horizontal cultural transmission, was proposed by Kirby (2002). It was originally studied as a computational model and later the model has been adjusted to experiments using humans (Kirby, Cornish and Smith, 2008).

Among many studies of "language evolution in the laboratory," Galantucci (2005) introduces one of the most influential experiments. In his experiment, two subjects who are staying in different rooms play a video game together over a monitor. They have to be cooperative to get a high score. They are allowed to communicate using a special communication tool. This tool allows the subjects to draw graphics but not letters. As the experiment proceeds, the difficulty of the video game increases. The pairs that ended the game with success shared many signs for rooms and enemy, which were drawn with the communication tool.

In most of the researches adopting an experimental approach, the final outcome often consists of lexical items. This comes from the fact that in most of the experiments, subjects are asked to perform a task together to make them communicate with each other.

Not only the lexicon but grammar is an integral part of a linguistic system. To get more variations in results, the communication observed in the experiments should not be limited to those that are task oriented. For example, we assume that "communication without purpose" can be important to trigger proto-language with both grammar and lexicon in experiments. This idea is supported by the research in developmental psychology: infants are known to be engaged in two types of proto-linguistic communication. The first is communication with an aim, such those that are task oriented. The second is a communication without an aim, in other words communication whose aim is communication itself (Bates, 1976). Gómez, Sarria and Tamarit. (1993) argue the importance of the second type of communication. It is pointed out that the ability to communicate without purpose is an indicator for the ability called "theory of mind." With "theory of mind," one can infer other people's minds, which are different from one's own. And this ability is known to be integral to the use of language grammar properly (Tager-Flusberg, 1993). Tomasello (2003) has also argued the

importance of shared attention in development and pointed out the role of communication just to share communication in acquiring language.

Actually, Uno, Marocco, Nolfi and Ikegami (in press) made an attempt to use the A-life approach to explore the relationship between communication without purpose and the emergence of grammar. The agents were supposed to stay together in the target area using signals. However, when agents were given uncertain information regarding the target area, they start staying together outside the target area using newly created signals, which was argued to be a proto-declarative sentence: a sentence used to share intentionality.

In this paper, we are going to take an experimental approach to see how communication gets structured when there is no purpose. We explore what are the characteristics of human communication (which might possibly be implemented in artificial systems) when individuals are just having fun. We asked subjects to communicate using our communication tool, which is called a “wall game.” The results show that there are two modes of communication. What emerged from the subjects’ communication is not a set of lexical items but the way an internal state of mind can be expressed as an external message. We argue that this can be seen as a proto-grammar.

Section 2 explains the basic design of our experiment. Section 3 and 4 show the results of the experiments. Finally, section 5 analyzes and discusses the results of the experiment.

## 2. Description of the Experiment

Twenty-six subjects (13 pairs) were asked to communicate using an artificial communication system, where the expressions were the spatial pattern of the triplet in a 3-by-3 bit square. They were allowed to rewrite the pattern alternatively. We call this pattern a “message.”

For the first 9 pairs, each subject sent 8 messages in turn, which is 16 messages in sum. For the next 4 pairs, each subject sent 15 messages and 30 in all. After all messages were exchanged, we asked them to report their intentions behind the sent messages, and their interpretations of the received messages in natural language. (Henceforth we call this data the “intention report.”)

We conducted the experiment mainly in Japanese. The reports shown in this paper are translated into English by the authors.

The two subjects stayed in different rooms. The messages were sent to each other over the Internet. Figure 1A shows a screen where one can compose messages. All the messages that are sent and received are shown to the subjects so that they can compose their messages based on their communication history. Figure 1B shows how the history of exchanged messages is displayed to the subjects.

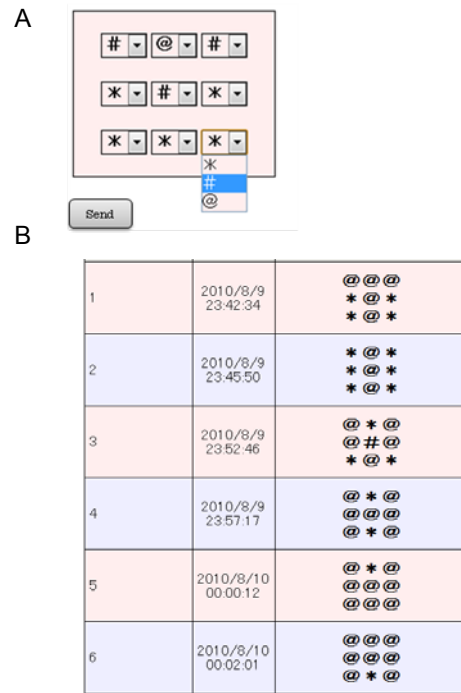

Figure 1: Two screen shots. A is a message composer. B is the timeline of exchanged messages.

Here are some examples of exchanged messages from our data. Player A sent (1) and Player B answered to it with (2). Then Player A replied to it with (3). Finally, (4) is an answer to (3) by Player B.

@ @ @	@ @ @	# # #	# @ @

Table1: Exchanged messages between Player A and Player B

We made a linguistic analysis of the intention report and mathematical analysis to the patterns. The results are given in the following sections, 3 and 4.

We performed the experiment under three conditions:

### Condition 1

Messages are exchanged between two subjects. Subjects write intention reports after exchanging all the messages (Appears in Experiment 1, 2, and 3).

### Condition 2

Messages are exchanged between two subjects. Subjects write intention reports in every round and players exchange messages (Appears mainly in Experiment 2).

### Condition 3

Each subject plays with the game on his/her own. Subjects write intention reports after writing all the messages (Appears in Experiment 3).

The basic game is condition 1. In condition 2, the timing of writing the report differs from that in condition 1. In condition 3, the game is played by a single player.

### 3. Experiment 1: Two modes of communication

#### 3.1 Linguistic analysis

To begin with, we analyzed the intention report from a linguistic point of view. We categorized the reports as three types: dynamical report, metaphorical report, and others.

What we call a “dynamical report” is a literal description of the patterns in the messages. For example:

- (D1) All kinds of symbols are used.  
(D2) The pattern is scrolled from left to right.

In these reports, patterns are described just as they are. The messages that these reports are made for are shown in Table 2 below.

On the other hand, in what we call a “metaphorical report,” the subjects create a story based on the symbols inside the pattern. They are not describing the pattern as it is. Instead, they are using metaphors (in the sense of Lakoff [1987]). They describe symbols or a string of symbols as something else. Here are some examples:

- (M1) A rabbit is in a cage.  
(M2) The rabbit made a hole in a cage to escape.

Here the player sees the symbol “\*” as a rabbit and a sequence of “@” as a cage, and “#” is a hole.

In this system, there is no way for one player to transmit her story to the other player. For example, while Player A intended to express a rabbit using the message shown as (M1) in Table 2, Player B made the following intention report for the same pattern:

- (D3) \* is surrounded by @.

In the category called “others,” the reports are not strongly connected to the patterns. For example, we have emphatic expressions such as (O1) or feelings of the players, which are irrelevant with the patterns such as (O2):

- (O1) Hello. Nice to meet you.  
(O2) This experiment is difficult.

(D1)	(D2)	(M1)	(M2)	(O1)	(O2)
* # @	@ # *	@ @ @	@ @ @	@ * @	@ # #
* # @	@ # *	@ * @	@ * #	* @ *	# * #
* # @	@ # *	@ @ @	@ @ @	# # #	* * *

Table 2: Examples of messages three types of reports are made for

The ratio of reports in each category used by each pair is given in Figure 2. It is shown that most of the reports are either dynamical or metaphorical.

Figure 2: Ratio of report types in Experiment 1. It is calculated from the accumulated reports of two players who exchanged messages. The ratio between metaphorical and dynamical reports varies over pairs.

#### 3.2 Mathematical analysis 1

In order to see the characteristics of the wall patterns in the two different report categories, we calculated the correlation between the Hamming distance of adjacent patterns and the frequency of each type of the reports. Hamming distance is defined as the number of changes required to match one character string with another string. Therefore, we regarded the wall patterns as linear character strings (e.g., (D1) in Table 2 is regarded as “\*#@\*#@\*#@”) to calculate it. The larger the Hamming distance of a couple of patterns, the less they are similar. In order to treat the report under mathematical analysis, the two categories of the report are indexed by counting the number of them in each turn (i.e., the metaphorical index is scored 2 for when both subjects interpret metaphorically, 1 for when one subject does, and 0 for when neither do). We calculated the correlation coefficient between Hamming distances and both the metaphorical indexes, and the dynamical indexes in each turn.

The results are shown in Figure 3. We found that when the Hamming distance between successive patterns gets smaller, the human subjects tend to use metaphorical reports. On the other hand, the Hamming distance between successive patterns gets larger when subjects use dynamical reports.

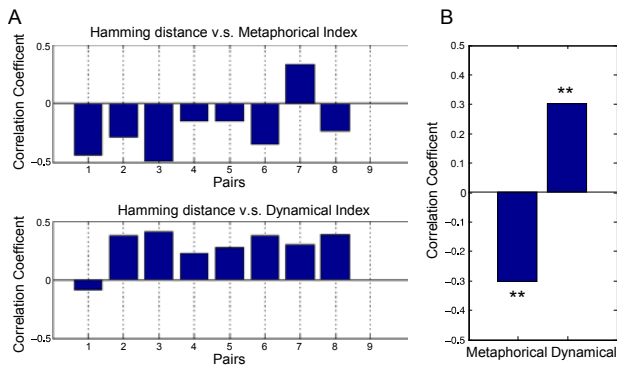

Figure 3: A: Correlation coefficient between Hamming distance and the number of two categories in reports for each pair. B: The same evaluation across all the pairs. Hamming distance has significant ( $p < 0.01$ ) positive correlation with the dynamical report, and significant ( $p < 0.01$ ) negative correlation with the metaphorical report.

### 3.3 Mathematical analysis 2

We also drew a state transition graph between successive patterns. To analyze the transition state of the patterns, 16 messages were not enough to have statistically valid results. We therefore focused on pairs 10 to 13 who exchanged 30 messages (15 each) in one trial. They performed two trials under two different conditions (i.e., conditions 1 and 2. See Section 2 for an explanation). We are going to discuss the contrast between conditions 1 and 2 in detail in Section 4. The point is that under condition 2, more metaphoric reports were tended to be used compared to condition 1.

In order to create the transition graph, we grouped the patterns used in a game by the numbers of symbols the pair used. We first separated the patterns into three rows, and grouped each row using only the constituent ratio of the symbols (e.g., “\*@\*” is grouped into “210”, “###” is grouped into “003”, etc.). Thus, each line represents 1 of 10 groups (0 for “012” ... 9 for “210”). We then assigned the groups a triple-digit number (e.g., 091 for “#@#/\*@\*/@#@”). Finally, we grouped all the patterns used in the game from the number, and calculated the transition between them.

Figure 4A shows the state transition graph calculated for the pair 11. The linearity of the transition graphs is defined as follows: “the number of nodes divided by the number of edges of a graph.” A linearity of the pair 11 under condition 1, whose main communication mode is dynamic, is calculated as 0.89. And the linearity of Pair 11 under condition 2, whose main communication mode is metaphoric, is as 0.97. The analysis of this pair suggests that the metaphoric mode has a tendency of having a lower linearity than the dynamic mode.

Figure 4B shows the correlation coefficient between the linearity and the number of the two report modes in all the trials by 4 pairs. The result shows that same types of transition are used repetitively in the dynamic mode but not in the metaphoric mode.

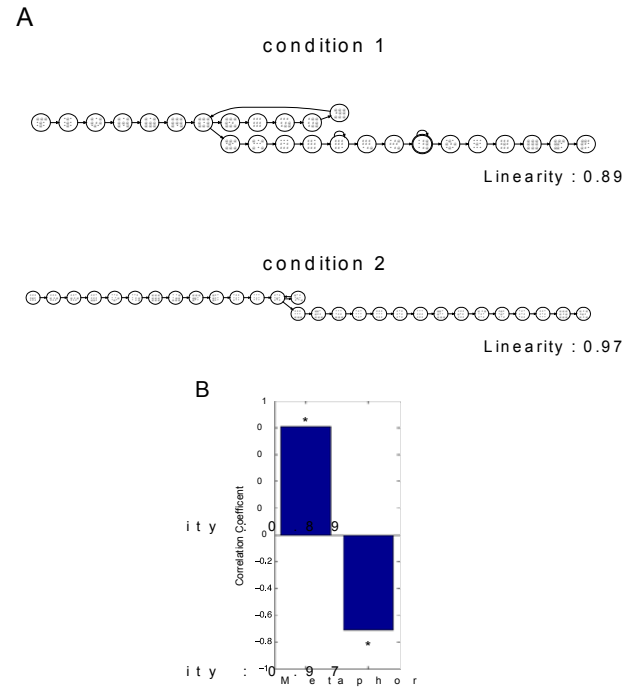

Figure 4:

A: Examples of state transition graphs obtained from results of the pair 11. Here, the linearity is defined as the ratio between the number of nodes and the number of edges. A higher Linearity is observed in condition 2, compared with condition 1.

B: The correlation coefficient between the linearity and the number of the two report modes in the 8 games. A positive correlation can be seen between the linearity and the metaphoric mode, and a negative correlation between the linearity and the dynamic mode.

Here we point out that there are two major modes in communicating with the system introduced in Section 2., metaphoric mode and dynamical mode. During the game, the subjects enjoyed processing patterns and trying to assign meanings to them. In a report, the former shows up as a literal description of dynamic patterns and the latter story is told using metaphors. This difference is correlated with the difference in changing the patterns, which can be partly calculated with the Hamming distance and linearity of the transition states.

## 4. Experiments 2 and 3

To know further about the two modes of communication pointed out in the last section, we made two additional experiments. Below we briefly review each experiment.

#### 4.1 Experiment 2: Message-by-message report

We asked 4 pairs who exchanged 30 messages in Experiment 1 (which we call condition 1) to exchange an additional 30 messages in the new trial (which we call condition 2). This experiment is to make the intentions behind the messages clear and to see the effects on subjects' behavior. In the new experiment, in every round players exchanged the messages they had in order to compile reports of their intentions.

Compare the ratios of the metaphoric and dynamic reports of conditions 1 and 2 shown in Figure 5. This result suggests that when subjects are more conscious of the intention of the message, they tend to be engaged in the metaphoric mode rather than the dynamic mode.

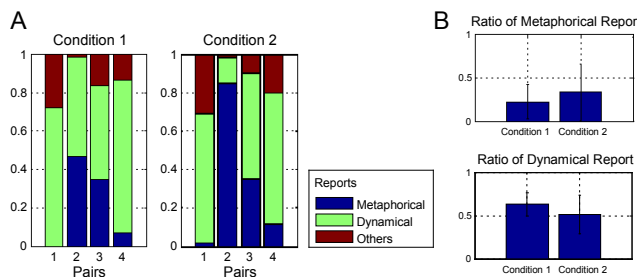

Figure 5:

A: Ratio of reports in each category in condition 1 and 2. In condition 1, the players did not have to make "intention reports" during the game. In condition 2 the players had to make "intention reports" every time they sent or received messages. It is calculated in the same manner as in Figure 1.

B: The ratios of the metaphoric reports and dynamic reports are averaged across all the pairs. There seems to be a tendency for dynamic reports to be more ascendant than metaphoric reports in condition 1, while the opposite tendency can be seen in condition 2.

#### 4.2 Experiment 3: Solitary play

In the third experiment, we asked each subject to play with the game by him/herself (we call this condition 3). We asked one of the subjects who experienced Experiment 1 to make 30 messages by him/herself without having another player "behind the wall" asking him/her to report his/her intentions. Compare condition 1 in Fig. 5 and condition 3 in Figure 6. The result reveals that subjects tend to use either one of the modes, not both of them, when they have no one to communicate with.

Figure 6: Ratio of reports in each category in condition 3. In this condition, subjects play the wall game alone. The reports are extremely biased into either metaphoric or dynamical.

At least the players get more varieties in behavior when they are together. Let's see an example that is congruent with the results in Experiment 2. Table 3 shows an exchange between two players.

(1)	(2)	(3)	(4)
From A to B	From B to A	From A to B	From B to A
# * *	# # #	* * *	* * @
# @ *	# @ #	* @ @	* * @
# # #	# # #	# # #	# # #

Table 3: Exchanged messages between Player A and Player B

Player A interprets the whole exchange in metaphoric mode. Below are the intention reports by player A for (1) to (4).

- (A1) @ is me and \* is a cherry blossom. Shall I go out by myself?
- (A2) I am also alone.
- (A3) It is more fun if we stay together.
- (A4) Different scene. Here \* and # are people. @ and @ joined them.

On the other hand, player B is communicating with dynamical mode from (1) to (3). At (4) he starts to use the metaphoric mode. Here are the intention reports by player B for (1) to (4).

- (B1) More #s.
- (B2) I added more #s.
- (B3) @ was added. \* appeared again.
- (B4) @ looks like an cute animal. # and \* are environments. So I moved @.

Player B started to change the mode of communication after communicating with player A. As shown in this sample, an interaction between two players facilitates switching between two modes.

All of the experiments that show the characteristics of two modes of communication using our wall game are

summarized in the following table. We interpret the results in the next section.

	Experiment 1		2	3	
	Intention	Hamming	Transition	On-spot	Alone
	Report	Distance	state	report	
Metaphorical mode	Metaphorical	Smaller	More linear	increase	N/A
Dynamical mode	Dynamical (literal)	Larger	Less linear	decrease	N/A

Table 4: Summary of the experimental results

## 5. Analysis and discussio

### 5.1 Interpretation of two modes

Different from previous evolutionary linguistic experiments, players of the wall game were asked to communicate without a purpose. The only motivation is to enjoy communicating with each other.

In this game, the easiest way to compose a message is to mimic what the other player did. However, this strategy has to be avoided because the communication becomes monotonous and predictable so that the players can easily get bored.

Accordingly, we assume that the behavior of the players is the one that tries to avoid mimicking each other and instead they need a strategy to make messages that has novelty for the other player. Two modes of communication can be understood from this point of view.

First of all, the dynamical mode is a mode in which the player pays attention to the patterns in the messages as they are. Therefore, the reports are literal descriptions of the patterns (dynamical report). To make an interesting change in messages only with patterns, there must be a distinct change. This explains why the Hamming distance calculated in Experiment 1 was relatively large. The frequently used patterns that can make interesting transitions are limited. For example, patterns with three lines are often used, as is shown in the transition from (D1) to (D2). This explains the result of Experiment 2, which shows that the transition state of the dynamical mode was less linear, which means that the same pattern was frequently used.

Turning to metaphorical mode, the players make their own stories based on the transition of the patterns. The story itself cannot be transmitted to the other player in this game. So for the Player B who does not share the story, the message by Player A in metaphorical mode is unpredictable and novel. It has been pointed out that metaphor helps people extend their understanding (Lakoff, 1987) and make inferences (Thibodeau and Boroditsky, 2011). In addition, we want to point out that metaphor helps people behave in a creative manner based on the observation in our experiment.

In metaphorical mode, as shown in Experiment 1, the Hamming distance is small. This is understandable when we realize that even small changes can be meaningful in a story. Compare (M1) and (M2). As shown in Experiment 2, the linearity of the transition pattern is big, that is, the same patterns are rarely used. This can be explained by the fact that in metaphorical mode what is meaningful is the difference between the current diagram and the last one. This means that

there is no particular pattern that has to be used in metaphorical mode.

In Experiment 2, we tried to capture the relationship between two modes and “attention”.

The subjects enjoyed processing patterns and trying to assign meanings to them. In a metaphorical mode, subjects conveyed a message more consciously, by paying more attention to the messages. In contrast, in the former process, that is, in dynamical mode, the subjects explored the texture of the 3x3 bits until they became so familiar with the game itself that it became consciously transparent

Let’s move to the result of Experiment 3. It shows that when the players are alone, they tend to use either one of the modes. When two players are together, both modes occur in communication. This suggests that coexistence of the two modes is enhanced by communication.

### 5.2 Proto-linguistic grammar

The outcome of the wall game experiment is two modes and the player’s switching behavior between the two modes. These two modes together form a procedure of taking our inner thoughts and our feelings and then expressing them outside through the media, i.e., in this case, the wall game. What we got is apparently not lexical items but a process: a process that can be seen as a process of producing linguistic expression. It corresponds to grammatical rules, which are used to compose sentences in natural language. The interesting observation here is that the “grammatical process” observed includes the exploration of the media. In dynamical mode, players try to find out the possibility of the pattern, and what kind of patterns can be used to make a distinctive message.

Our hypothesis is that the exploration of the nature of the media is an integral part of the emergence of grammar. Just by looking at natural language, whose media is already transparent to the users, it is difficult to see whether this is true or not. From this perspective, evolutionary linguistic approach seems to be promising. Since the results presented in this paper are still far from proving this hypothesis, currently, as shown in figure 7, we are making wall games with various textures so that how the player explores the media can be observed. This attempt might give us a way to look into all kinds of languages that would be theoretically possible.

Figure 7: We are now making various types of wall games to analyze the exploratory behavior of players in playing with the wall. (Designed by Seara Ishiyama)

## Abstract

The Chemical Organization Theory (COT) is an abstract reaction network model that has a deep connection to autopoiesis as they share the same central topic: Organization. The main characteristic of autopoietic systems is that they preserve their own organization; this constitutes their identity. In terms of COT, organizations are special reaction networks which are closed and self-maintaining. Organizations compose the majority of stable behaviours of a reaction network (Peter and Dittrich, 2011), in particular every fixed point can be mapped to an organization (Dittrich and Di Fenizio, 2007). Obtaining the set of organizations of a network is a central objective in COT, but it is usually a complex computational task. This work intends to reveal the underlying mathematical structure of organizations. We state a theorem of decomposition for organizations to understand the difficulties of verifying if a set of molecular species is an organization. This suggests a step towards the development of more efficient algorithms and the classification of reaction networks in terms of how complex it is to obtain its set of organizations. We also discuss the consequences of this theorem in relation to autopoietic systems.

## Introduction

During a 30-years period, from the 1950's to the 1980's, the field of biological systems and their generalized properties saw the birth of multiple theories (Eigen and Schuster, 1977; Kauffman, 1969; Maturana and Varela, 1973; Wiener, 1948; von Bertalanffy, 1968; Rosen, 1958). A wealth of formalisms were laid out, which focused on different perspectives on the fundamental properties of living systems, but as it was to be expected, there have been deep similarities between most of these theories (Hordijk and Steel, 2004; Jaramillo et al., 2010; Letelier et al., 2003).

Since their conception, most of these theories have been consigned to the theoretical domain having little incidence in applied sciences, with the possible exception of what is currently known as *systems biology*.

This situation may be because the process of translation between the language employed in these theories and the language commonly used in biology is not trivial (Cornish-Bowden et al., 2007). The chemical organization theory, inspired by Fontana and Buss (1994), provides an interesting departure from this tendency as it provides a language

which is not only clear and well-defined but also correlates directly to the biomolecular domain. Due to its mathematical foundations theorems can be formally proven and developed (Benkő et al., 2009; Peter and Dittrich, 2011; Peter et al., 2010). Also, COT is a powerful tool to analyze the asymptotic behaviour of reaction networks that other analytic or simulation methods cannot cope with. In particular, the chemical organization theory has been applied to biochemical domains (Centler et al., 2008b; Kaleta et al., 2006; Matsumaru et al., 2006), atmospheric photochemistries (Centler and Dittrich, 2007), and as a tool for the study of P-systems (Peter et al., 2010). It also has been proposed as a theoretical framework to design chemical computers (Matsumaru et al., 2007), and recently, for the study of social systems (Dittrich and Winter, 2008).

Thus, COT is very well suited to study autopoietic systems as both theories focus on the problem of self-maintaining organizations. At first it may seem inappropriate that a theory developed around artificial chemistries may be used to study autopoietic systems, but it should be noted that autopoietic systems are not obliged to a molecular structure or realization, that just happens to be the case of living organisms. Furthermore, the “protobio” (Varela et al., 1974) was both an early attempt to simulate autopoietic systems and an artificial chemistry. Therefore, any advance in COT might be transported directly to the theory of autopoietic systems, independent of the domain in which they are actually realized.

In this paper, we first introduce COT and its relation to autopoietic systems. Then, we present a decomposition theorem from COT and finally analyze its consequences for the long-term time behavior of biological systems.

## Autopoiesis and Chemical Organization Theory

Autopoiesis was developed as a theory for living systems by Maturana and Varela (1973). The central idea is that a living organism is a machine, constituted as a unit in space, which maintains its organization through its operation. Moreover, a living organism performs a set of pro-

cesses which generate the components necessary to realize these processes. Thus, the notion of organization as a network of interacting components which stably maintains itself in time is of most importance in this theory. Hence, a theory which concerns itself with such a concept may relate closely to autopoiesis.

The COT, which was introduced in Dittrich and Di Fenizio (2007) in the context of algebraic chemistries, is a mathematical theory, that by using the structures of sets and matrices, is able to formalize chemical reaction systems at a topological and dynamical level. In this theory, an organization is a reaction network which has the potential of being self-maintaining and thus matches very closely to the definition given by Maturana and Varela. Moreover, as “an autopoietic system is an homeostatic machine which has its organization as the variable it maintains constant”, organizations must be stable in time. The COT explores these considerations and has already had important results in this regard. In particular, in this work we present a decomposition theorem for organizations. In order to present our main result, we must first introduce the basics of COT.

## Chemical Organization Theory

### Basic Definitions

At the most basic level of this theory, we deal with two types of objects: molecular species (from now on species) and reactions. The species are the elements of a species set  $\mathcal{M} = \{m_1, \dots, m_n\}$ , and each reaction  $R$  is modeled by a pair  $R = (A, B) \in \mathcal{P}_M(\mathcal{M}) \times \mathcal{P}_M(\mathcal{M})$ , where  $\mathcal{P}_M(\mathcal{M})$  denotes the set of all the multisets formed by elements in  $\mathcal{M}$ . A multiset is defined by a pair  $(X, \eta_X)$ , where  $X$  is a set and the function  $\eta_X : X \rightarrow \mathbb{N}_0$  states the number of occurrences  $\eta_X(x)$  (multiplicity) of  $x$  in the multiset. In order to be consistent with the usual notation of chemical reactions, we will write the multiset  $(X, \eta_X)$  by  $\sum_{x \in X} \eta_X(x)x$ . Moreover, we will refer to the reaction  $R = (A, B)$  by  $R = A \rightarrow B$ , where  $A = (\mathcal{M}, \eta_A)$  and  $B = (\mathcal{M}, \eta_B)$ .

From now on, let  $\mathcal{R} = \{R_1, \dots, R_k\}$ , where  $R_i = A_i \rightarrow B_i$ , with  $A_i = a^{i1}m_1 + \dots + a^{in}m_n$  and  $B_i = b^{i1}m_1 + \dots + b^{in}m_n$ , for  $i = 1, \dots, k$  and  $j = 1, \dots, n$ .  $a^{ij}$  corresponds to the stoichiometric coefficient of  $m_j$  in reaction  $R_i$ , that is, the multiplicity  $\eta_{A_i}(m_j)$  of molecule  $m_j$  in  $A_i$ ;  $b^{ij}$  is defined in a similar way. Now we can define an Algebraic Chemistry, which captures the notion of system, as follows:

**Definition 1** An Algebraic Chemistry is a pair  $\langle \mathcal{M}, \mathcal{R} \rangle$ .

A species  $m \in \mathcal{M}$  is said to be *present* in a multiset  $(X, \eta_X) \in \mathcal{P}_M(\mathcal{M})$  if and only if its multiplicity  $\eta_X(m)$ , is greater than zero. The *reactants* and *products* of a reaction  $R = A \rightarrow B$  are the species present in  $A$  and in  $B$  respectively. The reaction  $R$  can be *fired* by a set  $X \subseteq \mathcal{M}$  if and only if all species present in  $A$  are in  $X$ .

From now on let  $X \subseteq \mathcal{M}$ . Note that there exists a maximal set of reactions  $\mathcal{R}_X \subseteq \mathcal{R}$  which can be fired by  $X$ .  $\mathcal{R}_X$

is composed by the reactions  $R_i = A_i \rightarrow B_i$  such that, if  $m$  is present in  $A_i$ , then  $m \in X$ . We call  $\mathcal{R}_X$  the *possible reactions* set of  $X$ .

In order to deal with the dynamical aspects of any system, it is desirable that the system maintains its identity. This leads to the question of whether the system, left to react for an arbitrary amount of time, will generate species which where originally absent. Note that in a general chemical setting, in which no species will be used up completely, all the reactions that can be fired will fire at some positive rate; therefore, it suffices to check if the set of possible reactions for the system produces any novel species. If it does not, we say that the set of species is closed. The following definition states this formally:

**Definition 2** We say  $X$  is closed if and only if for all  $R = A \rightarrow B \in \mathcal{R}_X$ ,  $m$  is present in  $B$  implies  $m \in X$ . Let  $G_{CL}(X)$  be the closure of  $X$ , then it is the smallest closed set containing  $X$ .

**Remark** The closure of a set has been proven to be unique (Dittrich and Di Fenizio, 2007).

Thus, any given set of species will react growing in qualitative novelty until it reaches its closure, but it is unclear whether the set will be stable in time, considering that during reactions species are consumed and their concentration could drop to zero. This motivates the study of dynamical properties of sets of species.

### Dynamical Aspects

The *stoichiometric matrix*  $\mathbf{S} = (s_{ij})$  associated with  $\langle \mathcal{M}, \mathcal{R} \rangle$  is a  $n \times k$  matrix, where  $s_{ij}$  is the stoichiometric coefficient of species  $m_i$  in the reaction  $R_j$  ( $s_{ij}$  is negative if species  $m_i$  is consumed by reaction  $R_j$ ). Indeed,  $s_{ij} = b^{ji} - a^{ji}$ . The stoichiometric matrix is at the core of current systems biology (Schuster et al., 1999; Schilling and Palsson, 1998) and its properties have been extensively studied (Kacser and Burns, 1973; Heinrich and Rapoport, 1974). Let the *flux vector*  $\mathbf{v} = (v_1, \dots, v_k)$  be a non negative vector such that the application of  $\mathbf{v}$  on the stoichiometric matrix  $\mathbf{S}$  represents a reaction process, i.e. for  $i = 1, \dots, k$ , the rate of the reaction  $R_i$  in the system is given by  $v_i$ . We define the *production rate vector* by  $\mathbf{f} = \mathbf{S}\mathbf{v}$ . Thus, for  $i = 1, \dots, n$ , we have that  $f_i$  is the rate of production of the species  $m_i$  in the reaction process determined by  $\mathbf{v}$ .

We can describe the dynamics of the species concentrations  $\mathbf{x} = (x_1, \dots, x_n)$  by the system of ODEs

$$\dot{\mathbf{x}} = \mathbf{S}\mathbf{v}(\mathbf{x}, \mathbf{k}), \quad (1)$$

where according to mass-action kinetics

$$v_i = k_i \prod_{j=1}^n x_j^{a_{ij}}$$

for  $i = 1, \dots, k$ , is the *flux*, and  $\mathbf{k} = (\mathbf{k}_1, \dots, \mathbf{k}_k)$  is a strictly positive vector denoting reaction rate constants. We call ODE (1) a *chemical reaction system*.

In order to relate the statical domain with the dynamical domain, we introduce the idea of abstractions and instances:

**Definition 3** The *abstraction* of state  $\mathbf{x}$  is the set  $\phi(\mathbf{x})$  with

$$\begin{aligned} \phi : \mathbb{R}_{\geq 0}^n &\mapsto \mathcal{P}(\mathcal{M}) \\ \mathbf{x} &\mapsto \phi(\mathbf{x}) \quad \equiv \{m_i \in \mathcal{M} : \mathbf{x}_i > \epsilon\}, \end{aligned} \quad (2)$$

where  $\mathbb{R}_{\geq 0}^n$  denotes the set of non-negative real numbers, and  $\epsilon$  is a concentration threshold. Moreover, given a set of species  $X \subseteq \mathcal{M}$ , a state  $\mathbf{x}$  is an *instance* of  $X$  if and only if its abstraction equals  $X$ .

## Chemical Organizations

The following definition is at the core of chemical organization theory:

**Definition 4** A subset of species  $X \subseteq \mathcal{M}$  is an *organization* if and only if

1.  $X$  is *closed* and
2.  $X$  is *self-maintaining*, i.e. there is a strictly positive flux vector  $\mathbf{v}$  so that

$$\mathbf{S}_X \mathbf{v} \geq \mathbf{0}$$

where  $\mathbf{S}_X$  is the stoichiometric matrix associated to the Algebraic Chemistry  $\langle X, \mathcal{R}_X \rangle$ .

Organizations are sets of species which cannot produce new species by their possible reaction set. Also, it is possible that during the operation of an organization, the concentration of none of the species decreases; thus, an organization either maintains itself in time or grows in terms of the concentration of its species. This definition shares fundamental properties with that of autopoietic systems to the extent that all autopoietic systems are organizations. Note that not all organizations are autopoietic systems as an organization that keeps growing is not homeostatic and will eventually rupture its container. This motivates the study of the fixed points and other attractors of the chemical reaction systems.

The following theorem relates fixed points and organizations<sup>1</sup>.

**Theorem 1** If  $\mathbf{x}$  is a fixed-point of the ODE (1), i.e.  $\mathbf{S}\mathbf{v}(\mathbf{x}, \mathbf{k}) = \mathbf{0}$ , then the abstraction  $\phi(\mathbf{x})$  is an organization.

Fixed points are related to the dynamic stability of chemical systems. Moreover, since fixed points determine most of the characteristics of the dynamic systems they belong to (Strogatz, 2000), Theorem 1 provides a link between the

long-term behavior of a chemical reaction system and its underlying reaction network. This allows the study of the system's dynamics by the chemical organization theory. Furthermore in (Peter and Dittrich, 2011), Theorem 1 is extended to other stable asymptotic behaviours such as periodic orbits and limit cycles. In addition, the necessary conditions for the existence of adequate flux vectors are explored in (Peter et al., 2010). Note that a fixed point in this context does not refer to thermodynamic equilibrium but to the maintenance of the size of the system in terms of the number of its components. The question about stability refers to the conservation of the structure or organization of the processes in a given timescale as the system is also subject to an evolutionary dynamic which can lead to change or desintegration. Now that we have introduced the idea of organization and shown some relevant aspects, we will focus on our main result; the decomposition theorem.

## Species Role in a Network

The idea behind the role of a species is that it can be classified in relation to a set of species by how it behaves in the set of possible reactions.

## Reactivity and Catalysts

**Definition 5** Let  $m \in X$ , then

- $m$  is *non-reactive* w.r.t  $X$  if and only if for all reactions  $R = A \rightarrow B \in \mathcal{R}_X$ ,  $m$  is not present in  $A$  nor in  $B$ .
- $m$  is a *catalyst* w.r.t  $X$  if and only if for some reaction  $R' = A' \rightarrow B' \in \mathcal{R}_X$ ,  $m$  is present in  $A$  and for all reactions  $R = A \rightarrow B \in \mathcal{R}_X$ ,  $\mathcal{A}(A, m) = \mathcal{A}(B, m)$ .
- $m$  is *reactive* w.r.t  $X$  if and only if for some reaction  $R' = A' \rightarrow B' \in \mathcal{R}_X$ ,  $m$  is present either in  $A'$  or in  $B'$  and for some reaction  $R = A \rightarrow B \in \mathcal{R}_X$ ,  $\mathcal{A}(A, m) \neq \mathcal{A}(B, m)$ .

We say that  $Y \subseteq X$  is a *non-reactive*, *catalytic* or *reactive* set of  $X$ , if for all  $m \in Y$ ,  $m$  is non-reactive, a catalyst or reactive w.r.t  $X$  respectively.

The following lemma is straightforward

**Lemma 1** There is a unique maximal non-reactive, catalytic and reactive set of  $X$ .

**Definition 6** The maximal non-reactive, catalytic and reactive sets of  $X$  are called the *non-reactive*, *catalytic* and *reactive* sets of  $X$  respectively.

## Overproduction

**Definition 7** Consider the Algebraic Chemistry  $\langle \mathcal{M}, \mathcal{R} \rangle$  and a non-negative flux vector  $\mathbf{v}$  such that  $(\mathbf{S}\mathbf{v})_i = \mathbf{f}_i \geq 0$  for  $i = 1, \dots, n$ . If  $\mathbf{f}_j > 0$  for some  $j = 1, \dots, n$ , we say that  $m_j$  is an *overproduced species* in  $\langle \mathcal{M}, \mathcal{R} \rangle$ .

<sup>1</sup>Proof can be found in (Dittrich and Di Fenizio, 2007).

Overproduced species have a positive production rate for certain flux vectors which do not lead to the consumption of any other species. We remark that on the one hand, the definition of overproduced species does not demand that the system is self-maintaining because the flux vector is only required to be non-negative, but on the other hand, overproduced species definition not only requires the non-negative production of all the species, but also the positive production of at least one species. Thus, overproduced species are the species that can be *indefinitely* produced by some *reaction pathway*. Note that although this seems to violate the law of mass conservation, real systems require a constant input of mass or energy, and thus, it is usual when simulating or analyzing chemical networks to include an outer source of mass which does not decrease when consumed by a reaction. The relevance of these species is that they can actually be overproduced without consuming any of the inner species of the system; hence, they embody the notion of input. The following lemma is straightforward.

**Lemma 2** *Let an overproduced species  $m \in X$  in  $\langle X, \mathcal{R}_X \rangle$ . If  $X \subset Y$ , then  $m$  is overproduced in  $\langle Y, \mathcal{R}_Y \rangle$ .*

**Corollary 1** *If  $X$  is a set of overproduced species in  $\langle \mathcal{M}, \mathcal{R} \rangle$ , then its closure  $G_{CL}(X)$  is also overproduced.*

**Lemma 3** *There exists a unique maximal set  $F$  of overproduced species in  $\langle X, \mathcal{R}_X \rangle$ .*

**Proof** If there are no overproduced species in  $X$  then the maximal overproduced set is the empty set. Otherwise the set containing all the overproduced species in  $\langle X, \mathcal{R}_X \rangle$  leads to a maximal overproduced set. Now we are going to prove that the maximal overproduced set is unique. Suppose that there are two maximal overproduced sets  $F_1, F_2 \in X$  and  $F_1 \neq F_2$ , let  $\mathbf{v}_1, \mathbf{v}_2$  the flux vectors required to verify the overproduced property of  $F_1$  and  $F_2$  w.r.t  $\langle X, \mathcal{R}_X \rangle$  respectively. Trivially,  $\mathbf{v}_1 + \mathbf{v}_2$  verifies the overproduced property of  $F_1 \cup F_2$  w.r.t  $\langle X, \mathcal{R}_X \rangle$ , and  $F_i \subset F_1 \cup F_2$  for  $i = 1, 2$ . As the inclusion is strict we have a contradiction.

**Definition 8** *The maximal set of overproduced species  $F$  with respect to  $X$  is called the overproduced set of  $X$ .*

**Remark** Consider the situation of adding a species  $m$  to an organization  $O$ . The fact that  $m$  is overproduced in  $O' = O \cup \{m\}$  does not guarantee that  $O'$  is an organization. For example, consider the set of species  $O' = \{a, b, c\}$  and the set of reactions

We have that  $O = \{a, b\}$  is an organization,  $c$  is overproduced in  $O'$ , but  $O'$  is not an organization.

Then, at first sight the overproduced species could be seen as a useless definition concerning the self-maintenance of a reaction network because the overproduced species ( $c$  in the

example) can catalyze the consumption of species that cannot be recovered in the network ( $b$  through reaction  $R_4$  in the example). However, the identification of the overproduced molecules of a set  $X$  simplifies the verification of the self-maintaining condition of any set that contains  $X$ . Indeed in the example above, we have that  $c$  is overproduced in  $\{a, c\}$ , thus we can avoid the calculation of the production of the species  $c$  when verifying the self-maintenance of  $O'$ .

## Roles and Organizations

From now on let  $N, E, F$  the non-reactive, catalyst and overproduced set of  $X$  respectively.

**Definition 9**  $X - (F \cup E \cup N)$  is the potential active cycle (PAC) of  $X$  w.r.t  $F$ .

**Remark** For any given flux vector which verifies the self-maintenance of  $X$ , the PAC has a production rate equal to zero. But PAC should not be confused with the set of species with a production rate equal to zero. Indeed, the non-reactive and catalytic species have a production rate zero, but they do not belong to the PAC. The following lemma states that no species can be only produced or only consumed in the PAC of an organization:

**Lemma 4** *Let  $C$  be the PAC of  $X$ . If  $X$  is an organization, then for every  $m \in C$  we have that  $m$  is consumed by some reaction  $R \in \mathcal{R}_X$  and produced by other reaction  $R' \in \mathcal{R}_X$ .*

**Proof** Let  $m \in C$ , then  $m$  cannot be non-reactive either catalyst. As  $m$  has production zero, then  $m$  is a reactive species w.r.t  $X$ . Then, there must exist a reaction  $R = A \rightarrow B \in \mathcal{R}_X$  s.t  $\mathcal{A}(A, m) \neq \mathcal{A}(B, m)$ . If  $\mathcal{A}(A, m) > \mathcal{A}(B, m)$ , as  $X$  is an organization, there has to exist some reaction  $R' = A' \rightarrow B'$  s.t  $\mathcal{A}(A', m) < \mathcal{A}(B', m)$ . On the other hand, if  $\mathcal{A}(A, m) < \mathcal{A}(B, m)$ , as  $m$  is not overproduced (because  $m \in C$ ), there has to exist some reaction  $R' = A' \rightarrow B'$  s.t  $\mathcal{A}(A', m) > \mathcal{A}(B', m)$ .

## PAC and Dependent Connectivity

We are going to define a special notion of connectivity which will allow us to separate the PAC of a set  $X$  in a number of partially non-overlapping sub-PACs, such that the self-maintenance of  $X$  can be studied from the self-maintenance of the sub-PACs. From now on, let  $X$  be a closed set<sup>2</sup>.

The following definition of connectivity appears in (Centler et al., 2008a):

**Definition 10** *Two species  $m_i$  and  $m_j$  in  $X$  are directly connected in  $\langle X, \mathcal{R}_X \rangle$  if and only if there exist a reaction  $R = A \rightarrow B \in \mathcal{R}_X$  such that  $\{m_i, m_j\} \subseteq A \cup B$ .*

<sup>2</sup>Verifying the closed property, and obtain the closure of a set of species is trivial compared with verifying its self-maintenance (Centler et al., 2008a)

**Definition 11** Two species  $m_i$  and  $m_j$  in  $X$  are connected in  $\langle X, \mathcal{R}_X \rangle$  if and only if there exist a sequence of species  $m_0, \dots, m_p \in X$  such that  $m_i = m_0$ ,  $m_k$  and  $m_{k+1}$  are directly connected in  $\langle X, \mathcal{R}_X \rangle$  for all  $k = 0, \dots, p-1$  and  $m_p = m_j$ .

We present a more restricted notion of connectivity than definition 11. This restriction only connects species that are non-independent when verifying self-maintainance.

**Definition 12** Two species  $m_i$  and  $m_j$  in  $X$  are dependently connected in  $\langle X, \mathcal{R}_X \rangle$  if and only if there exists a sequence of species  $m_0, \dots, m_p \in X - (E \cup F)$  such that  $m_i = m_0$ ,  $m_k$  and  $m_{k+1}$  are directly connected in  $\langle X, \mathcal{R}_X \rangle$  for all  $k = 0, \dots, p-1$  and  $m_p = m_j$ .

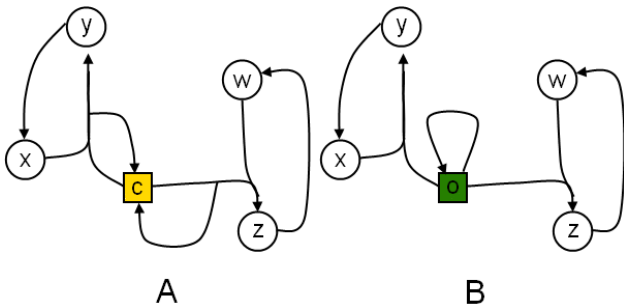

Figure 1: Following definition 11, both networks **A** and **B** are fully connected. Note that in **A**, the self-maintainance of  $C_1 = \{x, y, c\}$  and  $C_2 = \{z, w, c\}$  are independent. The same situation occurs in **B** with sets  $C'_1 = \{x, y, o\}$  and  $C'_2 = \{z, w, o\}$ . *Dependent connection* allows to connect all the species in  $C_1$  without connecting them to species in  $C_2$  and viceversa because  $C_1$  and  $C_2$  are connected through a catalyst. Analogously  $C'_1$  and  $C'_2$  are not dependently connected because they are connected through an overproduced species.

**Lemma 5** Let  $m, \bar{m} \in X$ .  $m$  is dependently connected in  $\langle X, \mathcal{R}_X \rangle$  to  $\bar{m}$  if and only if  $\bar{m}$  is dependently connected in  $\langle X, \mathcal{R}_X \rangle$  to  $m$ .

To continue, we need to mention that a computer science formalism called Petri Nets (Murata, 1989), has been considered as an interesting source of insights for the biochemical pathways research (Reddy et al., 1993, 1996). Petri Nets arose from the necessity to formalize concurrent processes. We will incorporate some fundamental topological parameters of Petri Nets to our analysis: the set of input transitions of a place and the set of input places of a transition.

**Definition 13** Let  $m \in \mathcal{M}$ . We define

$$\text{Act}(m, \mathcal{R}) = \{R = A \rightarrow B \in \mathcal{R} \mid m \text{ is present in } A\}.$$

We say  $\text{Act}(m, \mathcal{R})$  is the activable set of reactions of  $m$  in  $\mathcal{R}$ .

**Definition 14** Let  $R = A \rightarrow B \in \mathcal{R}$ . We define

$$\text{Req}(R) = \{m \mid m \text{ is present in } A\}.$$

We say  $\text{Req}(R)$  is the required set of species of  $R$ . Furthermore, for a set of reactions  $S \subseteq \mathcal{R}$  we define

$$\text{Req}(S) = \bigcup_{R \in S} \text{Req}(R).$$

The set of input places in Petri Nets corresponds to the set  $\text{Req}(\cdot)$ , and the set of input transitions corresponds to  $\text{Act}(\cdot, \mathcal{R})$ .

**Definition 15** We define  $\text{Causal}^*(m, \mathcal{R}_X)$  as the set of dependently connected species in  $\langle X, \mathcal{R}_X \rangle$  to  $m$ , and  $\text{Causal}(m, \mathcal{R}_X) = \text{Req}(\text{Act}(\text{Causal}^*(m, \mathcal{R}_X)))$ .

The following lemmas are derived straightforward from lemma 5 and definition 15:

**Lemma 6** Let  $m, \bar{m} \in \mathcal{M}$ .  $\bar{m} \in \text{Causal}^*(m, \mathcal{R}_X)$  if and only if

$$\text{Causal}^*(m, \mathcal{R}_X) = \text{Causal}^*(\bar{m}, \mathcal{R}_X).$$

**Lemma 7** Let  $R \in \mathcal{R}_X$ ,  $m, \bar{m} \in X - (E \cup F)$  s.t.  $m \notin \text{Causal}(\bar{m}, \mathcal{R}_X)$ . If  $R \in \text{Act}(\text{Causal}(m, \mathcal{R}_X) \cap \text{Causal}(\bar{m}, \mathcal{R}_X), \mathcal{R}_X)$  then  $R \in \mathcal{R}_{E \cup F}$ .

$\text{Causal}^*(\cdot, \cdot)$  provides a way to split a set  $X$  of species in dependent connected subsets. It is necessary to identify a the catalytic set  $E$  and the overproduced set  $F$  to generate such separation. The more elements are in  $E \cup F$ , the more chance of recognize the independent causal connected sets we have.

**Lemma 8** Let  $D$  be the PAC of  $X$ . Then

$$D = \bigcup_{m \in D} \text{Causal}^*(m, \mathcal{R}_X)$$

**Proof** Note that  $D \subseteq \bigcup_{m \in D} \text{Causal}^*(m, \mathcal{R}_X)$ . Let  $m \in$

$\bigcup_{m' \in D} \text{Causal}^*(m', \mathcal{R}_X)$ , then for some species  $m' \in D$  we have  $m$  is dependently connected to  $m'$ , then  $m'$  is also dependently connected to  $m$ . This means  $m$  is a reactive, non overproduced, and non-catalytic species. Then  $m \in D$ .

From now on we let  $D \subseteq X$  be the potential active cycle of  $X$ .

**Definition 16** Any set  $D' \subseteq D$  s.t.  $D = \bigcup_{m \in D'} \text{Causal}^*(m, \mathcal{R}_X)$  is called a base of  $D$ . Any minimal cardinality base of  $D$  is called a minimal base of  $D$ .

**Lemma 9** Let  $D', D''$  be two minimal bases of  $D$ . Then every species in  $D'$  is dependently connected to one and only one species of  $D''$ .

**Proof** Let  $m \in D'$  and suppose that there is no species in  $D''$  dependently connected to  $m$ . By corollary 6 we have  $Causal^*(m, \mathcal{R}_X)$  is not contained in  $\bigcup_{m' \in D''} Causal^*(m, \mathcal{R}_X)$ . Then there has to be at least one species dependently connected to  $m$  in  $D''$ . Now suppose there is more than one species dependently connected to  $m$  in  $D''$ . Let  $m_1, m_2 \in D''$  such species. As  $m_1$  and  $m_2$  are dependently connected to  $m$ , then  $m_1$  and  $m_2$  are dependently connected. By corollary 6 we have  $Causal^*(m_1, \mathcal{R}_X) = Causal^*(m_2, \mathcal{R}_X)$ . Then  $D''$  is not a minimal base of  $D$ .

A minimal base of  $D$  is a set which generates all the non dependent sub-PACs of the  $D$ . We are going to prove that the self-maintainance of a potential active cycle can be obtained from the self-maintainance of its non dependent sub-PACs.

**Lemma 10** Let  $D'$  a minimal base of  $D$ . Then

$$Act(D, \mathcal{R}_X) = \bigcup_{m \in D'} Act(Causal^*(m, \mathcal{R}_X), \mathcal{R}_X).$$

**Proof** Note that

$$\bigcup_{m \in D'} Act(Causal^*(m, \mathcal{R}_X), \mathcal{R}_X) \subseteq Act(D, \mathcal{R}_X).$$

Let  $R \in Act(D, \mathcal{R}_X)$  then for some  $m \in D$  we have  $R \in (m, \mathcal{R}_X)$ . From definition 16 we have that there is  $m' \in D'$  s.t  $m \in Causal^*(m', \mathcal{R}_X)$ . Then by corollary 6 we have

$$R \in Act(Causal^*(m', \mathcal{R}_X), \mathcal{R}_X) \subseteq \bigcup_{m \in D'} Act(Causal^*(m, \mathcal{R}_X), \mathcal{R}_X).$$

## Decomposition Theorem for Organizations

**Theorem 2** Let  $D' = \{\bar{m}_1, \dots, \bar{m}_d\}$  a minimal base of  $D$ . For  $i = 1, \dots, d$  let

$$D_i = Causal(\bar{m}_i, \mathcal{R}_X), \\ F_i = Causal(\bar{m}_i, \mathcal{R}_X) \cap F.$$

Let  $\emptyset \rightarrow Y = \{\emptyset \rightarrow y / y \in Y\}$ .  $X$  is self-maintaining if and only if for all  $i = 1, \dots, d$  we have that  $D_i$  is self-maintaining in the subnetwork  $\langle D_i, \mathcal{R}_{D_i} \cup \emptyset \rightarrow F_i \rangle$ .

**Proof**  $\Rightarrow$ : Let  $\bar{F} = \bigcup_{i=1}^d F_i$ . Note that  $X$  is self-maintaining in  $\langle X, \mathcal{R}_X \rangle$  if and only if  $X$  is self-maintaining in  $\langle X, \mathcal{R}_X \cup \emptyset \rightarrow \bar{F} \rangle$ . Let  $\mathbf{v}$  be a vector which verifies the self-maintainance of  $X$  in  $\langle X, \mathcal{R}_X \rangle$ . Let  $Act(D_i, \mathcal{R}_X) = \{R_{\alpha_1}, \dots, R_{\alpha_i}\}$ , then  $\bar{\mathbf{v}}$  lead to a non-negative production on all the species of  $Causal^*(\bar{m}_i, \mathcal{R}_X)$  where

$$\bar{\mathbf{v}}_i = \begin{cases} \mathbf{v}_i & \text{if } i = \alpha_j \text{ for some } j, \\ 0 & \text{else} \end{cases}$$

As the rest of species belong to  $\bar{F}$ , to reach their non-negative production we use the reactions in  $\emptyset \rightarrow \bar{F}$ .

$\Leftarrow$ : Let  $\mathbf{v}_1, \dots, \mathbf{v}_d$  the flux vectors which verifies the self-maintainance of  $\langle D_i, \mathcal{R}_{D_i} \cup \emptyset \rightarrow F_i \rangle$ ,  $i = 1, \dots, d$  and  $\mathbf{v}^F$  the flux vector which verifies the potential overproduction of  $F$  w.r.t  $X$ . Then there exist a non-negative number  $\beta$  s.t  $\beta \mathbf{v}^F + \sum_{i=1}^d \bar{\mathbf{v}}_i$  verifies the self-maintainance of  $X$ , where  $\bar{\mathbf{v}}_i$  is the flux  $\mathbf{v}_i$  represented as a flux vector for  $\mathcal{R}_X$ , i.e. completed with zeros in the coordinates representing reactions that are not in  $\mathcal{R}_{D_i}$ .

**Corollary 2** Let  $D'$  a minimal base of  $D$ . Then  $X$  can be non-overlapping decomposed (partitioned) as

$$X = N \cup E \cup F \cup D_1^* \cup \dots \cup D_d^*. \quad (4)$$

With  $D_i^* = Causal^*(m_i, \mathcal{R}_X)$ , and  $m_i$  the  $i$ -th element of  $D'$ . Moreover  $X$  is self-maintaining if and only if  $E \cup F \cup D_i^*$  is self-maintaining for  $i = 1, \dots, d$ .

## Stability, COT and Autopoiesis

Living organisms are systems far from thermodynamic equilibrium, therefore the question about stability refers to the conservation of the organization of the organism's processes. This issue requires some attention, as the processes an autopoietic system are homeostatic in essence, but they are always potentially subject to dramatic changes. A clear example of this is the cell cycle, which is driven by cyclic, i.e. non stationary, processes like the cyclins proteins family expression patterns. In relation to this, the autopoiesis theory describes living organisms as processes that produce the components that give rise to those processes, where some attributes are preserved and others may change (Varela et al., 1974) allowing a structural drift (Maturana and Mpodozis, 2000). Therefore, in a way, autopoietic systems are not obliged to exhibit stability in the long run.

The basis of structural drift in biochemical networks is metabolic regulation. This is managed by the modulation of enzymes expression and also by means of a co-catalysis phenomenon in which coenzymes and regulators interact with the enzyme structure-function relation. This metabolic regulation determines the cell's developmental *direction* between a wide range of possible organizations. In order to illustrate this idea, imagine a system *following* an attractor when suddenly the concentration of a given regulator reaches a level that triggers a deep change in the structure of the network. Now, the attractor mentioned above is absent and the system takes a different pathway in which another phase space shift can occur. If this process becomes cyclic, the entire loop can be described as a limit cycle, but a decomposition of phase space in a set of *contextual* mini phase spaces that emerge in different regulatory scenarios could contribute both to the understanding of biological operations as to the algorithms research in biology inspired AC simulations. Therefore, in the COT, the changes in structure can be represented as changes in the phase space, leading to a dependence of phase space with the state of enzymes and regulators.

Some future goals in biologically inspired AC are the study of cyclic behaviour and autopoiesis theory's structural coupling. Preliminary studies concerning artificial autopoietic systems have been done in (Peter et al., 2010), by making use of the P-systems formalism. A P-system is formed by a set reaction networks, each one enclosed by a membrane. The reaction networks can interact diffusing particles through membranes. In particular, it is shown how a bistable cyclic process can be reached among two different unstable reaction networks, by exchanging in low rates their subproducts, i.e. forming together an organization.

## Conclusions

In this paper we have shown how the chemical organization theory connects deeply to notions of autopoietic systems. Moreover, every autopoietic system is an organization, and thus, theorems derived for organizations are valid for autopoietic systems.

We introduce the notion of the role played by a species in a subnetwork of a reaction network. The different possible roles that a species can play in a subnetwork (non-reactive, catalyst, overproduced, active cyclic) give information about the structure of the subnetwork (lemmas 1, 3 and 4). We also introduce the notion of dependent connectivity in a reaction network (definition 12), which is useful to split a reaction network into the minimal parts required to verify the self-maintainance (Theorem 2). This theorem helps to simplify the organization verification not only by decomposing the set, but also when we keep track of the decomposition of the set to verify the self-maintainance of sets that contain it.

The fact that an organization can be subdivided into self-maintaining subnetworks which are mostly independent one from another (and not necessarily closed), is both striking and noteworthy. The decomposition theorem stated in this work shows that the long-term behaviour of an organization can depend on sets of species whose states are weakly coupled. This result opens new paths of analysis for a broad set of fields, from metabolic dynamics to ecological networks. This result also relates directly to a debated subject which is the composition of autopoietic systems by other autopoietic systems.

At this point a comment on the domain of applicability of this theorem is convenient. On some cases, like reactive flow systems where there is a spontaneous decay of every species, the decomposition is trivial, i.e., the system cannot be further subdivided. This is because each species of an organization would be overproducible (to counteract the decay). So, this paper addresses those systems where some species take part in reactions but do not decay spontaneously. In the case of living systems, every molecule decays spontaneously or, equivalently, dilutes when the system grows. This seems to make an argument towards the unapplicability of the decomposition theorem to living systems. However, the fact that every molecule decays in a

living system is only relevant at the right timescale. For a smaller timescale some molecules do not decay. Therefore, it is important to examine living systems at different timescales. Choosing a very long time scale, basically no system would continue to exist so that autopoiesis would not become visible. While with a smaller timescale more and more elements (molecules) would become stable and would not decay spontaneously. Here is where the decomposition can potentially be applied.

This decomposition theorem is suggested as a starting point for the complexity analysis of the organization verification problem as well as for the classification of reaction networks in terms of how complicated it is to compute their organizational structure. Although this is a relevant result for current systems biology as it simplifies analysis and simulations, and for artificial life, at it may guide the construction of artificial self-sustaining systems, it also demands revisiting questions on biological systems concerning their modularity, autonomy, and even the notion of their identity.

## Abstract

An insufficiently appreciated paradox in the origin of life is that the replication of information-carrying molecules requires the molecules to be very specifically shaped; but such specific molecules are hard to produce without natural selection. We demonstrate and investigate this problem by building a physical model of self-replication out of specifically shaped plastic pieces with embedded magnets, which float around on an air-hockey type table. We use a mechanism known as template replication, which works by the joining of complimentary strands, roughly analogous to the biological replication of DNA, except without the involvement of enzymes. Building a physical rather than a computational model forces us to confront several issues that have analogues in the microscopic, chemical world. In particular, in order to achieve a low mutation rate we must reduce as much as possible the formation of incorrect sequences, which can happen both spontaneously and as a result of strands joining in a misaligned way. The latter results in ever-lengthening sequences in a process known as the “elongation catastrophe”. We present an overview of our design process, illustrating the many interdependent adaptations that had to be made to the pucks’ shapes in order to solve these problems while maintaining a high rate of template replication. The chicken and egg question is how, in the pre-biotic world, could template replication be achieved without the presence of enzymes that require template replication in the first place? By building a real physical model a new answer to this question is suggested. We propose that early pre-biotic monomers required structural specializations that reduced the rate of formation of incorrect sequences, without the need of an encoded enzyme.

## Introduction

In the highly evolved biology of today a complex array of encoded enzymes is necessary for the replication of DNA and RNA polymers. These enzymes were not available at the origin of life, and so nucleotide template replication had to be non-enzymatic (Szathmáry, 2000; 2006). The best example of non-enzymatic template replication we have so far is still the work of Guenter von Kiedrowski (1986) who made the first non-enzymatic template replicator consisting of the hexanucleotide sequence GGCGCC that catalyses the templated ligation of CGG and CCG trimers.

In such experiments, replication must be carefully distinguished from spontaneous self-assembly which is typically easier to achieve than replication in stochastic systems. In the von Kiedrowski experiment there is a low rate of self-assembly (specifically elongation/dimerisation) by non-templated ligation of CCG and CGG. To prove replication one must compare the rate of formation of

GGCGCC in the absence and the presence of an initial seed of GGCGCC. The difference is the extent of true templated self-replication. Whereas self-assembly of random novel oligomers is fine for random search in sequence space, self-replication is crucial for evolution by natural selection, i.e. the production of offspring whose fitness correlates with parental fitness (Price, 1970). If most of the DNA in a proto-organism was self-assembled de-novo into random sequences and not replicated from the parent, the genome would be real garbage, as opposed to inherited junk.

This raises a paradox that is of no lesser importance than Eigen’s paradox regarding the error catastrophe (Eigen 1971). Our logically anterior paradox deals with the fact that specificity of self-replication over self-assembly is a critical pre-requisite for an evolvable physical template self-replicating system. Without specific ligation, random de novo synthesized sequences invade a population of replicating evolved sequences. These random sequences compete with evolved sequences for monomer resources thus diluting out evolved information (i.e. sequences that had arisen from a

**Figure 1:** A generic illustration of template replication and two side reactions that must be avoided. (a) Homologous template directed ligation (self-replication) results in the correct duplication of a sequence. (b) A new (incorrect) sequence is formed by non-templated spontaneous ligation. (c) Elongation of the original sequence by partially homologous template ligation at staggered ends. See (Fernando, Von Kiedrowski et al. 2007) for a full analysis of the elongation catastrophe.

lineage of template replication events). In addition evolved sequences become trapped inside elongating strands (that cannot easily unzip or denature) such that they cannot easily experience another round of replication, see Figure 1. We call this the elongation catastrophe and it raises what we will call the elongation paradox (Fernando, von Kiedrowski et al. 2007). How can specific ligation be achieved without complex enzymes that require template replication with specific ligation in the first place?

The minimal unit of template replication is a dimer (i.e. a polymer of length two) that can replicate three possible sequences, AB, BA, or AA(BB), as in Figure 1. The minimal unit of template replication has the capacity to replicate the specific configuration that it is in. It is this fact that allows template replication to potentially convey an unlimited amount of information (Szathmáry and Maynard Smith 1997) because of the compositionality of the genome (Fodor and Pylyshyn 1988) and to be evolvable due to the capacity for micro-mutation, i.e. small changes in the composition can generate correlated fitness variants (Price 1970). But there is a real danger with such a system that if ligation is not tightly controlled then novel random sequences can arise and evolved sequences can elongate (but not replicate) without limit, as in Figure 1(c).

Mutations must be able to occur in an evolvable system, but they must occur at a low rate in order to avoid Eigen's (1971) error threshold. A minimal evolvable system must therefore exhibit the replication of dimers with low rate of assembly of incorrect or elongated sequences. For this project we set ourselves the goal of producing a system where the average rate of replication of a seed dimer is greater than the rate of formation of all other sequences put together.

Interestingly, this elongation catastrophe was the fate of a 2D macroscopic system designed by Jarle Breivik for template replication that was faithful to some aspects of chemistry such as stochasticity and binding properties (Breivik 2001). He used 2D plastic shapes with embedded magnets and an oscillating temperature water bath. Unfortunately, despite the obvious ingenuity of the design, the original templates formed in an unseeded manner by spontaneous aggregation of "hydrogen bonded" pairs to form a double strand and no kinetic comparison between self-assembly and self-replication was made. From Figure 3 in Breivik's paper it appears that free ligation was responsible for the production of all the oligomers in that model by de novo synthesis of monomers in weakly bonded pairs. Strangely, the h-bonded pairs catalyze double p-bond formation, see Figure 3 in (Breivik 2001). It seems, no template replication was demonstrated, and if it did exist, it seems to occur much more slowly than the spontaneous formation of novel sequences. This is a problem for evolution by natural selection, not a feature. Breivik's system suffers severely from the elongation catastrophe and therefore could not be extended to undergo natural selection of sequences.

In fact, until now, to our knowledge it is still only the geneticist Lionel Penrose and his son Roger Penrose (Penrose and Penrose 1957) who have shown a relatively specific type of ligation reaction in a physical system without resorting to electronic switches and other features that make specificity of ligation trivial and thus reduce their utility in abduction to chemistry or the potential for later miniaturization (Groß,

Küchler et al. 2009). Penrose's devices use only gravity, collision, friction, and (passive and active) hooking. In the simplest model, two kinds of solid object A and B are agitated horizontally on a straight track. If seeded with either a AB or a BA dimer (AA and BB dimers cannot form in the Penroses' system) other monomers join together by being appropriately tilted, to form the identical dimer type, without novel AB or BA forms appearing spontaneously by un-catalysed ligation. E.F. Moore wrote of Penrose's design "If the reader attempts the problem of how to design the shapes of the units A and B so as to have the specified properties, the difficulties he will encounter in his attempt will cause him to more readily appreciate the ingenuity of Penrose's very simple solution to this problem." (Moore 1962).

However, 1D systems are severely limited in terms of extendibility to longer sequences to achieve unlimited heredity (Szathmáry and Maynard Smith 1997) because i. they may be constrained by the initial sequence of monomers along the chain (which is a problem if the identity of monomers cannot flip between A and B, which in some of Penrose's designs they can), and ii. information about the identity of units on the inside of a sequence must pass through all other bordering units before they can influence external monomers. Again, Lionel Penrose already carefully considered information transmission through units agitated in 1D, for example he invented in a length-dependent end-blocking device that prevents anything larger than 4-mers from forming, so avoiding the elongation catastrophe in one dimension. A more complete 1D self-replicator (still 1D because it is only agitated in the horizontal axis) was later invented by Penrose to allow the replication of dimers with more possible states/configurations defined by the arrangement of hooks stacked in the 2D axis orthogonal to the axis of agitation rather than perpendicular to that axis (Penrose 1959). So, in short, Penrose took the elongation catastrophe rather seriously.

Here for the first time we present a mechanical 2D stochastic self-replicator that has limited rates of non-catalysed spontaneous self-assembly (ligation) of monomers, and limited partial homologous templated ligation. Reducing the rates of these two side-reactions serves to some extent to curtail the elongation catastrophe. However, we note that our solution is hand-designed and partial. The elongation paradox is still not solved for the origin of life, i.e. we do not know how such infra-biological monomers could have arisen with these very specific capabilities; speculation on this based on this work is given in the conclusions.

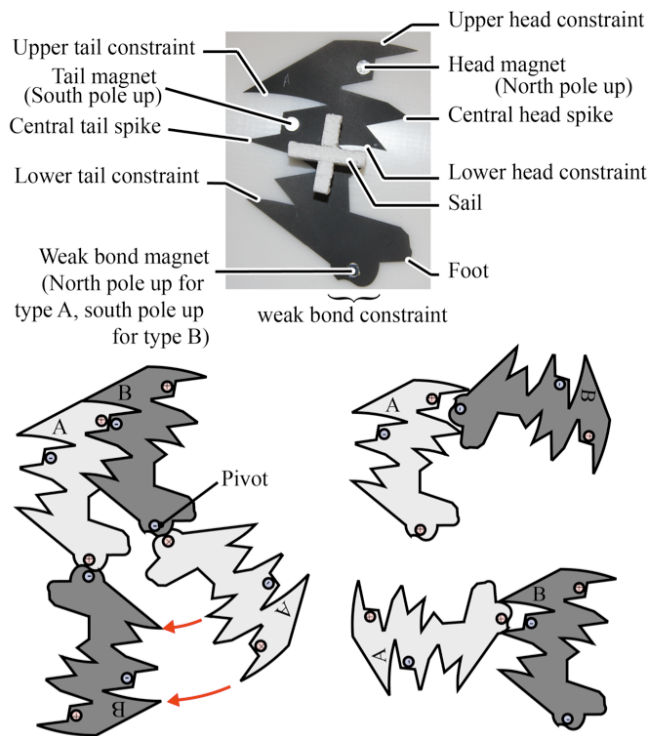

We built plastic monomers containing magnets and passive hooks and sails, that floated on an air-hockey table, and were blown by fans on the perimeter of the table, see Figure 2. Spontaneous elongation (untemplated ligation) was reduced by careful design of the physical equivalent of the phosphodiester bond. In addition, partial homologous ligation was reduced by careful design of the template complex.

Indeed, our system is a macroscopic close relative of von Kiedrowski's hexanucleotide replicators, because we have faced similar design challenges as in real chemistry, such as cyclisation and product inhibition. Guenter von Kiedrowski had to block the ends of his hexamers to prevent partial homologous ligation from catastrophically extending strands and depleting matter from the replicator cycle (Von

**Figure 2:** The design of the air-hockey style table containing the monomers. Sails on each monomer are blown by a perimeter of small fans. Another fan below the table passes air through small holes to suspend monomers over the table like small hovercraft.

**Figure 3:** The design of the monomers. The top photograph shows the names used in the text for important parts of the design. In photographs the two monomers are distinguished by the colour of their polystyrene sails (white for A, black for B), whereas in diagrams, type B is shown in a darker shade of grey. The lower-left diagram shows the mechanism by which templated ligation takes place (but see also Figure 4). The lower right diagram shows how the design prevents the weak bond magnets from bonding to the strong bond magnets.

**Figure 4:** The autocatalytic cycle for replication of an AB dimer. (a) A type 'B' monomer joins to the dimer. (b) A type 'A' monomer joins to the other h-bond and swivels into place via the mechanism shown in Figure 1. Catalysis can also take place if the monomers join in the opposite order; in this case both monomers must swivel on their weak bonds, which often occurs when the configuration collides with another object. (c) A p-bond is formed by template directed ligation and, simultaneously, one of the h-bonds is broken. A collision with another molecule or the table edge is required in order for this step to occur. (d) Another collision breaks the remaining weak bond, and the two strands separate, completing the cycle.

Kiedrowski 1986). However, in our system we have not explicitly blocked the ends, but have designed all the monomers so that end-blocking is 'emergent'.

The primary advantage of a physical system over a computer simulation is it forces us to confront the problems of template replication by changing the design of the monomers, rather than by changing the simulation to reduce the problems. Similarly, while real chemical monomers can have mechanically-implemented internal states, our self-imposed restriction of no electronic components prevents us from being able to implement any arbitrary mechanism, regardless of how easily it could be implemented mechanically in chemical systems.

Next we describe the design of the pucks (monomers) and then we conduct a classical seeding experiment to distinguish self-replication from self-assembly. This is the first demonstration of a 2D template replication system that is capable of low rates of spontaneous elongation yet high rates of self-replication (without the use of monomers containing electronically implemented finite state machines).

**Figure 5:** (a) The formation of a BBB trimer due to partial homologous ligation. The production of AAA and BBB trimers in this way is relatively common in our system (see Figure 9). (b) Staggered bonding is not possible between two AB dimers (or two BA dimers) because it would require the formation of an h-bond between magnets of the same polarity. (c) It is in theory possible for a further partial homologous ligation to extend a BBB trimer into a BBBB 4-mer. However, we did not observe this in any of our trials. We suspect this is because the two polymers have a high moment of inertia about the weak bond's pivot point, destabilising the bond and making it likely to break. (d) Polymers of length greater than two cannot replicate in the same way as dimers, because the "foot" mechanism does not allow the strong bond constraints to align with the weak bond pivot.

## Methods

A frictionless table, similar to those used for air-hockey, was purpose built and consisted of a flat plastic surface perforated with an array of 1.5mm diameter holes, spaced at intervals of 10mm. An enclosure underneath this surface was pressurized with a powerful fan to produce a steady jet of air from each hole, allowing suitably shaped objects to float above the table surface. Surrounding the table was a set of approximately 20 small fans that could be arranged to cause a stochastic motion of the pucks, albeit with a significant rotational element, see Video A in Supplementary Material. There was no "temperature" oscillation as in Breivik's experiment, i.e. the fans always rotated at the same speed. The walls of the table

allowed approximately elastic collisions. The puck design is shown in Figure 3.

Pucks are 1.5mm thick and made of plastic. The bases of the pucks are flat allowing a hovercraft type low friction floating of the puck above the table. The pucks were fabricated using a Versalaser cutter. Rapid fabrication of new designs was possible for prototyping. Pucks contain molybdenum disc magnets that can be oriented with the north or south pole facing upwards, allowing specification of attractive or repulsive interaction pairs.

The final design has the following features. The strong 'phosphodiester bonds' must not form spontaneously. This is achieved by embedding the magnets deep within the puck and producing a lock and key type join which can only form if the pucks collide at a very specific orientation. This orientation tends to occur only when the two monomers are 'hydrogen bonded' to a dimer template, and not when two pucks collide against each other as untemplated monomers. Once the pucks make the p-bond the magnets are very close together so the bond is strong. Thus the p-bond is difficult to form due to steric constraints but once formed is strong due to close magnets and mechanical rigidity. The h-bonds consist of an interaction between magnets that are further apart when the bond is formed, i.e. the bond is weaker. Also, there is a curve on the surface of the bond to allow pucks to rotate when h-bonded. This rotation brings the two h-bonded monomers into the appropriate configuration for the p-bond to form.

To reduce product inhibition, the pucks are shaped in such a way that two p-bonded dimers cannot be joined at both h-bonds. Thus, as the p-bond forms it breaks one of the two hydrogen bonds. The remaining h-bond is sufficiently weak that the two dimers can separate and undergo another round of replication.

There are two types of monomer, labelled 'A' and 'B', which differ only in the orientation of the magnets that form their h-bonds. 'A' type monomers can only form weak (h-)bonds with 'B' type monomers, and vice versa. Strong (p-)bonds can be formed between any pair of monomers, giving rise to four types of strong-bonded dimer, 'AA', 'AB', 'BA' and 'BB'. Template replication produces a new dimer that is both the complement and the reverse of the original. This results in three separate autocatalytic cycles: {AB}, with the reaction  $AB + A + B \rightarrow 2AB$ ; {BA}, with the reaction  $BA + A + B \rightarrow 2BA$ ; and {AA, BB} with the reactions  $AA + 2B \rightarrow AA + BB$  and  $BB + 2A \rightarrow AA + BB$ .

Misalignment with the generation of a staggered or dangling end as they are often called, can cause 'AA' dimers to be extended via catalysis to 'AAA' dimers, and similarly for the 'BB' type, by partial homologous ligation (see Figure 5). However, in all the experiments conducted we did not observe the production of 4-mers by partial homologous ligation. Importantly misalignment did not tend to occur for 'AB' and 'BA' dimers, which cannot catalyse partial homologous ligation dependent elongations unless another species of dimer is also present in the system. The explanation is given in Figure 5.

In summary there are the three principles that we used to limit the elongation catastrophe in this simple system.

1. Impossibility of formation of non-complementary h-bonded pairs.

**Figure 6:** A selection of unsuccessful iterations of the design, illustrating the ways in which various issues were solved. The designs are shown in chronological order. See text for details. Magnets are shown in red or blue depending on whether the north or south pole is oriented upwards. The weak bond magnets, whose orientation depends on the polymer type, are shown in white.

2. A high moment of inertia at the pivot point of a staggered end.
3. Improper alignment of p-bond passive hooks during an attempted templated ligation for N-mers where  $N > 2$ .

In combination these three factors significantly reduced the elongation catastrophe by limiting partial homologous ligation. The curved passive hooks previously described also helped by reducing the extent of non-catalysed ligation.

## A Phylogeny of Designs

A number of issues had to be solved simultaneously in order to produce a successful design. It took approximately 30 iterations to produce the final design, some of which can be seen in Figure 6. We have listed the issues that needed to be solved below.

i. The strong (p-)bonds must be unlikely to form spontaneously, i.e. the problem of reducing spontaneous generation.

ii. There must not be any reactions that catalyse p-bond formation, other than the intended template mechanism. For example, if two pairs of monomers joined by h-bonds come together, they must not line up at the right angle to form p-bonds.

iii. Once formed, the strong bonds must be strong enough that they rarely break. (In the final design they were strong enough not to break at all.)

iv. The strong bonds must form easily when catalysed by the weak bonds.

v. The weak (h-)bonds must form easily.

vi. The weak bonds must also break easily. This facilitates strand separation, as well as freeing up monomers that have become weak-bonded to other monomers, which would otherwise not be able to participate in catalysis.

vii. Once a dimer has catalysed the creation of another, the two 'strands' must be able to separate, i.e. the problem of product inhibition.

viii. The magnet in the weak bond must not be able to attach strongly to the magnet in the head or tail of another puck. Such unwanted bonds inhibit catalysis by occupying the bond points, and can also give rise to configurations that can catalyse the wrong type of dimer.

ix. The puck must be able to float effectively on the table. Designs with long thin protruding parts, or uneven weight distributions, can drag on the table's surface.

x. The pucks must not tend to jump off the table's surface and become stacked on top of one another. This tends to happen if two magnets with the same polarity are forced close to one another, or if the design features spikes that are too sharp.

Of these, issues i and ii were by far the hardest to solve. In most of our designs, including the final one, the strong bond works by requiring the two pucks to collide at a very precise angle. In many of the designs, if the collision occurred at a slightly different angle, a strong bond would often form anyway. This is because the head and tail magnets would tend to make the pucks slide into place to form a strong bond, or else the two pucks would sit together in a configuration where they could easily be nudged into the right position to form a strong bond. This was solved in the final design by adding long spikes to the strong bond constraints, in such a way that the magnets tend to pull the pucks away from, rather than towards, the strong bond configuration if the pucks are not correctly lined up. However, the pucks do still occasionally collide at the right angle to form a strong bond.

Since we could not substantially reduce the rate at which this occurs, we instead focused on increasing the rate of catalysis. We addressed issue iv by designing the weak bond to act as a pivot that guides the strong bonds into place.

Issue v was solved by making the weak bond protrude as much as possible from the body of the puck. This increases the range of relative angles at which two pucks can be oriented while still being able to form a weak bond. Issue vi was addressed by making the weak bond into a pivot that can swing fairly freely. As the joint hinges the two magnets are pushed further apart, so that the bond can break if it swings far enough. This could be fine-tuned by making very small changes to the magnets' positions. The "foot" mechanism was introduced to solve issue vii.

Issue viii was solved in the final design by the "spikes" in the head and tail sections (see Figure 3). These also help with issue i. The remaining issues were solved primarily by trial and error.

Figure 6 shows a selection of previous iterations of the design, illustrating some of these problems and how they were solved. Design (a) was ineffective because weak bonds formed only rarely. This is because the pucks have to be fairly specifically oriented with respect to one another in order for the weak bond magnets to come in range of each other. Additionally, the weak bond magnet of an 'A' type monomer can bond strongly to the tail magnet of another monomer, blocking catalysis. These two problems are solved in design (b) by making the weak bond protrude from the body of the puck, and by re-designing the strong bond so that the magnets are recessed away from the puck's edge. However, it is relatively easy for strong bonds to form spontaneously in this design, and they can also be catalysed by the edge of the table. The spikes added to the strong bonds in design (c) help to prevent spontaneous strong-bond formation, but they also interfere with the catalysis mechanism. This design also features a 'hump' on the opposite side to the weak bond; this is to prevent the edge of the table from catalysing bonds. Design (d) is the first to feature a weak bond that is designed to pivot around a particular point, with a correspondingly curved set of strong bond constraints. However, strong bonds can still form spontaneously quite easily, and weak bond formation is relatively rare.

Design (e) has a strong bond that is held together using repulsion rather than attraction (hence the head and tail magnets are of the same polarity). Unfortunately this tends to result in the magnets jumping off the table to stack on top of one another, since this is energetically preferable to being near one another in a repulsive configuration. The weak bonds have also been re-designed to be easier to form. Design (f) is similar but uses attracting magnets again; its main problems are that strand separation is very slow, and spontaneous strong bond formation is still an issue. Design (g) is the first to feature a mechanism to break one of the weak bonds when a strong bond is catalysed (two dimers cannot fit together in such a way that they are joined at both weak bonds). However, the spontaneous formation of strong bonds is still an issue, as is the formation of unwanted bonds between the weak and strong bond magnets. Design (h) uses Velcro rather than magnets for the strong bonds in an attempt to solve these issues. This idea was discarded because Velcro produces a loose joint, which means the strong bonds do not align accurately enough for catalysis to take place. However, we realised in testing this design that making the lock-and-key structures on the strong bonds wider helps to prevent spontaneous strong bond formation.

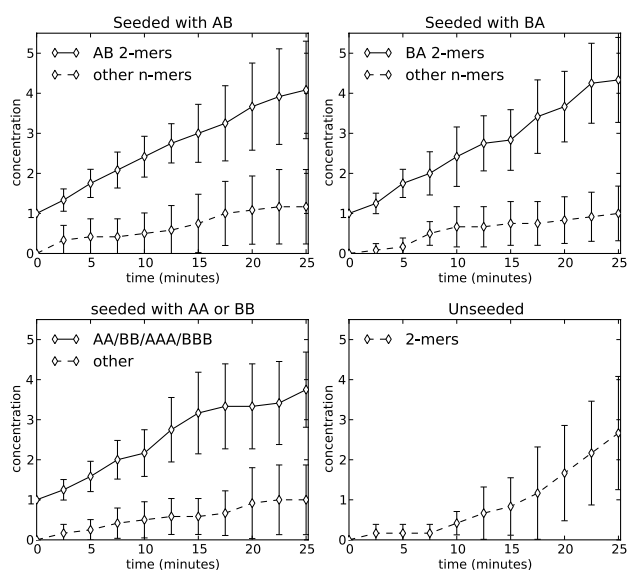

Design (i) is close to the final design and works fairly effectively. Its two remaining problems are that unwanted weak-strong bonds can form (although they are quite weak), and monomers can be attracted together by the strong bond magnets in such a way that a strong bond can form if they are nudged in the right way. These problems are solved in the final design by the addition of the central head and tail spikes (see figure 1), and by making the other spikes a lot larger.

We produced a total of 14 monomers, seven of type 'A' and seven of type 'B'. A total of 48 experiments were performed with the final design, each lasting 25 minutes. 36 of these were seeded trials, meaning that one dimer was added to a system containing the remaining 12 monomers. The system is allowed to run for a few minutes before adding the dimer, to ensure that the initial conditions do not affect the outcome. After the dimer was added we counted the number of each type of polymer every 2.5 minutes.

Of the 36 seeded trials, 12 were seeded with an 'AB' type dimer, 12 with type 'BA', 6 with type 'AA' and 6 with type 'BB'. Since 'AA' and 'BB' are two phases of the same

**Figure 7:** Photographs showing one round of the self-replication cycle. (a) An 'AB' dimer (circled) is placed into a system containing 6 'A' monomers (with white-topped sails) and 6 'B' monomers (black-topped sails). (b) A 'B' monomer joins to the 'A' part of the dimer via a weak bond. (c) An 'A' monomer joins via a weak bond to the 'B' part of the dimer, and its head constraints interlock slightly with the other monomer's tail constraints. (d) A collision with the table's edge or another molecule pushes the two monomers together, so that they form a strong bond. This breaks one of the two weak bonds. Note that both dimers are of type 'AB'. (e) Further collisions break the remaining weak bond, and the two strands separate. This completes the autocatalytic cycle.

**Figure 8:** Time series plots showing the results of letting the system run for 25 minutes, seeded with one dimer of a particular type, or with no dimer. In this plot, all polymers apart from those of the seed type are lumped into a single category. In the case of the trials seeded with AA or BB, we count AA, BB, AAA and BBB as a single category, since these can all be produced by the catalysis process from the seed type. Each plot shows the average over 12 trials. The error bars show a 95% confidence interval.

replicator, the latter two are plotted below as a single set of 12 trials.

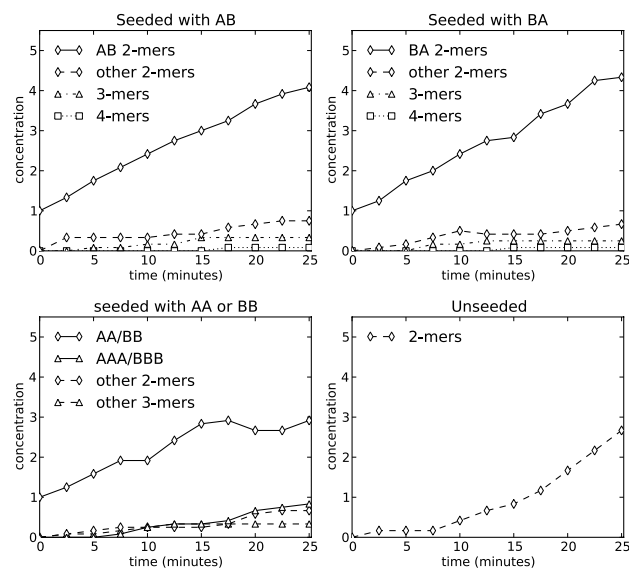

The control experiment involves initializing the system with seven 'A' type monomers and seven 'B' type ones, and is again run for 25 minutes. 12 such experiments were conducted.

## Results

The results are summarised below and in Figures 8 and 9. We count as a side reaction the production of any oligomer other than the seed type. In the AA/BB case we count AAA and BBB as copies of the original rather than as side-products, because there is no mechanism to prevent the formation of these 3-mers, and because they can still catalyse the production of new BB or AA dimers.

In 19 out of the 36 seeded trials, no side reactions took place during the 25 minutes of the trial. In these successful trials, an average of 4.3 duplicates (or, in the AA/BB case, elongations) of the seed were created in addition to the seed itself. The maximum possible number of copies is 6 in the AB or BA case, or 5 in the AA/BB case, with a miss-matched pair of monomers left over. This best-case performance was achieved in four of the trials.

In the remaining 17 seeded trials a side reaction produced an oligomer of a different species from the seed. In some trials this did not substantially disrupt the replication of the seed, but in others, particularly if the side reaction happened early in the trial, the side product produced more replicates than the seed dimer, effectively out-competing it by using up

**Figure 9:** Time series data from the same trials as Figure 8, with the reaction products split up by length. Note in particular the drop in concentration of AA and BB dimers towards the end of the trial as they are converted into AAA and BBB via elongation at staggered ends. (Error bars are omitted because they would be overlapping)

the monomer supply. Under some circumstances it is also possible for the side product to join to a dimer of the seed type in a staggered fashion (as in Figure 5), catalysing its elongation into a different species. For these reasons the mean number of duplicates of the seed after 25 minutes was only 1.7 in the 17 trials where side reactions occurred, or 3.1 over all 36 seeded trials. In four out of the 12 unseeded trials there were no side reactions, meaning that only monomers were present after 25 minutes. Over all 12 unseeded trials, an average of 2.7 oligomers were produced, of various species.

Time series data are shown in Figures 8 and 9, averaged over each of the four sets of 12 trials. In figure 8 all the side reaction products are lumped into a single category. The error bars show that the domination of duplicates of the seed over all other species is statistically significant to within a 95% confidence interval at every time step.

## Conclusions

The hexanucleotide replicator of von Kiedrowski was not evolvable because no mutant of the original sequence was capable of self-replication. Furthermore the ends of the molecules were blocked so that elongation was impossible. Breivik's model was not evolvable for the opposite reason; there was too much spontaneous generation and an elongation catastrophe. Here we have shown a way to achieve something in between, that at least has the potential for evolvability.

There is no doubt that the elongation catastrophe will be faced in all nanoscale self-replicating systems as well. Of-course, technology may allow such problems to be solved

somewhat trivially if monomers are allowed to contain switchable electromagnetic bonds (Groß, Küchler et al. 2009) and can implement a finite state machine (Griffith, Goldwater et al. 2005) thus avoiding issues of product inhibition and mismatching by simply allowing bonds to be arbitrarily made or formed based on perfect local information. However, this arbitrary programmability limits their utility in providing insight into possible molecular mechanisms of non-enzymatic template replication that depend on carefully evolved steric and force constraints, which is one of our main motivations here.

Of course, real molecular systems happen on vastly different spatial and temporal scales: our system has 14 monomers whereas a small chemical system might have  $10^{20}$ . In chemical systems interactions might occur only in a tiny majority of collisions, which we had to avoid in our experiments as it would have made the time scale too long. Nevertheless we believe the insights we have gained are useful.

The implication for the origin of life is that it is possible to produce monomers that self-limit to some extent the lengths of strands that can be self-assembled according to the mechanisms shown in Figure 5. It may be the case that such primitive methods may have been among the first evolved to combat the elongation catastrophe. The production of this physical model has (at least for us) been helpful as E.F. Moore said it would be.

## Acknowledgements

The work was funded by the E-FLUX FP7 EU Grant. Many thanks to Simon McGregor, Chris Buckley and Eors Szathmáry for critical discussion. Roderich Gross and Francesco Mondada were instrumental in suggesting to us the possibility of using air-hockey and fans for creating a stochastic environment. Jarle Breivik and Guenter von Kiedrowski's work was the great inspiration for this project.

## Abstract

This note reviews a bio-inspired scheme for aggregating autonomous agents in the absence of global communication or coordination, a problem that is known as *Decentralized Gathering*. We present results on the clustering behavior of the agents, as we vary the main parameter that controls the agents' aggregation. Our observations show that there exist two phenomenologically different behaviors, characterized by two different evolutions of the number of clusters with time. We relate these different behaviors to the coupling of two factors: a change in the scale of the interaction range of the agents and a change in the significance of the local fluctuations in the model.

## Introduction

Assume that a large number of autonomous and *identical* agents are scattered on a plane, and that there is no global authority to coordinate their actions nor any means of global communication. The problem of gathering these agents in a small area is known as the Decentralized Gathering. This problem is known to be difficult in general and is even be impossible to solve exactly in some continuous space frameworks (Prencipe (2007)).

One approach to solving the decentralized gathering problem consists of imitating the behavior of the amoebae species *Dictyostelium discoideum* (Fatès (2010)). The main characteristic of this approach is the existence of an *active* environment that conveys simple messages among the agents, which are called *virtual amoebae*. The agents interact with the environment by either initiating the transmission of a message or by detecting the existence of messages in their local environment. These two types of interaction are the building components for a stigmergic behavior.

The virtual amoebae aggregation scheme has been shown to exhibit a rich dynamical behavior (Fatès (2010); Vlassopoulos and Fatès (2010)) and to be robust. In this note, we focus on a Cellular Automaton-based (CA) instance of the aggregation scheme, as it has been described in (Fatès, 2010), and present a qualitative description of the two contrasting, clustering behaviors that can be observed in the model. As we will describe, these behaviors result from a

change of scale on the interactions among the agents, from short-ranged to long-ranged. Interestingly, the aggregation behavior persists despite this change of scale.

## Virtual Amoebae Aggregation Scheme

### Active Environment

The existence of an active environment simplifies the agent behavior, by delegating parts of its complexity to the environment and allows for “self-sustained” messages, that can travel arbitrary large distances. The active environment is modeled with a two-dimensional Greenberg Hastings reaction-diffusion cellular automaton (GHCA, see Greenberg et al. (1978)). The CA consists of an array of cells of dimensions  $L \times L$ , a set of cell states,  $\Sigma$ , a set of transition rules for the states and, for each cell, a set of cells that constitute its neighborhood  $\mathcal{N}_c$ .

In the GHCA,  $\Sigma = \{M, \dots, 0\}$ , where  $M$  is called the *excited* state,  $M - 1, \dots, 1$  are called the *refractory* states and 0 is the *neutral* state. A cell becomes excited only if it is neutral and if at least one of its neighboring cells is excited. An excited cell will become refractory in the next time step and then decrease its state until it reaches the neutral state. The dynamics of the GHCA involve “waves” composed of wavefronts of excited cells followed by refractory cells that extend outwards from an excitation. Most importantly, when two reaction-diffusion wavefronts meet, they annihilate.

### Agents

For simplicity, we consider agents as particles that can read the states of the cell on which they reside as well as the state of the neighboring cells. The virtual amoebae behavior is then summarized as follows: If the state of the cell where an agent resides is 0 (neutral), then, at each time step, the agent initiates (“fires”) a reaction-diffusion process with probability  $\lambda$ , by setting the state of the cell to  $M$ . If the cell is neutral and an excited neighbor is detected, the agent moves towards the excited neighbor, choosing randomly if more than one are excited. Otherwise, if the cell is in a refractory state, do nothing. Here,  $\lambda$ , the *firing rate*, is the most important parameter of the aggregation model. In our study, each cell

can hold at most two agents. Increasing the cell capacity affects mainly the spatial dimensions of the clusters and, for high values of  $\lambda$ , the aggregation time. Figure 1 shows the aggregation process for two different values of  $\lambda$ .

One may thus wonder what is causing the agents to aggregate in both cases, where we see a completely different quantitative behavior. A partial answer to this question is: the presence of fluctuations, both in terms of the density and in terms of emission of reaction diffusion waves.

## Clustering Behavior

In a previous work (Vlassopoulos and Fatès (2010)) we have shown that there exists an optimal value of  $\lambda$  such that the aggregation time is minimized. The two different clustering behaviors became apparent while studying the aggregation properties of the model (Fig. 1). In both cases, the agents, given a sufficient amount of time, will aggregate to a single cluster, but as we can observe, this is accomplished by exhibiting two completely different sequences of intermediate macroscopic configurations. In the second (bottom) figure, where  $\lambda$  is large enough, we observe that the agents form small clusters that progressively merge into bigger ones. This process continues until there are a few large clusters that persist for a relatively large amount of time before merging into a single one. However, in the first (top) figure we can observe that the agents “collapse” into a single cluster, without going through the formation of intermediate, persisting, clusters.

From our experiments so far, we have observed that this transition, i.e. from (A) the formation of competing clusters and progressive merging into a single one to (B) the “collapse” of the agents into a single cluster, and inversely, appears to be continuous. One important remark is that high values of  $\lambda$  favor small-range interactions among the agents, in the sense that the distance a wave will manage to travel, and consequently, the number of agents it will manage to interact with, before it is annihilated by the presence of other waves in the environment decreases as  $\lambda$  increases. Accordingly, small values of  $\lambda$  will allow a wave to travel larger distances and interact with more agents before it is annihilated, and therefore can be considered as larger-range interactions. To sum up, the aggregation process persists, in spite of the scale changes and the different macroscopic behavior that results from these changes.

## Fluctuations as a Source of Order?

What is the “driving force” of aggregation in the different scales we described? The common denominators that “destabilize” persisting clusters and cause agents to collapse in both behaviors are the fluctuations, in terms of density and in terms of emissions. The density fluctuations exist even for very small values of  $\lambda$ , but in this case, where the interaction wavelengths are greater than the grid size, they are not significant and the agents aggregate into one cluster. For

Figure 1: Aggregation instances for different values of  $\lambda$ . Top:  $\lambda = 1 \cdot 10^{-5}$  Bottom:  $\lambda = 8 \cdot 10^{-2}$ . Agents are shown with green and the reaction diffusion wavefronts with orange. The initial number of agents is 400.

high values of  $\lambda$  they become important and are the main reason for the generation of the initial small local clusters that will subsequently merge, until only one cluster remains, but also one of the reasons that cause cluster to merge, since that out of two clusters with (sufficiently) different number of amoebae, we expect that the larger one will emit more waves, in average. The fluctuations in the emission times are the driving force that causes the clusters to merge, for both small and large values of  $\lambda$ . However, it is interesting that we observe the same effective behavior of the system in different scales. More precisely, the same “forces” that cause two amoebae to merge into a cluster, will cause two clusters to merge into a larger one and so on, until only one cluster exists. The merging behavior seems to be similar at different scales, which leaves us with the question: are there quantities that are invariant with respect to rescaling?

To conclude, we described a bio-inspired model that shows how it is possible to exploit the presence of fluctuations in a constructive way, in order to drive a system to a desired final state. The existence of an active environment simplifies the overall model design, but also increases the significance of fluctuations, that constitute a major factor to the operation and robustness of the model.

## Abstract

Spatial aggregation of animal groups give individuals many benefits that they would not be able to obtain otherwise. One of the key questions in the study of these animal groups, or “swarms”, concerns the way in which information is propagated through the group. In this paper, we examine this propagation using an information-theoretic framework of distributed computation. Swarm dynamics is interpreted as a type of distributed computation. Two localized information-theoretic measures (active information storage and transfer entropy) are adapted to the task of tracing the information dynamics in a kinematic context. The observed types of swarm dynamics, as well as transitions among these types, are shown to coincide with well-marked local and global optima of the proposed measures. Specifically, active information storage tends to maximize as the swarm is becoming less fragmented and the kinematic history begins to strongly inform an observer about the next state. The peak of transfer entropy is observed to appear at the final stages of merging of swarm fragments, near the “edge of chaos” where the system actively computes its next stable configuration. Both measures tend to minimize for either unstable or static swarm configurations. The results here show these measures can be applied to non-trivial models, most importantly, they can tell us about the dynamics within these model where we can not rely on visual intuitions.

## Introduction

There are many examples of spatial aggregation in animal groups in nature including schools of fish, swarms of locusts, herds of wildebeest, and flocks of birds (Lissaman and Shollenberger, 1970; Parrish and Edelstein-Keshet, 1999; Sinclair and Norton-Griffiths, 1979; Uvarov, 1928). Such aggregations give group members the benefit of protection, mate choice, and information that an individual might not be aware of on its own such as the location of a food source, predator, or migratory route (Camazine et al., 2003; Partridge, 1982). There is considerable evidence in many species that individuals can only perceive their neighbors rather than the entire group (Camazine et al., 2003). Typically, these groups are referred to as self-organized since they form without any centralized control.

In self-organized groups, complex large-scale patterns and structures emerge through individual decisions based on

perception of local conditions. For example, in response to a predator, many schools of fish display complex collective patterns of motion, including compression, vacuole, flash expansion, milling, or form highly parallel translating groups (Parrish et al., 2002).

The key questions in the study of swarms and “swarm intelligence” concern how the local interactions map to the large-scale behavior. Finding answers to some of these questions has broad implications in ecological and artificial systems. The way in which information is propagated in animal groups is poorly understood (Couzin et al., 2006). Recently, there has been some effort to understand this transfer of information. Couzin et al. (2006) depict schooling of fish as a type of distributed information processing. The authors refer to the collective memory of the school, and describe a wave of turning (triggered by a small number of fish reacting to some sensory information) as “information cascades” spreading across the school. The authors comment that such mechanisms can transmit information at a speed faster than that of an incoming predator, with such computational capability providing an evolutionary advantage.

Conjectures also relate known phase transitions in flocking or schooling behavior to the underlying information dynamics of the computations they are carrying out. Miramontes (1995) describes phase transitions in the maximization of activation levels in ant foraging behavior with respect to ant density, and suggests that this is reflected in maximization of information transfer between the ants. In a similar vein, Couzin (2007) describes the phase transition of effective flocking behavior occurring only at intermediate sensory ranges between individual agents in terms of the capacity for information transfer that the sensory range allows: too short a sensory range does not allow enough information transfer to form cohesive groups; too large a range permits rampant spreading of irrelevant information which erodes group cohesion. These notions are very similar to the generic descriptions of the information dynamics of order-chaos phase transitions under the “edge of chaos” hypothesis (e.g. see Langton (1990)).

In this paper, we examine the propagation of information

in swarms using a recent framework that characterizes the information dynamics of distributed computation in terms of the elements of Turing universal computation (Lizier et al., 2008b, 2010, 2011, 2007). In particular we seek to measure how much information is stored, and how much information is transferred to and by each agent in the swarm at each time step. The information dynamics of distributed computation have recently emerged as an important tool for studying complex systems, such as cellular automata (CAs) (Lizier et al., 2007, 2008b) and random Boolean networks (RBNs) (Lizier et al., 2008a). This approach has quantitatively identified the coherent structures known as “gliders” as the dominant information transfer agents in CAs.

We note that the dynamics of animal groups can be seen as a type of distributed computation. As we will show, at each time step, each agent “computes” its new state as a function of its previous state and the relative states of each of its neighbors. In this way, information relevant to that computation can be stored in regular patterns of behavior, transferred from the relative state of each neighbor, and processed when an agent combines the effects of multiple sources together.

We begin this paper with an overview of the swarm model and the information dynamics framework. This is followed by discussion on how we applied the information dynamics framework to swarms, introducing specific techniques to handle the *amorphous* computational structure and measure state transitions using relative variables. Finally, the results are shown and discussed.

### Three Zone Model for Swarms

There are two methodologies for modeling and simulating aggregations of discrete individuals. Individual-based or agent-based models are discrete-time models that update individual positions and velocities based on positions and velocities at the previous discrete time-step. Particle models capture swarm dynamics as a coupled system of ordinary differential equations. Individual-based and particle models can be nearly equivalent if they are designed consistently and if the step size of the individual-based model is taken to be small. Regardless of the methodology, the interactions between individuals drive the dynamics of the model. A common behavioral model for swarms is to have each individual respond to neighbors in three concentric zones that are used to define the behavioral rules of motion (Aoki, 1982; Couzin et al., 2002; Huth and Wissel, 1992; Lukeman et al., 2010; Vicsek et al., 1995). The individual responds differently to neighbors in each of the three zones through repulsion, orientation, or attraction, respectively. An individual moves away from neighbors in the zone of repulsion, aligns its velocity with that of neighbors in the zone of orientation, and moves toward neighbors in the zone of attraction.

In the models featured in this study, we use continuous kernels to define the zones which describe individual behavior with smooth transitions from one type of movement

Figure 1: Normalized amplitudes of the social interaction kernels.

to another (see (Miller et al., 2011)). One of the advantages of this model is that it can be scaled up to a continuum limit where there are infinitely many individuals expressed through a density function and a velocity field. The dynamics of the system is governed by a system of partial differential equations which we can analyze using tools that are not available to discrete models. While our kernels do not have compact support, exponential decay guarantees that individual behavior is dominated by nearby neighbors; similarly, interactions with distant members is exponentially small. The three responses are combined to determine the desired velocity  $\vec{v}_d$ . For a reference individual  $i$ , we define the displacement vector  $\vec{s}_{ij} = \vec{s}_j - \vec{s}_i$ , where  $\vec{s}$  is the individual’s position. The behavioral input vector is then  $\vec{v}_d = \vec{v}_{r,i} + \vec{v}_{o,i} + c_a \vec{v}_{a,i}$ :

$$\vec{v}_{r,i} = \sum_{j=1}^N -\frac{1}{8\pi\sigma_1^4} \vec{s}_{ij} \exp(-|\vec{s}_{ij}|^2/4\sigma_1^2), \quad (1)$$

$$\vec{v}_{o,i} = \frac{\sum_{j=1}^N \frac{1}{4\pi\sigma_2^2} \exp(-|\vec{s}_{ij}|^2/4\sigma_2^2) \vec{v}_j}{\sum_{j=1}^N \frac{1}{4\pi\sigma_2^2} \exp(-|\vec{s}_{ij}|^2/4\sigma_2^2)}, \quad (2)$$

$$\vec{v}_{a,i} = \sum_{j=1}^N \frac{1}{64\pi\sigma_3^6} \vec{s}_{ij} |\vec{s}_{ij}|^2 \exp(-|\vec{s}_{ij}|^2/4\sigma_3^2), \quad (3)$$

where  $c_a$  specifies the relative importance of attraction to orientation and repulsion and  $\sigma_k$ ,  $k = \{1, 2, 3\}$ , are constants that control the sizes of the zones. A cross section of the amplitude of these kernels is shown in Figure 1. The behavioral input vector is used in different ways to control the change in velocity. Once the velocity has been determined, the positions are updated accordingly.

We examined the information transfer in two different second order models. Our variable speed model updates the velocity by setting

$$\vec{v}_i^{n+1} = \vec{v}_i^n + \delta\tau \cdot \kappa (\vec{v}_{d,i}^n - \vec{v}_i^n) \quad (4)$$

where  $\delta\tau$  is the time step length and  $\kappa$  is the turning rate. The constant (unit) speed model updates the direction  $\theta_i$  by

$$\theta_i^{n+1} = \theta_i^n + \delta\tau \cdot \kappa (\vec{v}_i^n)^\perp \cdot \vec{v}_{d,i}^n, \quad (5)$$

Figure 2: Information dynamics in a distributed network. For node  $Q$ , this figure displays the local active information  $a_Q(n+1, k)$  and the local transfer entropies  $t_{Z_1 \rightarrow Q}(n+1)$  and  $t_{Z_2 \rightarrow Q}(n+1)$  from each of the causal information sources  $\mathbf{Z}_Q \in \{Z_1, Z_2\}$  at time  $n+1$ .

where

$$(\vec{v}_i^n) = [\cos \theta_i^n, \sin \theta_i^n]^T, \quad (6)$$

$$(\vec{v}_i^n)^\perp = [-\sin \theta_i^n, \cos \theta_i^n]^T. \quad (7)$$

It has been shown that for  $c_a > 1$ , uniform infinite swarms are linearly unstable (Miller et al., 2011). Finite groups that are initialized on a square lattice reorganize into an attractor when  $c_a > 1$ . For the variable-speed model, this attractor is circular with a variable density. In the constant-speed model, the attractor is anisotropic as well as variable density.

### Information Dynamics

Information theory (MacKay, 2003) has been well used in complex systems (Langton, 1990; Miramontes, 1995; Schreiber, 2000), and is the natural domain to look for a framework to describe the information dynamics here. Lizier et al. (2007, 2008b, 2010, 2011) have proposed such a framework for local information dynamics, describing distributed computation in terms of information storage, transfer and modification at each spatiotemporal point in a complex system. In this paper, we focus on the first two terms.

The **information storage** of an agent in the system is the amount of information in its past that is relevant to predicting its future. We will compute the *active information storage* (AIS) component, which is the stored information that is currently in use in computing the next state of the agent (Lizier et al., 2011, 2007). We focus on the active information since it yields an immediate contrast in the relative contributions of storage and transfer to each computation. As shown in Fig. 2, the *local active information storage* for agent  $Q$  is defined as the local (or unaveraged) mutual information between its semi-infinite past  $q_n^{(k)}$  (as  $k \rightarrow \infty$ ) and its next state  $q_{n+1}$  at time step  $n+1$ :

$$a_Q(n+1) = \lim_{k \rightarrow \infty} \log_2 \frac{p(q_n^{(k)}, q_{n+1})}{p(q_n^{(k)})p(q_{n+1})}, \quad (8)$$

with  $a_Q(n, k)$  representing an approximation with finite history length  $k$ . The *active information* is the average over time (or equivalently weighted by the distribution of  $(q_n^{(k)}, q_{n+1})$ ):  $A_Q(k) = \langle a_Q(n, k) \rangle$ . From our computational perspective, an agent can store information regardless of whether it is causally connected with itself. This is because information storage can be facilitated in a distributed fashion via one's neighbors (Lizier et al., 2011).

The **information transfer** between a source and a destination agent is defined as the information provided by the source about the destination's next state that was not contained in the past of the destination. The information transfer is formulated in the *transfer entropy* (TE), introduced by Schreiber (2000) to address concerns that the mutual information (as a de facto measure of information transfer) was a symmetric measure of statically shared information. The *local transfer entropy* (Lizier et al., 2008b) from a source agent  $Z$  to a destination agent  $Q$  is the local mutual information between the previous state of the source  $z_n$  and the next state of the destination  $q_{n+1}$ , *conditioned* on the semi-infinite past of the destination  $q_n^{(k)}$  (as  $k \rightarrow \infty$ ):

$$t_{Z \rightarrow Q}(n+1) = \lim_{k \rightarrow \infty} \log_2 \frac{p(q_{n+1}|q_n^{(k)}, z_n)}{p(q_{n+1}|q_n^{(k)})}. \quad (9)$$

Again,  $t_{Z \rightarrow Q}(n, k)$  represents finite- $k$  approximation, and the *transfer entropy* is the (time or distribution) average:  $T_{Z \rightarrow Q}(k) = \langle t_{Z \rightarrow Q}(n, k) \rangle$ . A schema representation of the process to compute the local transfer entropy is shown in Fig. 2. Importantly, the transfer entropy properly measures a directed, dynamic flow of information, unlike mutual information measures which measure correlations only. Note that one can also condition the TE on another information contributor  $W$  to form the *conditional transfer entropy* (Lizier et al., 2010):

$$t_{Z \rightarrow Q|W}(n+1) = \lim_{k \rightarrow \infty} \log_2 \frac{p(q_{n+1}|q_n^{(k)}, w_n, z_n)}{p(q_{n+1}|q_n^{(k)}, w_n)}. \quad (10)$$

### Information Dynamics in Swarms

To apply the information dynamics framework to swarm models, we will need to make two important modifications to the use of Eq. (8) and Eq. (9).

**Accumulation of observations across agents:** In CAs, the probability distribution functions in Eq. (9) for the transfer entropy from agent  $Z_i$  to  $Q_{i+1}$  are estimated over observations from all agent pairs for the corresponding transfer channel (e.g. across one cell to the right per unit time step): the agents there were completely *homogeneous* in connectivity pattern and function. In RBNs, the probability distribution functions of Eq. (9) were estimated at single causal pairs  $Q$  and  $Z$  only, since the agents were *heterogeneous* in connectivity pattern and function.

In contrast to both of these applications, swarm computation is *amorphous*, with neither homogeneous computational structure across agents, nor with fixed computational relationships between heterogeneous causal pairs. That is, the causal relationships between agents change too rapidly to reliably estimate the probability distribution functions on any transient single causal pair. A pair of particles,  $p_1$  and  $p_2$ , could be close enough for a causal interaction at one time step, but move outside the interaction zones at next step. Therefore, calculating information transfer between single causal pairs over all time would not give us a good representation of the actual information within the system.

Helpfully, swarm models exhibit homogeneously *functional* agents, and so we can accumulate observations for the probability distribution functions in Eq. (9) from *every* transient causal interaction. That is, one adds individual causal interactions between many different agent pairs to the set of observations, without requiring any one of those agent pairs to maintain a causal relationship over all time steps. When one particle  $p_i$  is within proximity to have a causal effect over another particle  $p_j$ , their interaction is counted for the information-theoretic probability distribution functions, but when  $p_i$  is outside causal range of  $p_j$ , no observation is recorded. These probability distribution functions can then be applied to compute the local apparent transfer entropy between two different particles  $p_k$  and  $p_l$  which are causally connected at a different time step, because of the *homogeneous* nature of the *functionality* of each agent.

#### Measuring state transitions with relative variables:

Continuing the idea of accumulating observations over comparable interactions, we note that if two pairs of particles have the exact same *relative* positions and velocities, but have different *absolute* positions and headings, then the information dynamics of the two pairs should be the same. As such, we will focus our measurements on the computation of the *change* in velocity of the destination agent at each time step. Not only does this remain in the spirit of the original formulation of the transfer entropy by Schreiber (2000) (considering how much information a source adds about the state *transition* of the destination), but focuses directly on the causal relationship between particles (since a velocity change is computed rather than an absolute velocity).

Let  $p'$  be a particle that is within another particle  $p$ 's zones of interaction, so  $p$  and  $p'$  form a causal pair. Our aim is to find what influence does  $p'$  have on  $p$ . To reiterate,  $\vec{s}^n$  is the position and  $\vec{v}^n$  is the velocity at time  $n$ . The relevant variables for the conditional transfer entropy in Eq. (10) are:

$$z_n = \{\vec{s}_p^n - \vec{s}_{p'}^n, \vec{v}_p^n - \vec{v}_{p'}^n\}, \quad (11)$$

$$w_n = |\vec{v}|^n, \quad (12)$$

$$q_n^{(k)} = \vec{v}_p^n - \vec{v}_p^{n-1}, \quad (13)$$

$$q_{n+1} = \vec{v}_p^{n+1} - \vec{v}_p^n. \quad (14)$$

In other words:

- the source variable is the relative positions and velocities between the particles at time step  $n$ ;
- we condition the transfer on the speed of  $p$ ,  $|\vec{v}|^n$  at  $n$ ;
- the past state of the destination is the change in velocity of  $p$  at time step  $n$ ; this means we use  $k = 1$  due to the finite number of observations;
- and the destination variable next state is the change in velocity of  $p$  at  $n + 1$ .

Note that the destination past, next state and conditioned variables contain all of the relevant information about the state update  $q_{n+1}|q_n^{(k)}, w_n$  of the destination variable, from the perspective (or relative frame of reference) of  $p$  itself. The relative positional information at any time step (including the next step  $n + 1$ ) is then obtainable using the change in velocity terms. Given these destination variables, note that the source variable captures all relevant information from  $p'$  about the state transition of the destination.

Importantly,  $|\vec{v}|^n$  is included here since the absolute velocity of the particle may have some indirect influence on the change in state (e.g. by influencing how often the source and destination have recently interacted). We could additionally include  $|\vec{v}|^{n+1}$  in the next state  $q_{n+1}$  (then absorbing  $|\vec{v}|^n$  into  $q_n^{(k)}$  also to make a calculation of an ordinary transfer entropy here); however this ties the tuple  $(z_n, q_n^{(k)}, q_{n+1})$  to the absolute heading of  $p$ , removing the advantage of accumulating observations over comparable interactions that we had gained from the use of relative variables.

In this manner, the local conditional transfer entropy can be estimated for each transient causal relationship. Similarly, the local active information can be estimated from the destination and history of destination variables of each particle interaction. Agents in a swarm can be seen to use *stored* information when their behaviour is predictable from their own past (in isolation from other agents), and to *transfer* information in the way that their relative positions and velocities influence changes in velocity in other agents.

## Results

We applied the framework to swarm simulation with the particles initially in 3 squares in a checker configuration. Each initial square has  $28 \times 28$  particles, and thus we have a total of 2352 particles in the system. Fig. 8(a) shows a configuration close to the swarm's initial positions.

As discussed in earlier section, two different second order swarm models were used: variable speed and constant speed. As discussed earlier, for  $c_a > 1$ , swarms evolve into coherent attractors, here we set  $c_a = 5$  (Miller et al., 2011). We run the models until the swarms reach a steady state, that is, the shapes of the swarms do not change much. At this point, information transfer approaches zero and the computation can be seen as complete. Measuring the information dynamics during this transient period means that we are studying the computation of the swarm's steady state.

Figure 3: Total active information storage and information transfer over time for variable speed model. The values are averaged over 1000 repeated experiments, where each experiment randomly picked around 0.005% of the total interactions.

Figure 4: Average active information storage per particle and average information transfer per particle pair interaction over time for variable speed model.

The swarms reach a steady state at the time  $\tau < 100$  for variable speed model and  $\tau < 150$  for constant speed model. We used a step size of  $\delta\tau = 0.1$  (sufficient for resolving the dynamics of the swarms) and hence gather data for 1000 steps for variable speed model, and 1500 steps for constant speed model. At every step, each particle has on average several hundred neighbors within its zones of interaction, this means the total number of interactions is in the order of  $1 \times 10^9$ , which is much too large for the kernel estimation of  $p$ . Therefore, we randomly picked a fraction of the interactions at each time step for the calculation. We used a frequency of 20000, randomly picking 0.005% of the total interactions at each time step. This gives us approximately  $1 \times 10^5$  data points, thus we used a kernel width of 0.23 for kernel estimation with a normalized kernel. This is repeated 1000 times and the results averaged to give a better representation of the total interactions.

### Second order, variable speed model

Fig. 3 shows the total information storage and transfer at each time step over all time, e.g.  $\sum_Q a_Q(n, k)$ . Note that this is the average total over 1000 repeated experiments, where each experiment randomly picks 1 in 20000 interactions for the calculation. Therefore, the actual value should be 4 orders of magnitude larger than the values shown in this figure. Further, while the transfer values are summed over

all interactions, the storage values are summed over all  $p$ 's in the interactions with each  $p$  counted once.

Fig. 4 shows the average storage per particle and average transfer per interaction at each time step over time. Comparing this with the total information per time step, we can see that the second half of Fig. 4 has smaller magnitude relative to the first half. This shows that for  $\tau > 60$  the number of interactions in the swarm increased. However, the *shapes* of the plots do not differ from those in Fig. 3, which means the change in information dynamics values were not simply due to the change in the number of interactions.

In Fig. 3 we can notice three distinct epochs in the information dynamics of the swarm: (1) between  $\tau = 0$  and  $\sim 20$  where there is a small local maxima in the information dynamics; (2) between  $\tau \sim 20$  and  $\sim 60$  where the values remain low and constant; and finally (3) between  $\tau \sim 60$  and 100 where there were large changes in the values.

Fig. 5 shows some snapshots of key steps during the swarm simulation as identified by Fig. 3. Comparing the two, we can see that the first epoch corresponds to when the three initial squares 'collapse' to form three discs (Fig. 5(a)&(b)); epoch 2 corresponds to the three discs moving but not interacting with each other (Fig. 5(c)); and the final epoch is when the three discs come into contact with each other to form a single swarm (Fig. 5(d)-(j)).

Epoch 3 is the most interesting for the swarm simulation in terms of the resulting information dynamics within the system. Both information values start increasing at around  $\tau = 59.5$  (Fig. 5(d)) when the three separate groups become close enough for the outer particles of each to affect and be affected by those in the other groups.

As the groups merge, the two outer groups move towards the middle group, squeezing the middle one and triggering increases in both storage and transfer. This behavior continued until  $\tau = 75.1$  when the middle group was squeezed to the smallest size it can stand as seen Fig. 5(e), when transfer reaches a local maximum. High local transfer shows that the source is informative about the next state of the destination.

Between  $\tau = 75.1$  and 76.6 (Fig. 5(e)&(f)), the swarm tried to reorganize itself to a more stable configuration. This can be seen from the drop in transfer but rapid increase in storage values until at  $\tau = 76.6$  when the values reach local minimum or global maximum, respectively. High local storage shows the history strongly informs an observer about the next state. Thus, the increase in average storage value per particle as shown in Fig. 4 shows that the particles' velocities are increasingly predictable from their history.

Between  $\tau = 76.7$  and 78.9 (Fig. 5(f)&(g)), the swarm finally merged into one group. Fig. 3 and 4 shows that during this time information storage decreased while transfer increased, indicating a transition to another (more stable) swarm configuration. At  $\tau = 78.9$ , the storage value reaches a local minimum and the transfer value reaches the global maximum. The maximum transfer entropy value shows that

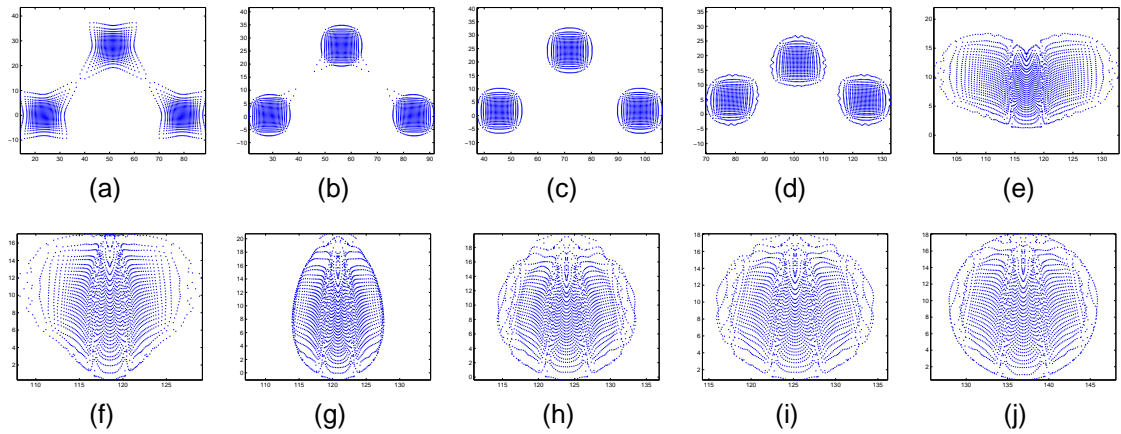

Figure 5: Swarm behavior for variable speed model at 10 different time steps,  $\tau$ : (a) 9.5, (b) 14.4, (c) 30.0, (d) 59.5, (e) 75.1, (f) 76.6, (g) 78.9, (h) 82.0, (i) 83.3, (j) 95.0.

at this point in time, the source agent (the relative position and velocities between particles) are most informative about the next state of  $p$ . Thus, as the swarm is merging into one group, the individual particles are under the most influence from their neighbors.

For  $\tau > 79.0$ , the swarm reorganized itself to find the most stable configuration, which was achieved around  $\tau = 95.0$  (Fig. 5(j)). As the swarm organized itself, both values fluctuate between local optima, while the overall values decrease. Fig. 5(h)&(i) ( $\tau = 82.0$  &  $83.3$ ) show local minimum and maximum in transfer that followed the global maximum. In these plots that the shape of the swarm fluctuates as it tries to find the most stable configuration.

It is also interesting to note that for  $85.8 < \tau < 86.2$ ,  $88.3 < \tau < 89$  and  $89.9 < \tau < 90.5$  the overall transfer entropy value dipped below 0. Negative local transfer entropy indicates that the source misleads an observer about the next state of the destination given the destination's history (Lizier et al., 2008b, 2010). This can occur when large numbers of interactions (e.g. in chaotic systems) can make the effect of any single source misleading when considered on its own. The negative transfer entropies here show that for a few time steps, most of the particles in the swarm had changes in velocity that were relatively unlikely given their relative position and velocity of their neighbors.

### Second order, constant speed model

Fig. 6 shows the total active information storage and information transfer at each time step for constant speed model. We can roughly see the three epochs of swarm dynamics in this plot:  $0 < \tau < 22.0$ ,  $22.0 < \tau < 48.0$ , and  $\tau > 48.0$ ; though the epochs are not as distinctive as those in Fig. 3.

Fig. 7 shows the average storage per particle and average transfer per causal pair at each time step for constant speed model. We can see from the storage plot in this figure that the number of interactions increases in epoch 3, since the average storage in epoch 3 is not much larger than those in

Figure 6: Total active information storage and information transfer at each time step over time for constant speed model.

Figure 7: Average active information storage and information transfer per particle pair interaction over time for constant speed model.

epoch 1, but the total is much larger. For transfer, we can see that average value in epoch 1 is larger than those in epoch 3, which means for this model, there are more interactions with high local transfer entropy when each group of particles is “collapsing” into itself than when the groups are merging. Further, while Fig. 6 shows a definite global maximum in transfer in epoch 3, the average shows very little difference in the per interaction values. This means there are a lot more interactions at  $\tau = 93.2$  (global maximum) than at  $\tau = 58.0$  (the first local maximum in epoch 3).

Fig. 8 shows 10 snapshots of the swarm behavior at key

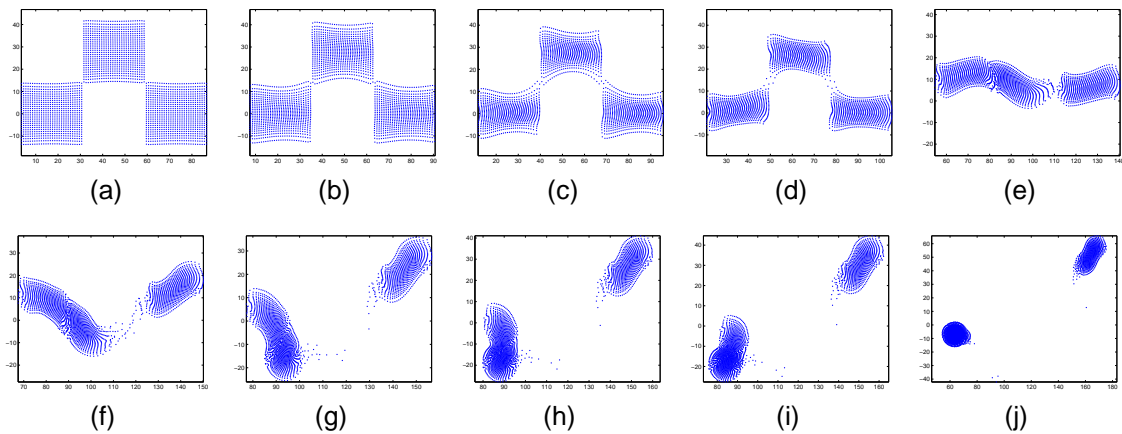

Figure 8: Swarm behavior for constant speed model at 10 different time steps,  $\tau$ : (a) 3.2, (b) 7.4, (c) 12.3, (d) 22.0, (e) 58.0, (f) 71.3, (g) 83.0, (h) 89.0, (i) 93.2, (j) 118.0.

steps as identified by Fig. 6. Fig. 8(a)-(d) shows the swarm during epoch 1, Fig. 8(e)-(i) shows the behavior during epoch 3, and Fig. 8(j) shows the final configuration when the swarm reaches steady state. These snapshots show that when particles have constant speed, the swarm organizes itself into anisotropic attractors as discussed in earlier section. Moreover, the three groups did not ultimately merge into one as in the variable speed model, but stayed as two groups.

Between  $\tau = 0$  and  $\tau = 22.0$ , both values went through a couple of oscillations before finding a steady state for the three groups. This is similar to the behavior of the swarm in variable speed model, as shown in Fig. 3. Fig. 8(a) corresponds to the first transfer local maximum, Fig. 8(b) shows the configuration when both information attain local minimum, and Fig. 8(c) corresponds to the local maximum for the storage value. While the swarm configuration does not differ much, Fig. 6 shows us that the information storage and transfer by the particles were constantly changing as the swarm organized itself.

For  $\tau > 22.0$ , as two of the groups start to merge, the transfer entropy attains the first (in epoch 3) local maximum at  $\tau = 58.0$  (Fig. 8(e)). The local minimum for transfer at  $\tau = 71.3$  is shown in Fig. 8(f), and the next local maximum at  $\tau = 83.0$  is shown in Fig. 8(g). We can see from these two snapshots that during this time the group on the left rotated  $90^\circ$  clockwise. Furthermore, we can still distinguish the two groups. The local storage increases steadily from  $\tau > 22.0$  until at  $\tau = 89.0$  (Fig. 8(h)) it reached the global maximum. At  $\tau = 93.2$  (Fig. 8(i)) the transfer entropy reached the global maximum when the group on the left finally merged into one where we cannot distinguish the boundary between the original two groups. This is similar to the plots in Fig. 3 where the global maximum for storage occurs before the global maximum for transfer.

For  $\tau > 93.2$ , both values of information dynamics decreased steadily until the swarm reaches a steady state at  $\tau = 118.0$  (Fig. 8(j)) where both values are constant.

## Discussion and Conclusions

This study examined information dynamics in swarms, applying a recently developed information-theoretic framework of distributed computation to an established individual-based swarm model. The approach verified our conjecture that swarming dynamics can be interpreted as a type of distributed computation. In particular, we adapted two localized information-theoretic measures (active information storage and transfer entropy) to the task of tracing over time how much information is stored, and how much information is transferred to and by each agent in the swarm. The state variables used in tracing the information content (stored and transferred) were chosen to be velocity and acceleration (i.e., change in velocity) — this means that the information dynamics were traced in a kinematic context. The experiments were carried out with two swarm models (variable speed and constant speed), while gathering and randomly sampling data over long transients.

The swarming dynamics were shown to be capable of exhibiting distinct configurations, including isolated groups of particles with low levels of interactions, groups that were actively merging together, and single merged groups that were retaining stable configurations, with varying degrees of inter-particle interactions. Importantly, these types, as well as transitions among these types, were shown to coincide with well-marked local and global optima of the proposed localized information-theoretic measures. Specifically, active information storage (obtained in terms of kinematics, that is, via velocity-based states) was observed to maximize during re-organization from a more fragmented to a less fragmented non-static configuration. One may argue that such a transition corresponds to an increase of kinematic order as the kinematic history begins to strongly inform an observer about the next state. Active information storage tended to minimize for either disordered/unstable configurations (with chaotic inter-particle interactions) or static con-

figurations (with low degrees of interactions): in either of these cases the kinematic history does not help the observer to predict velocity and acceleration at the next time point.

Transfer entropy, on the other hand, was observed to maximize at final stages of re-organization from more fragmented to a less fragmented non-static configuration. It may be argued that these stages correspond to the “edge of chaos” when the system actively computes its stable configuration, and the inter-particle interactions intensify as well. Transfer entropy was found to be minimal for either static or very unstable configurations (too far into the chaotic regime). Moreover, chaotic dynamics often exhibited negative local transfer entropy indicating that the source misleads the observer about the next state of the destination given the destination’s history — a sign of information modification. A detailed analysis of this aspect is left for future research.

Overall, these observations allowed us to interpret distinct phases of self-organizing swarm dynamics via the elements of distributed computation: storage, transfer, and (eventually) modification of specific kinematic information. This exemplifies once more that the process of self-organization can be described in terms of information dynamics, and makes another step towards a general theory of (guided) self-organization.

## Abstract

Wildlife corridors mitigate against habitat fragmentation by connecting otherwise isolated regions, bringing well-established benefits to conservation both in principle and practice. Populations of large mammals in particular may depend on habitat connectivity, yet conservation managers struggle to optimise corridor designs with the rudimentary information generally available on movement behaviours. We present an agent-based model of jaguars (*Panthera onca*), scaled for fragmented habitat in Belize where proposals already exist for creating a jaguar corridor. We use a least-cost approach to simulate movement paths through alternative possible landscapes. Six different types of corridor and three control conditions differ substantially in their effectiveness at mixing agents across the environment despite relatively little difference in individual welfare. Our best estimates of jaguar movement behaviours suggest that a set of five narrow corridors may out-perform one wide corridor of the same overall area. We discuss the utility of ALife modelling for conservation management.

## Introduction

One of the most obvious effects of our own species on the planet has been the clearing of forests to make way for agriculture. In many parts of the world this means that the natural vegetation that remains tends to be divided into isolated patches (see figure 2 for an illustration) with disruptive consequences for the local wildlife. The establishment and maintenance of “corridors” connecting otherwise isolated areas of habitat have therefore been put forward as important tools in conservation biology (Bennett, 2000; Hilty et al., 2006). The idea of a corridor is to connect local sub-populations into a single meta-population and thereby reduce the risk of local extinctions due to human activity (hunting, land development, etc.) and, more importantly, to improve the species’ long-term survival chances by increasing the size of the gene pool.

Bennett (2000) shows that evidence for the effectiveness of habitat corridors is mixed: they have been more helpful for some species than others. Indeed, habitat fragmentation is itself a concept that depends on the details of the behavioural ecology of the species concerned (consider, for

Figure 1: A jaguar photographed using a stealth camera. Image courtesy of the Jaguar Corridor Initiative, Belize.

example, the difference between a bird and a snail in their ability to move between habitat patches). The current paper puts forward a simulation model to help assess the effectiveness of different corridor policies for the jaguar, *Panthera onca*.

The jaguar (figure 1) is an apex predator that stalks and ambushes its prey. It is the third-largest of the big cats and the largest big cat species in the Western hemisphere. Its range extends from the southern United States to northern Argentina. Jaguars are stealthy and elusive, and thus there is still much we do not know about their behaviour. However, one of the better-studied jaguar populations is in Belize, on the Caribbean coast of Central America. In particular, the Cockscomb Basin Wildlife Sanctuary (CBWS), a 425 square-km reserve in southern Belize, has been a productive jaguar fieldwork site for several decades (Rabinowitz and Nottingham, 1986a; Harmsen et al., 2010b). Biologists working there have been instrumental in setting up the Jaguar Corridor Initiative (Rabinowitz and Zeller, 2010), a cooperative effort between scientists, conservation groups, and regional governments to establish corridors connecting known jaguar populations.

Assessing the usefulness of a corridor initiative is diffi-

cult when we do not fully understand the behaviour of the species involved. Two of us (AW and CPD) are conducting ongoing fieldwork at the CBWS in Belize, but we recognize that data on jaguar numbers and movement, collected through means such as stealth cameras and radio-tracking, will not be sufficient on its own. Such data collection efforts need to be combined with modelling in order to improve our understanding of jaguar behaviour. There has been some recent progress on statistical, data-driven modelling in this regard (see for example the Bayesian approach of Colchero et al., 2011) but we believe there is also utility in the agent-based modelling approach characteristic of work in artificial life.

Agent-based models explicitly represent the behaviours of individual organisms, allowing us to simulate both the interactions between individuals, and those between the individual and the environment (Grimm, 1999). For our purposes, the advantages of these types of models are the ability to integrate individual behaviours with landscape dynamics, to model individual-level adaptive processes such as learning and memory, and to study collective responses to changes in landscape composition. The potential to explore many alternative scenarios also provides distinct advantages over classical ecological models.

Agent-based modelling approaches have been widely used already, of course, under the banners of both artificial life and of ecology, to study the movement of animals through their environments. Examples include Nonaka and Holme's (2007) model of optimal foraging in clumpy environments, Wheeler and de Bourcier's (2010) work on the evolution of territorial signalling, and Hemelrijk's (1998) model of the spatial aspects of dominance hierarchies in chimpanzees.

In constructing a model of jaguars moving around in their habitat and using (or *not* using) corridors, we will need a way to model their decision-making about where to go next. This is an opportunity to integrate the "least-cost modelling" paradigm from landscape ecology (Adriaensen et al., 2003) with the agent-based approach. The idea behind least-cost modelling is simple: it is a species-specific calculation based on the assumption that dispersing organisms are more likely to use a route of least resistance when traversing a landscape. In other words, whenever they are faced with a choice while moving around their spatial network, they will choose the lowest-cost option. Cost estimates are themselves derived from data on how frequently the animals are observed in particular landscape types, and their preference for one type over another in choice tests.

Least-cost modelling techniques are standard in many GIS (Geographical Information System) packages which offer built-in cost and distance functions that allow for rapid model construction (Rayfield et al., 2010). A raster-based grid of the landscape is generated with a cost assigned to each cell that represents the lowest cumulative cost from

that cell to the source cell. This cost is the inverse of the degree of functional connectivity of the landscape according to the species in question (Driezen et al., 2007) and thus the end product of the calculation can be seen as a probability distribution across the landscape describing the likelihood of the animal settling at any given position. Rabinowitz and Zeller (2010) developed an ambitious least-cost model of jaguar dispersal across their entire range in Central and South America.

Validating least-cost models is not easy, however. Driezen et al. (2007) produced one of the only studies to successfully compare the output of least-cost models with empirical data on animal movement. They used statistics on landscape-wide cost values and compared these to real hedgehog paths, constructing and presenting a novel approach to matching empirical movement trajectories with generated least-cost maps. Watkins (2010) demonstrated that this approach could be taken further through integration with agent-based modelling.

The aim of the current project is to build a simple agent-based model of jaguar behaviour, employing a least-cost view of movement, in order to look at how the spatial structure of corridors intended to connect disjoint forest habitats could affect conservation goals. In short, we ask the reader to imagine two separated expanses of forest (as occurs in many locations in Belize) and enough resources to protect a few tens of square kilometres of remnant forest from further disturbance and human development. What would be the best corridor design policy? One wide corridor? Multiple thin corridors? A series of small "islands" between the two forests? How much could we expect of such a corridor once constructed, i.e., what effects would it have on individual welfare and on genetic mixing at the population level? We contend that the answers to these questions will be an emergent function of jaguars' preferences for different landscape types and their territorial interactions with each other.

This work is intended to be the first in a series of increasingly detailed models of jaguar ecology. The integration of real GIS data into the model is beyond the scope of the current study — we think there are basic questions to ask of an abstract model first — but is the logical next step for future models. Basing simulated models in real landscapes can only improve our ability to draw conclusions about system-level behaviours in realistic environments.

## The model

The first step in constructing our model is devising a map layout that reflects the essentials of the problem. Figure 2 shows a typical Belizean landscape and illustrates the fragmentation of forest habitat that occurs due to road construction, tree-clearing for farming, urban development, etc. The key feature of our simulation will thus be two separated blocks of forest, surrounded by cleared farmland. Each forest section will hold an initial population of jaguars; the

Figure 2: An aerial view of a typical landscape in Belize. Note that regions of ideal jaguar habitat (i.e., forest) are separated by roads and cleared farmland. Image: Google Earth.

question is how easy or difficult it will be for them to travel from one forest zone to another.

Figure 3 shows the potential corridor designs that we will investigate. We begin with the basic two-forest layout in the top left corner. Note the blue edges where the forest meets farmland; we assume that these transitional zones are of intermediate appeal to the jaguars. The next design (top centre) features a corridor connecting the two forest sections. We also consider (top right) a layout with additional area added to the forest sections: this is equivalent to a control condition in which we spend the conservation budget on extending each forest rather than connecting them. Next we consider whether corridor width is more or less important than the number of corridors by looking at three- and five-corridor designs. In each case the same total area is devoted to the connecting corridors. These are followed by one- and three-island designs — alternatives to a direct corridor — and a design made up of many randomly placed islands. Again, the total area devoted to corridor is a constant. Finally we also look at a “contiguous forest” layout where the entire map is forested: this is another control condition in that it allows us to compare jaguar ecology in a modern fragmented habitat with what it might have been before human colonization.

The map is not meant to be a precise rendition of any particular location, but we do need to establish a scale in order to incorporate what is known about jaguar population density, movement rates, and territory size (our primary references in this were Schaller and Crawshaw, 1980; Harmsen et al., 2010c). The map is represented as a  $100 \times 100$  grid of squares, with each square being 500 metres on a side. This means that the entire map covers  $50 \times 50$  km, with each of

Figure 3: Map layouts investigated in the simulation. Core forest is in green, forest edges are blue, and farmland is khaki. First row: no corridor, one corridor, no corridor but equivalent area added to the forest. Second row: three corridors, five corridors, one island. Third row: three islands, random islands, contiguous forest.

the basic forest sections measuring  $15 \times 40$  km and with a 10 km expanse of farmland between them. For comparison, the 2500 square km area of the map represents about 10% of the land area of Belize.

In most layouts the map includes 1275 square km of forest (the exceptions are the no corridor layout with 1200 square km and the contiguous forest condition with 2500 square km). Each run of the simulation begins by placing 100 jaguars into randomly chosen forest squares, which corresponds to a density of 7.84 jaguars per 100 square km. This is consistent with Rabinowitz and Nottingham (1986b) who found a minimum home range size of 10 square km per animal, and also with Harmsen et al. (2010c) who estimated densities of 3.5 to 11.0 individuals per 100 square km in the CBWS, which is itself thought to be a “hot spot” for jaguar numbers. Our simulated population of 100 jaguars thus represents a medium to high population density.

Edge effects are known to be important in landscape ecology, and so we added an edge-detecting routine to the initialization of our map. Any forest square that borders a farmland square (in any of 8 neighbouring positions) is labelled as an edge square. These are shown in blue in figure 3.

What about temporal scale? Schaller and Crawshaw (1980) recorded daily travel of between 1 km and 3 km straight-line distance for jaguars, with males travelling further than females. In our model male jaguars move one grid square every timestep; if all eight surrounding squares have equal cost, the movement will be in a random direction. In order to get plausible straight-line daily travel distances

know the exact values that should be plugged in. The point is not to make a precise predictive model but to see whether it is possible to explain the basics of jaguar movement with some simple rules. In this regard, we do have circumstantial evidence: jaguars have occasionally been observed in pastures both in Belize and Brazil, and we know that jaguars are somewhat territorial. If we chose much higher values for the landscape cost of farmland, the jaguars would not leave the forest at all, even under extremely crowded local conditions. Conversely, if we make the cost of encountering another jaguar's pheromone too high, the animals will spill out into the farmland in great numbers in an effort not to encroach on each other's territory.

Our simple pheromone mechanism is actually a reasonable model of how jaguars maintain their territorial boundaries in the real world. Jaguars are not as likely to mark their passage with urine or scat as other felids are (Schaller and Crawshaw, 1980; Harmsen et al., 2010c) but they are known to scent-mark by scraping trees in their territory (Harmsen et al., 2010a).

There is one more cost to be considered: we also made the jaguars sensitive not just to pheromones deposited by others but also to their *own* pheromone trails. The cost of entering a grid square where you were the last occupant is equal to 15% of the pheromone level (i.e., the effect is about 7 times weaker than for the pheromones of others). This reflects the fact that a section of forest where the animal has not hunted recently is a better prospect for prey than the same grid-square they occupied the day before. The effect is to stop the jaguars back-tracking on their own path. A solitary jaguar in a large expanse of forest will therefore perform a random walk strongly biased towards yet-unvisited grid squares, in effect carving out a territory of maximal size for itself.

Unlike much ALife work, there is no genetic algorithm in our model: our central question is not evolutionary but ecological. In the same vein as Hemelrijk (1998) we are not asking about the evolution of the animals' strategies, but about the implications of how a hypothesized behavioural program would play out when followed by multiple animals in a simulated spatial world.

The goal is to use our model of jaguar movement behaviour to evaluate the effectiveness of different corridor layouts — but what can we measure in order to do that? The jaguars' behavioural strategies are not evolving, so we cannot measure “fitness” per se. Instead we look at the average cost level for the grid squares each jaguar chooses to enter over the course of the run. This is effectively a measure of “jaguar welfare”. Low cost grid squares (i.e., what jaguars want) are places in the forest that have not recently been visited by other jaguars. The low cost ultimately reflects the fitness benefits of being in such places: these are areas with high prey availability, low risk of being killed by farmers, low risk of costly fights with other jaguars, etc. Higher val-

ues on the average-cost measure will therefore be associated with stress or over-crowding. If one corridor layout can reduce this value compared to another, this is evidence for its jaguar-conservation effectiveness.

We are not simulating enough detail of the jaguar's lifestyle to look at mating behaviour directly, but we can look indirectly at whether different corridor layouts would encourage a larger breeding population as opposed to isolated sub-populations. We have done this simply by recording the proportion of jaguars that finish the year on the opposite side (east-west) of the map compared to where they started. A value of 0% indicates two isolated sub-populations, whereas 50% would indicate random mixing.

## Results

Figure 4 shows a typical screenshot from the simulation. We can see that the model has been successful in reproducing male territories of a plausible size of 10 to 20 square km, and that a minority of jaguars have resorted to hunting in farmland. When watching the animation over time it is very easy to interpret the jaguar movements as “patrolling” a territory and avoiding conflicts with each other; the forest edges are used as “pathways” around territories; established core territories shift only gradually; and the jaguars that are forced out into farmland eventually get back into the forest when they are lucky enough to find an undefended edge section. Figure 4 shows the “one corridor” layout, and we can see that the corridor is certainly occupied by jaguars and thus might be leading to genetic mixing between the two sub-populations.

However, we can also see a threat to this exchange: note that the brown and the yellow territories in the centre of the corridor act as barriers to the transit of any other (male) jaguars. Our qualitative impressions when watching the simulation run with different corridor layouts were that the geography of the corridor could certainly make a difference as some layouts, notably the five-corridor map, led to “channeled” movement back and forth across the corridor, whereas other layouts such as the one in figure 4 led to blockages.

Figure 5 shows the comparison of the average-cost values across all 9 conditions. The obvious pattern here was that the layout did not seem to make a great deal of difference to the average cost experienced by each animal, except in the “contiguous forest” case. It is obvious that the contiguous layout will lead to lower average costs, however, as the same number of jaguars are distributed across about twice as much forest, giving larger territory sizes and fewer encounters with the pheromones of others.

The “no corridor” and “random islands” conditions lead to slightly higher costs than in other conditions. In the former case this is simply because there is less forest territory available; in the “equal area” control condition this difference disappears. The “random islands” condition leads to

Figure 5: Mean cost figures per jaguar per timestep compared across the nine different map layouts. Standard errors are calculated across 25 replications of each condition with different random seed values.

most of the corridor squares being edge squares, and there is a concomitant increase in average cost. On this evidence it would seem that corridor design does not make much difference to jaguar welfare, and that the critical thing is simply to have as much favourable habitat available as possible.

What of the genetic mixing results? If we look at figure 6 we see the mean level of movement across the centre-line of the map, over the different conditions. The differences here are much more dramatic. The “contiguous forest” condition is again the most favourable for the jaguars, with 34% mixing (approaching the 50% level that you would get if the jaguar locations were shuffled at random). This contrasts with the “no corridor” conditions that support only 7 or 8% mixing. The island-based corridor designs perform very badly as well, although things are not quite so bad with the “random island” design. The striking finding from figure 6 is that corridor-based designs perform best, and that the more corridors and/or the thinner the corridor, the better. Observation of these runs suggests that the strong performance of the five-corridor design (26% swapping) is because the thin pathways promote rapid movement, often through the edge squares if another animal has recently

passed through the forest squares, and the very thin strip of core forest (just 500 metres wide) is not big enough to support a territory. Wider corridors (the three-corridor and the one-corridor cases) were better than island-based designs, and certainly better than no corridor at all, but did not match the mixing levels of the five-corridor case due to the tendency for the corridor to become blocked by an established territory.

## Conclusions

We were pleased with the qualitative results of the model in that we managed to replicate plausible territorial behaviour in jaguars using the least-cost paradigm and only a few assumptions. The model has brought novel aspects of the corridor design problem to light, notably the possibility that some corridor layouts could be counter-productive due to being large enough to support internal territories that then acted as obstacles to travel by other animals. We feel that the agent-based modelling approach we have begun here has the potential to be extremely useful in drawing out the implications for different theories about jaguar behaviour and thereby helping to determine which of those theories is a

Figure 6: Proportion of jaguars that move from one side of the map's centre-line to the other by the end of the simulated year, compared across the nine different map layouts. Standard errors are calculated across 25 replications of each condition with different random seed values.

better match for the multi-faceted and incomplete observational data we have on the real animals (see Di Paolo et al., 2000, for an account of how this process can work). There are many parameters in the model for which we have had to guess at an appropriate value, but the idea is to take these values as a starting point and use them in an iterative process of model refinement in future comparisons with empirical data from Belize.

We began our modelling with a hypothetical question about the best corridor design to choose if you had the resources to reforest a few tens of square km of Belizean farmland separating two forests. We can answer that question unequivocally: of the corridor layouts we explored, the five-corridor layout was the most effective. We had expected that we might see significant differences in the average landscape cost value experienced by the jaguars across the different corridor designs, but this turned out not to be the case. Average landscape cost, given a constant population of jaguars, seems to be explained almost entirely by the availability of core forest grid squares. This suggests, for example, that constructing a new conservation corridor in Belize would

not lead to a big boost in the landscape's carrying capacity for jaguars. Instead, the key difference observed between our corridor designs was their capacity to promote migration from one side of the map to the other, and thus to promote genetic mixing at the whole-population level. The five-corridor case achieved levels of cross-map migration that were almost comparable to the "contiguous forest" condition, which is a great outcome from a conservation perspective.

Having established that this agent-based least-cost modelling approach is viable, there are several ways in which we could improve the model. Incorporating real maps of the Belizean landscape using GIS packages is an obvious way of increasing the model's fidelity, although we believe it is important not to rush this process: we need to understand the dynamics of how our simulated jaguars behave in simplified environments first. Still, using GIS data would also allow us to build a richer least-cost model, incorporating data on jaguar preferences for entering or avoiding terrain such as hills, differing densities of forest, roads, and urban areas.

In terms of the corridor design problem, a weakness of

the current model is that we only compared six specific corridor layouts with three control conditions. If we settled on a way to represent the spatial layout of a corridor, e.g., as a bitmap, we could use a genetic algorithm or other optimization technique to search for the best *possible* layout for the connecting corridors. This is perhaps slightly premature at this stage as the model is in an exploratory mode; we do not yet know enough about jaguar movement behaviour to be sure that such an optimized layout would be accurate enough to serve as a reliable conservation policy recommendation. Nevertheless we would at least be in a position to say *why* we believed a certain corridor design was optimal.

In conclusion: jaguars are rare, elusive, and hard to study. In coming years, we expect that improvements in radio- and GPS-tracking technology should see an increase in the data we have available on how they move around their environment. However, as that data comes in, it will be important to be able to evaluate it in the light of competing theories about how jaguars make decisions about hunting, mating, territory defence, etc. The agent-based simulations of artificial life can clearly help in doing this.

The natural energy minimisation behaviour of a dynamical system can be interpreted as a simple optimisation process, finding a locally optimal resolution of constraints between system variables. In human problem solving, high-dimensional problems are often made much easier by inferring a low-dimensional model of the system in which search is more effective. But this is an approach that seems to require top-down domain knowledge; not one amenable to the spontaneous energy minimisation behaviour of a natural dynamical system. However, in recent work we investigated the ability of distributed dynamical systems to improve their constraint resolution ability over time by self-organisation. Using a ‘self-modelling’ Hopfield network with a particular type of associative connection we illustrated how slowly changing relationships between system components results in a transformation into a new system, a low-dimensional caricature of the original system, in which the energy minimisation behaviour is significantly more effective at globally resolving system constraints. This uses only very simple and fully-distributed positive feedback mechanisms that are relevant to other ‘active linking’ and adaptive networks. Here we overview the implications of this neural network model for understanding transformations and emergent collective behaviour in various non-neural adaptive networks such as social, genetic and in particular, ecological networks.

**Optimisation in Dynamical Systems.** Physical dynamical systems with a large number of simple equivalent components have been shown to exhibit ‘emergent collective computational abilities’ [8] such as implementing content-addressable memory or solving constraint satisfaction problems [9,10]. In the latter, Hopfield and Tank equate the energy minimisation behaviour of a dynamical system with an optimisation process – i.e., the system moves to configurations that better-resolve the conflicting constraints between system variables. But actually, energy minimisation in a simple dynamical system is equivalent to the simplest possible optimisation algorithm, namely gradient descent (or incremental improvement), which in anything but the simplest of problems tends to find only locally optimal solutions. In human design-engineering and optimisation, high-dimensional problems are often made much easier by inferring a low-dimensional model of the system (e.g., a high-level representation that exploits modularity/problem decomposition), such that local search in this new space is better able to find a globally optimal resolution of constraints. This is an approach that seems to require top-down domain knowledge and design intelligence, but sophisticated model-building algorithms can exploit such an approach bottom-up by learning and exploiting problem structure from observed

correlations, probing epistatic interactions, or simply ‘memoising’ hard-won partial solutions [18,16,15,14,19,2]. Nonetheless, such approaches do not appear to be amenable to the spontaneous energy minimisation behaviour of a simple dynamical system. But can other types of dynamical systems, specifically self-organising systems, perform more sophisticated forms of optimisation? And conversely, can an optimisation framework help us to better understand the behaviour of natural self-organising systems?

Our questions are motivated by consideration of self-organising multi-agent systems, such as species in an ecosystem or agents in a socio-economic network, and their potential to exhibit emergent collective behaviours. In particular, we are interested in the possibility that such systems can spontaneously transform into a new system, operating at a higher level of organisation [21,13], and that such a dynamical transformation may facilitate (or may even be equivalent to) a transition in the ability to resolve constraints between the system components. Abstractly, these systems can be characterised as ‘adaptive networks’ [5] sharing the property that the structure of connections between agents affects changes to the agent behaviours and, vice versa, that the agent behaviours affect changes to the structure of connections between agents. The Hopfield network [8] easily accommodates such state/topology coadaptation and, at a very abstract level, provides a suitable system to explore how self-organisation in adaptive networks alters their ability to resolve conflicting constraints between system components.

**Transformations in meta-dynamical systems/adaptive networks.** In formalising the behaviour of a system that transforms its dynamics over time we cannot treat the parameters of the system as fixed – instead we need to pull them into the model such that they become variables controlled from within the model. But we characterise a transforming system as a ‘meta-dynamical system’ [3]. That is, the network topology defines the parameters of the state dynamics, but the connections of this topology are in actuality (slow changing) variables. In the sub-space of state dynamics defined for any given topology, or in the larger joint space of state variables and topology together, we simply observe a dynamical system doing what it does naturally, minimizing energy – there is no sense in which the system is ‘improving’ its ability to minimise energy. But when we regard the connections as ‘changing parameters’ of the state dynamics, then we can characterise these changes in terms of how they transform the dynamics of the state variables. In particular, we

can assess whether this transformation *improves* the ability of the state dynamics to minimise energy.

Using a ‘self-modelling’ [23] Hopfield network with Hebbian learning [1,6] as a model adaptive network, we recently showed that it is possible for simple distributed mechanisms, gradually changing the connections of the network, to cause it to effectively rescale its dynamics and hence move from local to global energy minimization by encapsulating implicit dynamical sub-structure [26] (Fig.1).

Fig.1: The distribution of attractor-state energies found over time in a restart Hopfield network without learning (rHN-0), with ordinary Hebbian learning (rHN-S), and with ‘generative associations’ (rHN-G). The latter transforms the system into one which easily and reliably minimises total energy. See [26].

## Transformations in Biological Adaptive Networks.

Although this recent work utilised a Hopfield network with Hebbian learning, a separate recent result shows that the same type of behaviour is expected spontaneously in other (non-neural) adaptive networks [25]. Specifically, when individual self-interested agents on a network can alter network connections (e.g. alter their fitness dependencies with others by changing their resource-utilisation profile, or alter the proportion of time/resources they invest in a relationship, or alter the probability of interaction or co-dispersal with others) and they do so to maximise their individual utility then the alterations they choose are necessarily Hebbian. Intuitively, this occurs because short-sighted selfish agents reinforce the status-quo [4], or increase the robustness/stability of the current state configuration [24], and this has the same dynamical consequences on the subsequent dynamics of the system as Hebbian learning does when it stores a training pattern in a neural network. Accordingly, related work develops the implications of this model for genetic networks [24] (with relation to evolvability and robustness [11,17]), social networks [4] (games on networks with active linking [20]) and ecological networks [12] and finds that the same dynamics occur spontaneously in all these systems. In this presentation we focus particular attention on ecosystems and the ‘generative’ type of associations (Fig.1) that have the effect of forming coalitions [20,28] or new selective units [27,22]. We suggest that this provides a formal framework for characterising the selective pressures/adaptive consequences involved in the formation of evolutionary transitions [13].

# Spatial structure creates community-level selection for nutrient recycling

Hywel T.P. Williams<sup>1</sup>, Richard A. Boyle<sup>1</sup> and Timothy M. Lenton<sup>1</sup>

<sup>1</sup> College of Life and Environmental Sciences, University of Exeter, Stocker Road, Exeter EX4 4QD, UK  
h.t.p.williams@exeter.ac.uk

Nutrient cycling is a ubiquitous feature of ecosystems at all scales, allowing productivity to rise beyond the limits set by external nutrient inputs. Nutrient cycling occurs as a side-effect of the metabolism of a diverse set of species that each performs a step in the recycling loop. Recycling loops can be large and involve many steps. At each step the possibility exists for ‘side-reactions’ in the form of species with metabolisms that consume an intermediate metabolite but do not create the product needed to complete the recycling loop. Also, at least some of the biochemical reactions in any closed recycling loop must be endergonic (energy-consuming) and thus recycling loops may be vulnerable to invasion or parasitism by species that consume intermediates but do not produce costly products needed to close the loop. The possibility of such destabilising side-reactions appears to conflict with the apparent stability and ubiquity of nutrient recycling in nature.

Here we propose that the ecosystem-level autocatalysis provided by nutrient recycling offers a productivity benefit that can be selected at the level of the biological community, provided that certain conditions are met: (1) the benefits of recycling must be localised so that they preferentially accrue to participants, (2) metacommunity structure must be such that multi-species communities can propagate intact. We use an idealised model of a simple microbial ecosystem (Boyle et al, submitted) to show that spatial structure can be sufficient to provide these conditions and allow community-level selection (Williams and Lenton, 2007a, 2008) to stabilise and promote nutrient recycling.

The model is an individual-based evolutionary simulation of a microbial community composed of three species which interact via their metabolic products. The community is distributed across multiple patches arranged in a ring topology to give an approximation to a 1D spatial environment. Each patch is internally well-mixed and connected to its neighbours on either side by a slow rate of diffusive mixing. Three chemical substrates are consumed/produced in the metabolism of the three microbial species. All species are assumed to be identical apart from their pattern of resource utilisation, i.e., no species has any competitive advan-

Figure 1: Patches are internally well-mixed and connected (in a ring topology) by a slow rate of diffusive mixing. Each patch is supplied with nutrient substrate X at a uniform rate. The “source” species consumes X and produces a secondary substrate Y. The “mutualist” species consumes Y and regenerates X (incurring growth rate cost  $\kappa$ ). The “parasite” species consumes Y and produces substrate Z, which is not consumed by any species.

tage other than from the relative availability of their respective metabolic substrate. The “source” species consumes substrate X and produces substrate Y as a waste product. The “mutualist” species consumes substrate Y and regenerates substrate X as a product. The “parasite” species consumes substrate X and produces substrate Z. Since we assume that the reactions  $X \rightarrow Y$  and  $Y \rightarrow Z$  are exergonic (energy-releasing), the reaction  $Y \rightarrow X$  must therefore be endergonic. Thus the mutualist species incurs an energetic cost which we implement as a growth rate penalty  $\kappa$ . The level of  $\kappa$  at which both mutualists and parasites coexist (i.e. are equal competitors) quantifies the strength of community-level selection for recycling, since coexistence implies balanced selection pressures at the individual level (for parasites) and the community level (for mutualists).

Each patch is supplied with substrate X at a steady rate, while all material substrates are removed from each patch by a slow rate of dilution. Thus in the absence of any microbial

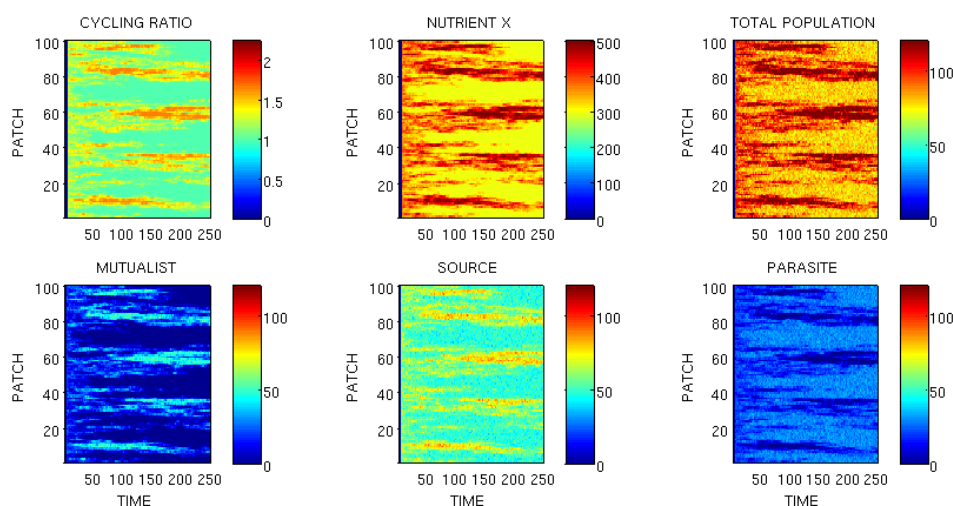

Figure 2: Example of model results showing spatial patterns in a system of 100 patches. Over time (horizontal axes) a heterogeneous distribution of species and resources over space (vertical axes) emerges from the initially homogeneous distribution. Nutrient cycling ratios are positively correlated with high density of mutualists (since this species regenerates resource X) and patch-level productivity, and negatively correlated with parasite density. Global coexistence of mutualists and parasites is stabilised by patch-level fecundity selection for recycling based on between-patch gradients in community productivity, which counteracts the within-patch advantage of the parasite.

populations the system would equilibrate with a fixed concentration of  $X$  and zero concentrations of  $Y$  and  $Z$ . The microbial community is initialised with a uniform distribution of individuals from each species. Microbes can diffuse to neighbouring patches with low probability at each timestep. There is no material mixing. Microbes grow dependent on the availability of their required substrate and reproduce by fission when their biomass reaches a fixed threshold. Microbes can die from starvation when their biomass drops below a critical threshold or stochastically with low probability (serving to represent all other causes of mortality). The system is numerically integrated using Euler's forward method.

Analytic and numerical results show that for any non-zero cost of recycling (i.e. any  $\kappa > 0$ ) parasites always exclude mutualists within a single isolated patch. Yet spatial simulations show sustained coexistence of mutualists and parasites. Mutualist frequencies in local patches are positively correlated with nutrient recycling and patch productivity. The mechanism for global coexistence of mutualists and parasites is patch-level fecundity selection; patches with higher frequencies of mutualists have higher total productivity and hence export more individuals (of all kinds) to neighbouring patches, counteracting the within-patch advantage of parasites. This is confirmed by mutualist extinction and loss of recycling when patch productivity is normalised to remove between-patch productivity gradients. Varying the spatial heterogeneity of the system by varying the between-patch mixing rate shows that recycling rates (and hence global productivity) are positively related to the 'patchiness' of the sys-

tem; low positive mixing rates that maximise spatial heterogeneity also maximise recycling. Removing spatial structure by implementing perfect between-patch mixing recovers the single-patch result of mutualist exclusion and no recycling.

The community-level selection mechanism we propose is not necessary for the formation of nutrient recycling loops in nature, which can be easily formed by aggregation of metabolically diverse species that each gain a selfish benefit from the biochemical transformations they conduct (Williams and Lenton, 2007b). However, the synergistic benefits of recycling permit community-level selection to stabilise and promote recycling, even in cases where participation incurs an individual-level cost. This finding suggests a number of testable predictions: (1) nutrient recycling should be favoured in spatially structured environments such as soils and microbial biofilms, (2) community-level productivity benefits can stabilise costly trophic mutualisms in spatially structured environments, and (3) species with complementary metabolisms should evolve traits that promote their spatial association.

# Artificial Cells as Reified Quines

Lance R. Williams<sup>1</sup>

<sup>1</sup>University of New Mexico, Albuquerque, NM 87131  
williams@cs.unm.edu

## Abstract

Cellular automata were initially conceived as a formal model to study self-replicating systems. Although reproduction by biological cells is characterized by exponential population increase, no population of self-replicating machines modeled as a cellular automaton has ever exhibited such rapid growth. We believe this is due to the inability of cellular automata to model bonded complexes of *reified actors* undergoing random independent motion.

To address this limitation, we introduce a model of parallel distributed spatial computation which is highly expressive, indefinitely scalable, and asynchronous. We then use this model to define two examples of self-replicating *kinematic automata*. These machines assemble copies of themselves from components supplied by diffusion and increase in number exponentially until the supply of components is depleted. Because they are both programmable constructors and self-descriptions, we call them *reified quines*.

## Introduction

Much as Turing had done twenty years earlier when motivating his computing machine by first describing a notional human computer which computed with paper and pencil (Turing, 1936), von Neumann motivated his self-replicating machine by means of a thought experiment (Burks, 1970). von Neumann's machine assembled copies of itself from a set of components undergoing random independent motion on the surface of a lake. The components consisted of girders, hands, muscles, sensors, switches (*and*, *or* and *not* gates), and delays, together with tools for welding and cutting. von Neumann ultimately concluded that the physics of his machine was too removed from reality to be interesting, while unnecessarily complicating the study of the information processing problems inherent in self-replication. Accordingly, the bulk of his subsequent efforts were concerned with abstract machines not physical machines, and the class of abstract machine he adopted, *cellular automata*, has dominated the field for the past fifty years.

Although self-replication by biological cells is characterized by exponential population increase, no population of self-replicating machines modeled as a cellular automaton has ever displayed such rapid growth. Indeed, populations

of the most fecund (Langton, 1984) grow only as a quadratic function of time. We believe this is due to the inability of cellular automata to model bonded complexes of *reified actors* undergoing random independent motion.

Random independent motion, or *diffusion*, plays a crucial role in our work. First, as in von Neumann's kinematic model, components required for self-replication are supplied by diffusion. Second, diffusion changes the length of bonds, and vital operations must wait until bonds are of sufficient length. Third, the products of self-replication are dispersed by diffusion, which is essential for exponential population growth because it prevents overcrowding.

## Quines

Self-replicating machines can be divided into two types. The *Darwinian* type contain a self-description (genotype) and replicate by both copying it (yielding a copy of the genotype) and decoding it (yielding a copy of the phenotype). In contrast, the *Lamarckian* type replicate by copying the phenotype directly. Computer *worms* are Lamarckian, while *quines* (programs written in high-level languages which print themselves) are Darwinian. Worms don't need a self-description because of the nearly unique capacity for *reflection* possessed by machine language programs running on digital computers with von Neumann architectures. Programs and data reside in the same memory; programs *are* data. In contrast, most high-level programming languages lack the capacity for reflection. It follows that quines, like biological cells, must replicate by copying and decoding self-descriptions.

## Prior Work

The prior work with goals and approach most similar to our own is that of Hutton (2007), who has developed an artificial cell with a membrane in a 2D artificial chemistry. Hutton's cell consists of a membrane formed from a ring of 14 atoms internally bisected by a string of 5 atoms which serves as a partial genome. The membrane is permeable to unbonded atoms but impermeable to bonded atoms. The entire structure is copied atom-by-atom, through the action of 39 reaction rules which define a universal chemistry. Atoms are of

6 different types and can possess up to 62 states each. The reaction rules have a very restricted form; both left and right hand sides consist of a single pair of atoms (either bonded or unbonded), and each in a specified state.

The most impressive aspect of Hutton's work is the partial genome. This is an arbitrary string of atoms which can be used to encode any reaction rule. It is translated into a bonded pair of atoms which functions as an enzyme. Because it is contained inside a membrane impermeable to bonded atoms, it is hoarded by the cell for its exclusive use. Although enzymes can (in principle) be used to replace any of the reaction rules in the artificial chemistry (the single exception presumably being the rule governing the use of enzymes), this has only been demonstrated for a single reaction rule and Hutton (2005) states that a genome 700 atoms long (and a correspondingly larger membrane), would be needed to replace the full set.

### Actor Model

Biological cells are membranes made of lipids which contain water, enzymes, and DNA. The DNA encodes the enzymes and the enzymes (in water) form metabolic pathways which collectively: 1) copy the DNA; 2) translate the DNA into enzymes; and 3) make the membrane grow and divide. In our view, biochemistry is parallel distributed computation and enzymes are *actors*. Membranes don't just concentrate and isolate enzymes, they define private *absolute address* spaces. In effect, they permit the construction of idiosyncratic biochemistries, defined by specific sets of enzymes, the descriptions of which are encoded by the cells' own DNA.

The *actor model* is a model of parallel distributed computation (Hewitt et al., 1973). An actor is a process which possesses a unique absolute address. Using these addresses, actors send and receive messages to and from other actors. In response to receiving a message, actors can change state, create new actors, and send new messages. Significantly, and unlike cellular automata, computation in the actor model is event-driven and asynchronous.

With respect to the goal of constructing reified quines, the actor model has a number of shortcomings. First, because of its use of absolute addresses, it is not indefinitely scalable; in an actual implementation, the average time required to deliver a message increases as the number of actors increases. Second, there is no satisfactory method to generate guaranteed unique addresses in a parallel distributed manner. Third, and most significantly, the actor model is not reified—actors exist in an abstract space, not in a space which is isomorphic to physical space.

### Reified Actor Model

Although as originally conceived, actor models are not reified, it is possible to create a reified actor model or *movable feast* (Ackley and Cannon, 2011). In a movable feast, all

actors have unique positions on a 2D grid. Actors possess a finite number of states and can sense and change the positions and states of actors in their  $n \times n$  neighborhoods. Significantly, actors can create *bonds* with other actors in their  $n \times n$  neighborhoods. Bonds are *relative addresses* which are short, symmetric, and automatically updated as actors undergo random independent motion (restricted by the lengths of bonds).

The set of actors reachable through a sequence of bonds of length less than or equal to  $k$  comprise an actor's *bond graph  $k$ -neighborhood*. Actors can sense and change the positions and states of actors in their bond graph  $k$ -neighborhoods.

Like conventional actor models, computations in a movable feast are event-driven and asynchronous. Unlike conventional actor models, movable feast computations are based on the application of graph rewrite rules possessed by individual actors to the actors' bond graph  $k$ -neighborhoods. Sets of related graph rewrite rules are grouped into *behaviors*, which are indivisible and conferred as units. Actors can *possess* multiple behaviors but can *denote* at most one behavior. Significantly, an actor can confer the behavior it denotes on other actors through bonds. The distinction between possessing and denoting mirrors the phenotype-genotype distinction in biological cells and the program-data dichotomy in quines.

The update scheme in the movable feast consists of picking an actor at random, picking a behavior possessed by that actor at random, and applying the first graph rewrite rule with a pattern matching the actor's bond graph  $k$ -neighborhood.

### Kinematic Automata

The vertices of a *bond graph* are actors and the edges are bonds; both actors and bonds can be of one or more types. Because they are reified, actors have unique positions on a 2D grid. In homage to von Neumann, we define a *kinematic automaton (KA)* to be a set of reified actors possessing type specific behaviors assembled in a bond graph.

A *description* of a KA consists of a bond graph and a *behavior graph*. The behavior graph represents the relation between the set of types and the set of behaviors, *i.e.*, the *behavior relation*. Actors are finite state machines with transition functions defined by the behaviors they possess (Fig. 1). It follows that a KA is an asynchronous network of communicating finite state machines (Brand and Zafropulo, 1983); the set of behaviors possessed by its actors define a graph rewriting system (Klavins et al., 2004) which transforms the embedding and topology of the network over time.

A *programmable constructor* for a class of KA's is a KA which takes a description of a KA in the class and builds it. Example classes are *reified-strings* and *reified-sets*. A programmable constructor may (or may not) be in the class it builds. A *self-description* is a KA where the bond graph represents the behavior graph using an encoding scheme; it is

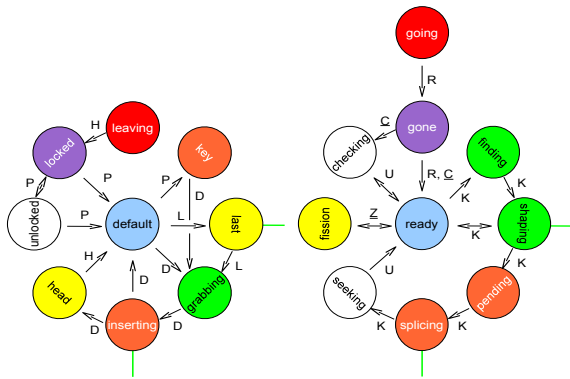

Figure 1: State transition diagrams for actors in reified-string (left) and reified-set (right) quines. Letters denote behaviors mediating state transitions. Green sticks mark states where the actor possesses a *hand* bond.

this use of dual meaning which resolves the seeming paradox of self-description—how can a thing contain a description of itself?

## Reified-String Quine

A *reified-string* is a KA consisting of a chain of reified actors linked by bonds. Apart from the head (tail) each actor in the reified-string has a unique predecessor (successor) to which it is bonded by a *prev* bond (*next* bond). A behavior graph can be represented using an adjacency list representation which in turn can be represented as a string. For example, let  $H$ ,  $D$ ,  $P$ , and  $L$  be types denoting behaviors and let  $\#$  be a punctuation type, then  $Q = \#HDP\#DDP\#PDP\##HDP\#LDPLL$  is a reified-string self-description where actors of all types possess behaviors  $D$  and  $P$  while actors of type  $\#$  also possess behavior  $H$  and actors of type  $L$  also possess behavior  $L$  (the repeated  $L$  marks the end of the string). A reified-string self-description which is also a programmable constructor for the class of reified-strings is a *reified-string quine*.

## Behaviors

To build a reified-string quine we must define a set of graph rewrite rules which when grouped into behaviors  $H$ ,  $D$ ,  $P$ , and  $L$  yield a  $Q$  which is a programmable constructor for reified-strings:

- $H$  – initiates decoding phase using *tip*
- $D$  – copies string using *grab*, *insert* and *transport*
- $P$  – confers type specific behaviors by decoding string using *key*, *lock*, *unlock* and *confer*
- $L$  – initiates copying phase, assembles daughter, and effects fission using *cleave*.

The reified-string quine copies itself in two phases. During the *copying* phase, the bond graph is copied actor-by-actor. During the *decoding* phase, the adjacency list representation

Figure 2: *Grab* graph rewrite rule. An actor in the *grabbing* state possessing behavior  $D$  and denoting behavior  $X$  forms a *hand* bond with an unbonded actor denoting the same behavior in its  $n \times n$  neighborhood. It then enters the *inserting* state.

of the behavior graph is decoded, conferring the behaviors specific to each type on the copies.

## Copying

Copying begins at the tail of the reified-string and advances towards the head. *Grab* and *insert* rewrite rules from behavior  $D$  cause each actor to

- form a *hand* bond to an unbonded actor of matching type in its  $n \times n$  neighborhood (Fig. 2)
- set that actor's state to *leaving*
- insert it into the reified-string nearer the head (Fig. 3).

In effect, the hand advances towards the head as each actor in the mother cycles through the *default*, *grabbing* and *inserting* states. Meanwhile, the *transport* graph rewrite rule from behavior  $D$  swaps actors in the *default* state with actors nearer the tail in the *leaving* state, an action which quickly moves them to the head. At the completion of the copying phase, the copied actors (which will eventually comprise the daughter) form a reversed chain in the *leaving* state attached to the mother's head.

## Decoding

The *tip* graph rewrite rule from behavior  $H$  (possessed only by actors of type  $\#$ ) recognizes when the head actor has been copied and begins the decoding phase, implemented by graph rewrite rules from behavior  $P$ . In the decoding phase, the reified-string is interpreted as an adjacency list representation of the behavior graph. This is accomplished as the copied actors traverse the mother a second time (in the reverse direction). During this traversal, each actor has its type specific behaviors conferred on it. The *key* rewrite rule causes actors denoting behaviors adjacent to actors of type  $\#$  to enter the *key* state. Actors in the *key* state *unlock* adjacent actors of matching type in the *locked* state while

Figure 3: *Insert* graph rewrite rule. An actor in the *inserting* state possessing behavior *D* waits until its *prev* bond is of maximum length. It then inserts the actor at the end of its hand into the reified-string by bisecting the *prev* bond and enters the *default* state. The inserted actor's state is changed to *leaving* and the state of the actor previously at the end of the *prev* bond (and nearer the head) is changed to *grabbing*.

Figure 4: *Confer* graph rewrite rule. An actor in the *default* state possessing behavior *P* and denoting behavior *Y* confers behavior *Y* on the actor nearer the head when that actor is in the *unlocked* state. It then exchanges position with it, moving it towards the tail.

actors in the *default* state *confer* the behaviors they denote on adjacent *unlocked* actors (Fig. 4). Finally, actors in both *locked* and *unlocked* states are moved towards the tail.

The daughter's actors, now possessing their full complement of behaviors, are assembled into a complete reified-string at the end of a *hand* bond at the mother's tail by graph rewrite rules from the *L* behavior. When an actor in the *last* state sees two others denoting the same behavior as itself at the end of its hand, it sets both its own state and that of the nearer of the two to *grabbing* and deletes its hand (Fig. 5). This separates mother and daughter reified-strings and initiates the process of self-replication in each.

## Reified-Set Quine

In the reified-string quine, the behavior graph was encoded using an adjacency list representation, which is capable of representing arbitrary graphs. However, the reified-string quine's behavior graph was far from general—two behaviors

Figure 5: *Cleave* graph rewrite rule. When an actor in the *last* state sees two others denoting the same behavior as itself at the end of its hand, it sets both its own state and that of the nearer of the two to *grabbing* and deletes its hand.

Figure 6: Reified-string quine with *hand* bond (drawn green) in the middle of the *copy* phase. Letters indicate actor type and colors indicate actor state.

(*D* and *P*) were possessed by all actors while the remaining behaviors (*H* and *L*) were possessed by only a single actor each. If we restrict ourselves to behavior relations comprised solely of *generic* behaviors and *specialized* behaviors, a more compact encoding scheme can be used.

A *reified-set* is a KA consisting of a ring of reified actors linked by *prev* and *next* bonds. A reified-set self-description which is also a programmable constructor for the class of reified-sets is a *reified-set quine*.

Reified-set quines have one great advantage when compared to reified-string quines, namely, the order of the actors in the ring is unimportant. More precisely, there is an equivalence class of bond graphs which encode a given behavior relation. Because actors can swap positions without changing the encoded behavior relation, they can possess a behavior which continually mixes their positions in the ring, ensuring that any two actors will eventually be adjacent. This

Figure 7: *Shape* graph rewrite rule. An actor in the *shaping* state possessing behavior  $K$ , when adjacent to its *continuation*, confers the behavior denoted by its continuation on the actor at the end of its hand. It then exchanges position with its continuation and leaves it in the *shaping* state.

permits a much more expressive form of parallel distributed computation than was possible with the reified-string. Indeed, if each actor in the reified-set possesses a unique *address* and a unique *continuation* then the reified-set can execute sequential programs which perform one operation for every actor. In our work, an actor's address is just the name of the behavior it denotes and its continuation is the name of another behavior. In effect, the reified-set, implemented within a *reified* actor model using *relative* addressing, can simulate a conventional *non-reified* actor model with a small *absolute* address space.

### Behaviors

Let  $X$  denote a generic behavior and  $\underline{X}$  denote a specialized behavior then  $Z = \{\underline{C}, K, U, S, N, R, M, \underline{Z}\}$  is a reified-set quine with the following behaviors:

- $\underline{C}$  – *create* daughter pinch
- $K$  – *find* matching actor, confer type specific behaviors using *shape*, then *splice* it into the reified-set
- $U$  – *seek* continuation
- $S$  – *swap* positions with adjacent actor
- $N$  – *nothing*
- $R$  – *ratchet* actors past *pinch* bonds
- $M$  – *minimize* bending energy (Williams and Shah, 1992)
- $\underline{Z}$  – *fission*.

While the reified-string quine copied itself in two consecutive phases, the reified-set quine copies itself using processes called *copy-decode*, *export*, and *verify* running concurrently in mother and daughter *subbrings*.

### Copy-decode

Copy-decode is implemented by graph rewrite rules from behaviors  $K$  and  $U$ . It is a sequential program of sixty four

Figure 8: *Create* graph rewrite rule. An actor possessing and denoting behavior  $\underline{C}$ , in the *going* state, when adjacent to another actor in the same state, forms a *pinch* bond with the adjacent actor and enters the *checking* state (initiating the *verify* program in the daughter subring). The state of the adjacent actor is set to *ready*.

Figure 9: *Ratchet* graph rewrite rule. When at the front end of the mother's *pinch* bond, and adjacent to an actor in the *going* state, an actor with behavior  $R$  waits until its *next* bond is of maximum length. It then moves the adjacent actor past the *pinch* bond by bisecting the *next* bond, leaving the exported actor in the *gone* state.

steps which runs in the mother subring and is comprised of two nested loops—the outer loop copies the bond graph and the inner loop decodes the set representation of the behavior graph. Both loops iterate over the eight actors in the reified-set. The outer loop begins when an actor in the *finding* state:

- forms a *hand* bond to an unbonded actor of matching type in its  $n \times n$  neighborhood
- gives the daughter actor the name of its continuation (it will be the name of the daughter actor's also)
- enters the *shaping* state.

An actor in the *shaping* state waits for its continuation to be adjacent. When this happens, the actor:

- confers the behavior denoted by its continuation on the daughter actor at the end of its hand (Fig. 7)
- swaps positions with its continuation (leaving it in the *shaping* state)
- enters the *pending* state.

Figure 10: *Fission* graph rewrite rule. An actor possessing and denoting the behavior  $\underline{Z}$ , when in the *fission* state and located at either end of a *pinch* bond, looks for a second actor in the *fission* state in its bond graph  $k$  neighborhood in the other subring. If one exists, the *prev* and *next* bonds joining mother and daughter are rerouted so they coincide with the mother and daughter *pinch* bonds; the actors in the *fission* state enter the *seeking* state.

This begins the next iteration of the inner loop. The inner loop continues until an actor in the *shaping* state finds itself adjacent to its *pending* continuation. When this happens, the inner loop exits and the actor enters the *splicing* state. An actor in the *splicing* state waits until its *next* bond is of maximum length. When this happens, the actor:

- inserts the actor at the end of its hand into the reified-set by bisecting the *next* bond (leaving it in the *going* state)
- enters the *seeking* state.

This begins the next iteration of the outer loop. When an actor in the *seeking* state possessing and denoting behavior  $\underline{Z}$  finds itself adjacent to its *pending* continuation the copy program has finished, and the actor enters the *fission* state. It remains in the *fission* state until the *verify* process (running in the daughter subring) also completes.

## Export

Export is implemented by a set of graph rewrite rules from behaviors  $S$ ,  $R$  and  $\underline{C}$  which run concurrently with *copy-decode* and *verify* in both mother and daughter subrings. The *swap* graph rewrite rule swaps actors in the *ready* state with actors in posterior positions; a second rule portages actors around actors with *hand* bonds. These rules serve two purposes. First, they continually mix the positions of the actors in both the mother and daughter subrings, ensuring that any two actors in the same subring will eventually be adjacent. This is necessary for the *copy-decode* and *verify* programs to make progress. Second, they cause actors in the *going* state in the mother subring to move towards the gate formed by the mother and daughter *pinch* bonds—bonds created by the single rewrite rule in behavior  $\underline{C}$  (Fig. 8).

Graph rewrite rules from behavior  $R$  control a gate formed by a pair of parallel *pinch* bonds which separate the mother and daughter subrings. Another graph rewrite rule swaps

pairs of actors joined by *pinch* bonds. This routes actors in the subrings across the pinches, effectively short-circuiting the mother and daughter subrings and ensuring that the mother's and daughter's actors cannot mix. Indeed, the only actors which can get past the mother's *pinch* bond are actors in the *going* state and they can only pass in one direction. The actor at the front end of the mother's *pinch* bond, when adjacent to an actor in the *going* state, waits until its *next* bond is of maximum length. It then moves the adjacent actor past the *pinch* bond by bisecting the *next* bond, leaving the exported actor in the *gone* state (Fig 9). Another graph rewrite rule performs a similar operation at the back end of the daughter's *pinch* bond, leaving the imported actor in the *ready* state.

## Verify

*Verify* ensures that the daughter has received the full complement of actors before fission occurs. It is implemented by graph rewrite rules grouped in behaviors  $U$  and  $\underline{Z}$ . One might think that fission could occur as soon as the actor which is copied last is imported into the daughter subring. However, because of the asynchronous nature of the *export* process, there is no guarantee that the last actor copied will be the last one imported. In fact, import order inversions are common. For this reason, a simple eight step program (one for each actor in the reified-set) is run in the daughter subring to verify that the full complement has been imported.

An actor in the *checking* state in the daughter subring waits until it finds itself adjacent to its continuation. When this happens, it enters the *ready* state and sets the state of its continuation to *checking*. The one exception is the actor representing the behavior  $\underline{Z}$ —this actor is copied last and does not seek its continuation but enters the *fission* state instead.

An actor possessing the behavior  $\underline{Z}$ , when in the *fission* state and located at either end of a *pinch* bond, looks for a second actor in the *fission* state in its bond graph  $k$  neighborhood in the other subring. If one exists, the *prev* and *next* bonds joining mother and daughter are rerouted so that they overlap the *pinch* bonds; the actors in the *fission* state enter the *seeking* state, initiating the *copy-decode* program in mother and daughter, now separate (Fig. 10).

## Discussion

In the introduction, an analogy was made between enzymes and actors, and it was suggested that the primary computational function of a cell's membrane is to create an address space within which actors can send and receive messages without interference from the actors of other cells. The analogy is compelling. However, we have deliberately avoided calling the movable feast an *artificial chemistry*. One reason for not doing so is that we are trying to achieve with *dozens* of actors what is accomplished in a biological cell by *billions* of enzymes. If we are to succeed then we cannot be too literal in our imitation of the biological cell; our goal

should be to build an airplane not a bird.

## Communication

Hutton (2007) states that the primary obstacle to constructing an artificial cell with a complete set of enzymes of the sort he has described is the unwieldiness of the vastly larger genome and membrane such a cell would require. However, a more fundamental obstacle may be the difficulty of ensuring communication between enzymes and locations where reactions need to be catalyzed.

Do the enzymes of an artificial cell need to be confined within a 2D space bounded by a 1D membrane? Or can they comprise the membrane itself? Both approaches isolate a cell's enzymes from those of other cells. The second has the advantage that a simple mixing behavior guarantees communication between enzymes and locations where reactions need to be catalyzed.

## Modularity

All quines are grounded in terms defined externally in the host programming language. A programming language can have terms which are elementary and general (like Lego bricks) or complex and highly specialized (like stereo components). The terms can have uniform interfaces (like USB devices) or interfaces which limit reuse (like the pieces of a jigsaw puzzle).

The terms comprising the genome of the reified-set quine are behaviors defined outside the quine itself. A crude upper bound on the number of reified-set quine genomes would be  $2^B$  where  $B$  is the number of behaviors. Of course  $B$  can be made arbitrarily large initially, but wholly new behaviors cannot evolve; evolution is limited to discovering viable combinations of pre-existing behaviors.

Do these exist? Are there viable and interestingly different reified-set quines near  $Z$  in genome space? In partial answer to this question, we have constructed two additional examples of reified-set quines which use very different strategies to ensure that the daughter cell has received its full complement of actors. The first,  $X$ , accomplishes this by running a second instance of *copy-decode* inside the daughter subring instead of *verify*. In effect, the daughter demonstrates its viability by constructing the granddaughter. The second,  $Y$ , uses a modified *copy-decode* program which waits until it sees the most recently copied actor in the daughter subring (through the pinches) before it continues.

All three reified-set quines share behaviors  $K$ ,  $S$ ,  $R$  and  $M$  while two ( $X$  and  $Z$ ) also share  $U$ . This demonstrates that behaviors can possess a degree of modularity and potential for reuse and can be mixed and matched meaningfully. While the three reified-set quines were designed and did not evolve, the fact that they exist suggests that a future system more like Hutton (2007), with a genome containing reified descriptions of graph rewrite rules subject to mutation, would explore a genome landscape populated by viable

Figure 11: Six reified-set quines. Letters indicate actor type and colors indicate actor state. In the mother subring of the topmost quine, the *copy-decode* program has completed, while the *verify* program is still running in the daughter subring. *Hand* and *pinch* bonds are drawn green and red.

Figure 12: Exponential growth of non-competing populations of reified-string quines,  $Q$ , and reified-set quines,  $Z$ .

and interestingly different artificial cells.

## Experimental Results

In each of the three experiments, approximately 11000 unbonded actors were randomly placed on a grid of size  $512 \times 512$  to achieve a 4% area density. Except for pairs joined by *prev* or *next* bonds, actors were excluded from  $5 \times 5$  neighborhoods surrounding other actors. The maximum bond length equaled 4, the diffusion constant equaled 0.5, and search neighborhoods were of size  $11 \times 11$ .

In the first experiment, the unbonded actors were of types comprising the genomes of the  $Q$  reified-string quine and the  $Z$  reified-set quine. The proportion of each type matched that of the two genomes. A single reified-string quine and a single reified-set quine were then placed in the grid, after which, populations of both increased exponentially, in the

Figure 13: Exponential growth of three non-competing populations of reified-set quines. Z is the quine described at length in this paper while X and Y use alternative strategies to verify that the daughter has received its full complement of actors.

Figure 14: Three populations of reified-set quines compete for a shared resource, the *K* behavior. The Z quine outcompetes the X and Y quines.

process converting essentially all unbonded actors into approximately 300 copies of each quine (Fig. 12).

In the second experiment, the unbonded actors were of types comprising the genomes of the X, Y, and Z reified-set quines. As before, the proportions of each type matched those of the genomes; types common to all three, *e.g.*, *K*, were three times as numerous as unique types, *e.g.*, *U*. Single X, Y, Z reified-set quines were then placed in the grid. Populations of all three increased exponentially, yielding 424 copies of the Z quine, 345 copies of the Y quine, and 233 copies of the X quine (Fig. 13). The differences in these numbers can be attributed to the fact that (after all unbonded actors have been consumed) the final population consists of a mixture of individuals at various points in the self-replication process and which therefore exhibit a range of sizes. The Z quine is the most efficient at converting unbonded actors into copies of itself while the X quine is the least. This is presumably due to the fact that the X quine

requires its daughters to demonstrate their viability by constructing granddaughters. Consequently, the average size of X quine instances is significantly larger than the average size of Y or Z quine instances.

The conditions of the third experiment were nearly identical to those of the second except that the number of unbonded actors of type *K* (common to all three genomes), was reduced by a factor of three. Consequently, populations of X, Y, and Z quines were forced to compete for the under-represented shared resource. The winner of the competition was the Z quine, which succeeded in constructing nearly 400 complete individuals, while the X and Y quines succeeded in constructing less than 50 each (Fig. 14).

## Conclusion

A highly expressive, indefinitely scalable, and asynchronous model of parallel distributed spatial computation has been introduced and used to define a series of self-replicating kinematic automata. These machines assemble copies of themselves from components supplied by diffusion and increase in number exponentially until the supply of components is depleted. Because they are both programmable constructors and self-descriptions, we call them *reified quines*.

## Abstract<sup>†</sup>

The production of autonomously functioning, integrated, complex networks of physico-chemical processes requires the creation of some mode of informational representation in molecular form (genes), not only as a matter of fact but also as the only plausible way of designing such systems to achieve control with a level of specificity typical of molecular biological processes. Likewise, only through their natural selection as parts of systems which express the information in them could DNA sequences of kilo-, mega- or giga-base length attain specific representational meanings of biological significance. Nothing worthy of the designation “Artificial Life” will exist until an information-interpreter/constructor coupling of the sort that emerged at life’s origin on our planet is recapitulated in the laboratory. Attempts to achieve such a goal require very careful scrutiny and the ethics of such endeavours should be discussed within the context of a radical critique of how human agency is constituted and how it is linked to fundamental biological processes.

## Introduction

The central thesis of Schrödinger (1944) concerning the question “What is Life?” was that the processes of biological inheritance require that information be stored in some stable, replicable, microscopic array which he chose to describe as a “quasi-periodic crystal”, using a term first coined by Delbrück (Timoféeff-Ressovsky *et al.*, 1935). Schrödinger reasoned that finely differentiated characteristics of large organisms, such as the Habsburger Lippe, that could be genetically transmitted across generations spanning centuries, must be encoded in some structural feature of the chromosomal material of an individual cell. Although his speculations concerning the atomic form of the genetic representation of heritable information were quite wide of the mark, the elucidation of the quasi-periodic linear polymeric structure of base-paired double-stranded DNA (Watson and Crick, 1953) is reasonably interpreted as a confirmation of Schrödinger’s hypothesis.

In the ensuing decades molecular biologists have uncovered in exquisite detail, and continue to do so, the ways in which the autonomous operation and maintenance of individual cells and multi-cellular organisms depends on the expression of genetic information. The paradigm of genetic expression is the biochemical control of basic metabolism that is achieved through protein synthesis. The genetic code defines a one-to-one mapping from specific base sequences of nucleic acids to corresponding amino acid sequences of proteins, which then

serve as catalysts for the multitude of elementary chemical transformations that must be effected for a cell to survive.

In spite of the success of molecular biology, very little attention has been paid to understanding, within the definitively empirical context of the discipline, some of the deeper theoretical problems presented by the idea of natural systems coming to contain an abstract self-representation in physical form. To say that the pairing of DNA sequences with the systems in which they occur is achieved through Darwinian natural selection is to beg the question “Why do some DNA-system pairings allow the generation of living organisms and others not?” Physically pairing the *E. coli* genome with a DNA-free human (stem) cell, or *vice versa*, does not produce a viable result; however, replacing the genome of *M. capricolum* with that of *M. mycoides* does (Gibson *et al.*, 2010). Thus, in spite of the many similarities in the molecular biological processes operating in different organisms, such as the near universality of the informatic rules of protein synthesis, cells cannot be construed as containing a universal constructor of the sort considered by von Neumann (1949) in his theory of self-reproducing automata. The quasi-Platonic mathematical space of genetic sequences in which all possible organisms are defined, as envisioned by neo-Darwinists (Dawkins, 1986), is an illusion. Selection of a phenotype may be a result of some arbitrary, autonomous change in the behaviour of the interpreter/constructor, rather than the result of a genetic change. A full account of biological evolution requires a description of the structural constraints that define which DNA sequences are amenable to interpretation by corresponding molecular biological systems, not just an analysis of the phylogenies of genetic sequence elements and their incidentally associated phenotypes (Wills, 2009).

This line of argument exposes the very point at which current theories of the autonomy of living systems reach their limit. The apparently general biological constructors employed by proponents of synthetic biology (Gibson *et al.*, 2010) are, in fact, virtually intact (denucleated) cells from a taxon closely related to the species of origin of the novel DNA with which the interpreter/constructor is presented. The constructor itself is a very complex system comprised of an enormous number of macromolecules, many of them specific proteins, which have only ever appeared in the cosmos as a result of their coexistence with their genetic representation. Clearly, modern biological constructors have evolved from more primitive ones. Although this process has been one of coevolution with genetic sequences, it cannot be reduced to

<sup>†</sup> The presentation of this paper at ECAL 11 in Paris is dedicated to the memory of Fernando Pereira, who was killed in Auckland on 10 July 1985 during France’s terrorist attack on our common enterprise, to which I was expert adviser, opposing the military misuse of scientific knowledge.

the evolution, through natural selection, of those sequences, as Dawkins (1986) would have it. Some means of interpreting genetic information, by way of a biological constructor, must have existed before nucleic acids of any biological value could be said to have survived as a result of natural selection.

Now that language from the theory of automata and informatics is used ubiquitously in molecular biology to describe the fundamental relationship between genetic information and the results of its expression, the chicken-egg, protein-DNA dilemma should be recast as the problem “What came first, the biological constructor or its genetic representation?” And of course the dilemma is only resolved by saying that neither precedes the other in biology, the history of which is the product of their conjoint evolution.

In this paper I will investigate the implications of this view of the origin of life as an information-constructor coupling event in relation to projects which aim to create living systems *de novo*. I conclude that our understanding of this natural coupling is so primitive that there is currently no prospect of creating true Artificial Life. I will also present a pessimistic view of the possible consequences of pursuing high-impact transformative technologies which piggy-back on the intricately elaborated intact versions of the information-constructor coupling that can be mined from extant organisms and adapted by human to the pursuit of power and ill-conceived goals.

## Biological specificity

Schrödinger (1944) enunciated the modern view of molecular biological information as a solution to the problem of explaining the stability of biological inheritance in the face of the perpetual disordering effects of microscopic thermal processes. Two decades later physico-chemical details of ribosomal protein synthesis had been elucidated and explained in terms of the existence of a genetic “code”, establishing a paradigm for the way in which genetic information is expressed in cellular systems. Although the idea of a symbolic code, a translation table between alphabets, had no precedent in the description of the physics and chemistry of natural systems, it quickly became the context of virtually all discourse about molecular biological processes. The principal theoretical expression of the new mode of description of biochemical processes was framed by two principles put forward by Crick (1958), the Sequence Hypothesis and the Central Dogma. The Sequence Hypothesis addressed a problem which was implicit in Schrödinger’s view of inheritance – the source of biological specificity, that is, what differentiates one organism from another, or one biochemical process from another, down to the level of taxon-specific molecular structures.

According to the Sequence Hypothesis (Crick, 1958) “the specificity of a piece of nucleic acid is expressed solely by the sequence of its bases and ... this sequence is a (simple) code for the amino acid sequence of a particular protein”. Then, in what we would now take as a very rough first-order approximation, the functional specificity of proteins, folded chains of amino acids, was reduced to sequence information under the assumption that “the folding is simply a function of the order of the amino acids” in the protein. Crick had obviously made simplifications that were not entirely justified

but none that caused the broad-brush picture to be abandoned as discoveries of more elaborate molecular biological processes accumulated. The Sequence Hypothesis provided the first explanation of how stably stored molecular information “got out” and had some effect in cells. Furthermore, it gave some insight into how genetic information afforded control to be maintained over internal cellular processes of metabolism and, as was discovered shortly afterwards, gene expression (Jacob and Monod, 1961). The large effects that small differences in the amino acid sequence of a protein could have on its catalytic properties clearly demonstrated the biological specificity of genetic information.

There have been many attempts, without an appeal to the existence of genetic information, to describe the appearance in the world of biochemical-like order in molecular systems. The emergent autocatalytic sets proposed by Kauffman (1986) represent perhaps the best-known systems that, in the abstract at least, meet the fundamental criterion of displaying a thermodynamically driven disorder-to-order transition in a complex network of interacting molecules. However, none of these systems has “rules” of any sort that are comparable with the quasi-cybernetic Turing-machine-like operations typical of the processes of protein synthesis and the genetic code. It is as if every new feature of these non-genetic systems emerges *de novo* from functional disorder, whereas in genetically controlled catalytic systems functional novelty can be achieved by modularizing intact subsystems whose operation is restricted to a range of variation determined by the invariant mode of their informational encoding. In fact it is difficult to envisage how the precise specificity of differentiated processes needed to define diverse individual taxa could be maintained without recourse to some kind of information whose storage system was protected from the vagaries of thermal disturbance.

The same argument can be applied to systems which store information in a combinatorial rather than a sequential fashion. As a direct consequence of their very nature, “compositional genomes” (Segré *et al.*, 2000) have very limited information storage capacity and a recent study indicates that systems employing this mode of genetic information storage do not have the capability to evolve through natural selection (Vavas *et al.*, 2010). Even if they could, their limited information storage capacity would set a low upper bound on the functional specificity that could be achieved through genetic expression. The specific nano-level control of molecular biological processes requires a very high density of information storage, such as can be achieved in the sequences of nucleic acids. That is not to say that combinatorial information is not of functional significance in biological systems, the signal transduction code described by Barbieri (2003) being a pertinent example. Rocha and Hordijk (2005) have considered these problems from a quite general perspective and concluded that any system capable of evolution requires functionally useful information to be stored in some inert form so that it can serve as a stable representation from which alternative dynamic configurations of the system can be constructed.

The argument of Schrödinger (1944) concerning the need for some system of atomic or molecular information storage is as relevant to explaining the stability of the processes that

determine and maintain biological specificity as it is to explaining the stability of biological inheritance. It seems implausible that the level of structural and functional specificity typical of molecular biological systems could be stably maintained through relationships among the available dynamic states of an autocatalytic network, dispersed as these inevitably are across spatial domains much larger than any structural features of individual molecules. The conclusion that the level of functional specificity displayed by dynamic molecular biological systems requires informational specification in a form that can be contained in a region of space even much smaller than a single cell seems inescapable. On the other hand, this does not mean that Crick (1958) gave an adequate account of the character of the processes that determine biological specificity, for he neglected altogether the thermodynamic aspect of molecular biological information processing (as opposed to information storage) that Schrödinger referred to as the “negentropy” principle and which Kauffman (1993) and others have addressed in their analyses of disorder-to-order transitions, especially in far-from-equilibrium systems (Prigogine and Nicolis, 1971).

### “What is Life?” again

Even if the Sequence Hypothesis of Crick (1958) is taken to be a heuristic device rather than being empirically testable, its simplicity and elegance obscure a deeper flaw in the picture of how cells are able to maintain themselves and reproduce. That flaw has not been corrected during the decades in which it has been discovered that the biochemical control of intracellular processes is much more complicated and elaborate than it first appeared to be. No matter how refined a description of a cell’s molecular biology may be, if it implicitly assumes that the specificity of molecular biological processes originates solely in genetic sequence information then it fails as a scientific explanation because it gives no account of the origin of the means of interpretation of the information. Following Crick, one is forced to assume that the ribosomal machinery and all of the other components of the protein synthetic apparatus, or some earlier, simpler version of it, were provided by evolution as a molecular biological “free lunch”.

The genetic meaning of any nucleic acid sequence cannot be determined except within the context of a physico-chemical system that acts as an interpreter or constructor of some sort. And the hallmark of the molecular components of cellular interpreter/constructors is their extremely refined specificity of action. Furthermore, the integrated action of a large number of components with very specific structures and interactions is needed to maintain the specificity of any one of them. This could not be achieved in the absence of genetic information, as we have just observed, but it is equally true that nucleic acid sequences would be devoid of biological meaning in the absence of integrated, functional specificity. Thus, it could be said that biological specificity originates as much in itself as in the genetic information it uses to maintain itself.

On this basis a limited definition of elementary life may be given down the following lines: *a complex, microscopic, dynamic, physico-chemical system may be said to be living if recurrent synthesis of its structurally specific molecular*

*components occurs as a result of their mutual co-existence with a store of molecular information whose interpretation is defined by the processes occurring in the system.* This suggested definition expresses the maxim given as the title to this paper, that “life requires genetic representation and *vice versa*”, but compared to the enduring view of Crick (1958) it emphasizes a quite different aspect of genetic information in biological systems.

Crick (1958; 1970) described the role of genetic information in molecular biological systems in his Central Dogma, which is most easily stated in the form “once information has got into protein it can’t get out again”. Although application of the Central Dogma was limited to the determination of the polymeric sequences of nucleic acids and proteins, its combined effect with the Sequence Hypothesis, identifying specificity with sequence information, was to create a view, still widely held among molecular biologists, of genes as the ultimate determinants of all biological specificity. And this view has been elaborated even more widely in the neo-Darwinian interpretation of evolution, according to which genetic mutation is the ultimate source of all biological novelty (Dawkins, 1989).

Contrary to this picture of living systems portrayed by the Central Dogma and neo-Darwinism, the tentative definition of elementary life provided above gives prime place to the maintenance of self-representation in genetic information as the cardinal feature of living systems, not the determinative existence of genetic information *per se*. The Central Dogma is often stated as the epithet “DNA makes RNA makes protein” under the implicit assumption that the means of information transfer are a given. Biological information transfer is taken unproblematically to have arisen as a result of molecular selection. It is conceded that the elementary molecular biological interpreter (the apparatus of protein synthesis and the code) was somehow bootstrapped into existence through a series of molecular events which remain a fascinating physico-chemical puzzle, but the possibility that information theoretic aspects of the origin of coding were the dominant constraining features of the process is seldom contemplated. However, the current enquiry leads us to redirect attention into the origin of life to focus on the emergence of an interpreter of genetic information (Wills, 2009), not its accumulation through natural selection (Eigen, 1971).

### Origin of life

According to the definition espoused in this paper, the most important feature of life’s origin is the emergence of an autocatalytic system of molecular components whose synthesis has an obligatory dependence on extant information stored in some molecular/atomic form. At first the catalytic specificity represented in such a system is likely to have been very restricted and the amount of information stored very small. One could envisage a system in which the autocatalytic set comprised no more than early representatives of the Class I and II amino-acyl tRNA synthetase (AARS) proteins whose polymeric sequences were differentiated by the specific placement of amino acids from two distinguishable classes, perhaps {glycine, alanine} and {valine, aspartic acid}. Through their combined operation, these proteins would

mutually produce themselves as a result of their individual capabilities of roughly differentiating between two classes of primitive codons, perhaps {GGC, GCC} and {GUC, GAC} (Eigen and Winkler-Oswatich, 1981), in two special genetic sequences, which may even have been complementary nucleic acid strands (Rodin and Rodin, 2006). A precursor system may have employed a one-letter code for these four amino acids (Francis, 2011). Although this is all speculation it serves to illustrate in elementary form what the proposed definition of life takes to be the prime feature of molecular biological systems – the necessity of information-processing dependent constructive autocatalysis.

It has been demonstrated that some physico-chemical systems afford, even from initial conditions comprising completely random synthetic events, the stepwise autocatalytic emergence of increasingly specific coded information processing (Wills, 2009; Füchslin and McCaskill, 2001; Markowitz *et al.*, 2006). And what is most interesting is that the obligatory facilitating feature of the emergence of coding in such systems is the satisfaction of what may be described as informatic boundary conditions (Wills, 1993; Neiselt-Struwe and Wills, 1997). These conditions amount to constraints on the complex relationship between the distribution of catalytic activities among molecular structures and the specific genetic sequences needed by an autocatalytic set of information-dependent synthetases. When the appropriate informatic boundary conditions are satisfied coding can be sustained in the presence of a genetic sequence that serves as a self-representation of a particular autocatalytic set of information-dependent synthetases. Generalizing this feature of molecular biological information-processing leads to the conclusion that any definition of life must include some description of purely formal features of correspondences between symbolic sequences, of which particular polymers and their physico-chemical properties are no more than particular instantiations.

As a simple calculation demonstrates (Wills, 1993), a genetic sequence potentially interpretable as a source of information for coding autocatalysis has virtually zero probability of coming into existence as a result of undirected competition between replicating polymers. This leaves open only one plausible path to life: an autocatalytic system directing the selection of nucleic acids whose sequences are “reflexive” (Wills, 2001) *vis-à-vis* their translation into functional form, “interpretation as self-representation”. The coupling between autocatalytic processes and the replication of information polymers necessary to effect the directed selection of meaningful genes cannot occur in a homogeneous system (Wills, 1994; Füchslin and McCaskill, 2001) and therefore some sort of spatial localization of associated molecular processes is entailed in the very notion of emergent information-processing at the origin of life. Autonomous control of such localization is germane to the definition of life given by Gánti (2003) as well as the idea of a cellular autopoietic network (Maturana and Valera, 1980).

On these grounds it seems highly implausible that nucleic acids could attain any representational meaning of biological significance except through their natural selection as components of systems, which express the information in them. If life is defined, as proposed, in terms of the information-interpreter/constructor coupling observed in

extant molecular biological systems, then this amounts to saying that genetic representation is impossible except in spatially localized living systems. Our understanding of the emergence of an information-interpreter/constructor coupling at the origin of life is still primitive, the question having been addressed only in studies by Füchslin and McCaskill (2001) and Markowitz *et al.* (2006). At least the need for a non-equilibrium phase-transition in the dynamics of systems that synthesize polymers randomly has been established; as has the way in which the complexity of the alphabet for genetic representation can increase in a stepwise manner (Wills, 2009) leading to a rapid expansion in not only the amount of information that can be stored but also the specificity of function of individual molecular components that can be maintained in such systems.

Beyond the genetic code that determines the specificity of ribosomal protein synthesis there are many other modular processes in biological systems that are amenable to the direct transfer of symbolic information. Barbieri (2003) associates the emergence of higher level codes with major transitions in the trajectory of biological evolution.

## Synthetic biology

It is widely accepted that the life of every organism, however life is to be defined, is derived from the life of its parent(s) such that all terrestrial life can be traced back to a single origin some three to four billion years ago. If we assume that organisms always contain genetic information and we allow an abbreviated definition of the life of an organism as *recurrent synthesis of its structurally specific molecular components* then we see that there is inter-generational continuity in the specificity of the controlled, microscopic, irreversible processes occurring in cells as well as inter-generational continuity (with variation) in the genetic complement of cells. Life has continued as an unbroken chain since its origin because cells acquire their complex dynamic state, as well as their genes, through the processes of biological inheritance.

According to our proposed definition of life we can take genes to be sequences of symbols rather than the physical entities, the nucleic acids, in which they are instantiated. This is not in any way at odds with the manner in which molecular biologists have thought about and manipulated genes ever since the language of a genetic “code” was first developed. In fact the process of genetic engineering consists increasingly of procedures of calculation using symbolic sequences. The process of instantiating designed genes as DNA molecules and inserting them into cells is just the very last step in the typical production of a modified organism. Physical causation is of little consequence in the whole process.

In describing their latest enterprise with *Mycoplasma*, a team at the J. Craig Venter Institute claims to have created a new taxon, also referred to as a “synthetic cell”, by starting from digitized genome sequence information (Gibson *et al.*, 2010). In making the claim that the cell is synthetic these scientists are suggesting that mental processes have been in some way causative in bringing the cell into existence. The alternative is to accept a restriction to explanations in terms of physical causation, on which basis there is no distinction between what is natural and what is artificial or synthetic.

Adopting that point of view we would say that the modified organism came into existence as a result of the firing of particular neurons in particular human brains and particular changes in particular electronic circuits. However, the same result would have been arrived at through a quasi-infinite set of similar world-lines with nothing particular in common except their completely arbitrary specification as involving the same symbolic representations of genetic sequences. So, let us first accept the team's claim to some kind of causative agency. What is the extent of their agency in the cell's coming into existence?

The team started with an intact cell of *M. capricolum*, removed its DNA and replaced it with synthetic DNA, whose sequence had been copied from *M. mycoides* and then slightly altered. If, unbeknown to them, there had been a single error in the sequence they synthesized, corresponding to a fatal mutation, then they would have had no grounds to claim the creation of a synthetic cell. That being the case, it seems illegitimate to ascribe agency to symbolic information-processing associated with matter configured in human neurological form and no agency whatsoever to matter configured in the form of *M. capricolum*. This problem is not resolved by the statement of Gibson *et al.* (2010) that “the DNA software builds its own hardware”. In fact, ascribing constructive agency to an entity comprised of symbols (software) violates the scientifically conventional continuity of physical causation. By any normal delineation between physical and symbolic entities one would have to say that it is the hardware which builds itself by reading the information in the genetic software made available to it. A cell envisaged as computer hardware that can remain operational and transform itself to new specifications when the program it is executing to maintain itself is suddenly swapped for a different one seems more worthy of the descriptions “creative” and “innovative” than members of *H. sapiens*, conceived as assemblages of molecules which effect minor changes in DNA sequences *in vitro*. However, the idea espoused in the definition of life proposed in this paper is that agency in living systems arises from neither software nor hardware but from the coupling between them that corresponds to symbolic self-representation. [It is quite usual for biologists to ascribe some sort of active agency to natural selection, offering explanations such as “selection made a change to the system that improved function” (Johnson and Lam, 2010).]

Scientific discourse is ill-equipped to start defining the nature and extent of agency entailed in the autonomous operation of living systems, because there is no agreed formal description agency that can serve as a basis for either theoretical analysis or empirical enquiry. But then, without admitting that ethics are essentially about the status and rights that are appropriate to diverse agents, scientists have little hesitation in taking their own assessments of the significance of what they have done as a context for framing discussion of ethical aspects and implications of their field of research. As Gibson *et al.* (2010) state “We have been driving the ethical discussion concerning synthetic life from the earliest stages of this work”. It would be foolish to denigrate such efforts or the deliberations behind them. However, it is difficult to see how such a discussion could acquire any worthwhile depth in the absence of a penetrating critical analysis of global institutional structures that give inordinate weight to scientific perspectives

in which agency is treated as if its existence were purely metaphorical, except when associated with humans. More concerning this shortly.

## ALife and Living Technology

In terms of the definition of living systems proposed in this paper, creating an artificial form of life will entail the construction of a never-before-seen coupling between a self-maintaining, complex, physico-chemical system and its self-representation in a store of molecular information. It would be difficult to convince this author that a system whose primary mode of information transfer resembled ribosomal protein synthesis in any significant detail could qualify as being truly artificial. This assessment is made on the grounds that the self-representational information-interpreter coupling found in terrestrial biological systems constitutes a “design”. [It is noteworthy that use of the term “design” is not being restricted to symbolic representations associated with brain states of members of *H. sapiens* and their artefacts; or those belonging to other supposed intelligences, whether they be material, purely mental, aetherial, or spiritual, however such categories might be conceived of.] The design for specifying the construction of a supposedly artificial system employing nucleic acid to protein information transfer and mimicking details of ribosomal protein synthesis, in essence the life of the constructed system, could reasonably be called “(a) property” that had been appropriated, almost entirely, from an extant living system. A cell created from homogeneous preparations of individual components to operate as an encapsulated nucleic acid-protein-ribosome system would indeed qualify as an example of the “synthetic cell” that Gibson *et al.* (2010) actually have failed to achieve, but it would not be Artificial Life because its design would have been copied from the version of life found naturally occurring on this planet.

At this point it seems relevant to ask what might motivate construction of a form of Artificial Life that truly met the criteria that have now been outlined. It is nearly two centuries since Shelley (1818) identified the motivation to cobble together organisms from dead parts as a quest to take in hand the intrinsic power of what is conceived to be the principle of life; in mythological terms, the fire of the gods stolen from Zeus by Prometheus and given to mortals. For Bedau *et al.* (2010) the harnessing of such power is implicit in the creation of technology that incorporates the most basic features of living systems. Although they do not focus exclusively on Artificial Life, they deem technology to be living “if it is powerful and useful precisely because it has the core properties of living systems, including such properties as the ability to maintain and repair itself, to autonomously act in its own interests, to reproduce, and to evolve adaptively on its own” and predict that during our lifetimes we will see “technology that is robust, autonomous, self-repairing, self-reproducing, evolving, adapting, and learning — a powerful combination of life's core properties that no current technology yet embodies” with the final assessment that “this transition will be a truly singular event in human history”.

Although they acknowledge potential dangers, Bedau *et al.* (2010) see ripe opportunities for living technology in medicine, environmental sustainability, energy cycles,

advanced materials, individually adapted manufacture, self-organising software, *etc.* They also consider it possible to initiate an evaluation of living technology without either discussing the nature of life, except in terms of a list of core properties, or tackling the problem of “design” – the relationship between physical reality and its representation on which the natural/artificial divide is founded. These authors then find it unsatisfactory that most people think about *Frankenstein* (Shelley, 1818) or *Prey* (Crichton, 2002) when they hear about protocells – rather minimal artificial life forms far simpler than the most elementary modern bacteria – without even a hint that what they are proposing might fail to respect a value that is intrinsic even to the most primitive living systems. Humanity’s construction of ethics is only now beginning to adjust to the idea that our behaviour may be an affront to norms that precede our evolutionary arrival in the cosmos. Could it be that the historical transition envisaged by proponents of Artificial Life and Synthetic Biology will play out as the encounter of *H. sapiens* with some aspect of reality of which, so far, we have only the faintest inkling, the “life” we cannot yet adequately define, but which is as fixed and immovable in its reactive behaviour as the physical aspect of reality, something we will discover to our own self-determined peril? That is what *Frankenstein* (Shelley, 1818) is about primarily, not the shocking monster.

Both Gibson *et al.* (2010) and Bedau *et al.* (2010) make it clear that the prospect of creating Artificial Life raises new questions of ethics and they appeal to well-accepted values like human health, environmental sustainability and human rights as the proper context for in-advance ethical evaluation of the emerging technology. Elsewhere, another group (Bedau *et al.*, 2009) has proposed ethical guidelines for enterprises concerned with artificial cells; and the ramifications of current activity in Synthetic Biology has been subjected to quite detailed analysis (Rabinow and Bennett, 2009), albeit from a perspective deeply imbued with the values of postmodernity (Forman, 2010). Laudable though these efforts are, none involves consideration of the possibility that the socially constructed motivation for pursuing Artificial Life, that is, the appropriation by *H. sapiens* of nature’s inherent capacity for self-construction through symbolic representation, may be misdirected in the sense that it will ultimately prove to be a mode of self-destruction rather than self-construction. How are we to judge?

The remainder of this paper can be taken as an illustrative approach to this problem, an attempt to start down a pathway that may assist to conceive of and realise a different representation of humanity’s future.

## Global, historical implications

Scientists are generally unlikely to warm to much of his philosophy, let alone his politics, but Martin Heidegger has to be credited with having set in motion many of the last century’s most profound considerations relevant to the relationship between physical reality, its representations and its utility. The early Heidegger (1939) was convinced by Aristotle’s portrayal of the real world whose processes are open to observation (*physis*; nature) as more than a succession of material states. He found the role of *techné* (technique, know-how) as a cause of change in the world to be crucial for

a proper understanding of human reality. In his discussion of Aristotle’s truism “a human being is generated from a human being, but not a bedstead from a bedstead” (since Antiphon had observed that, at most, a tree would grow from a planted wooden bedstead), Heidegger (1939) explains that there has been a historical misunderstanding of the role of *techné* in the generation of things that grow, as opposed to artefacts. Elsewhere he describes *physis* as “the realm of things that emerge and linger on” (Heidegger, 1959) conceiving of nature’s essence in terms more biological than simply physical or mechanical. According to Heidegger, our misconstruing of nature as a self-making artefact provides the ground for our mastering nature through technology and making it subject to our own narrow purposes. The later Heidegger (1977) is more concerned with the historical consequences of our technological mastery of nature and he characterizes technological society’s consciousness of the real world as *Ge-stell* (“En-framing”), a conception that leads us to treat existence, our own even, as *Bestand* (“standing reserve”), at hand, ready for use.

Whether or not one is sympathetic to Heidegger at all, he is the major figure in a philosophical tradition that can hardly be ignored by scientists finally seeking to exercise, in advance, some responsibility for actions of theirs that may have momentous historical consequences. One of the things we learn from that tradition is to question the structure of consciousness and its dependence on the vagaries and arbitrariness of internal constructs, especially as these influence and constrain our conception of nature; and that means bringing to bear rigorously, in a self-reflective fashion, considerations and critical analyses from all disciplines, especially those that challenge the complacency of the modern scientific perspective and the culture of power in which it is embedded. In respect of assessing the value of Artificial Life, we have to ask, outside of the comfort of the cultural context of our own experience, what each of the things that self-evidently has value, like health, environmental sustainability, and human rights, actually is; from what more general point of view might these things have value (and therefore justify the pursuit of ALife); whether they have anything like a “natural” connection to terrestrial life; and therefore whether these values are related to ALife in a way that may not become obvious in the process of creating the technology. The ethical issues raised by Artificial Life cannot be framed without deconstructing some of the most basic tenets of international law, global business practice and even scientific experimentation, namely, human ownership of and control over the functional processes and genetic identity of biological systems. While Rabinow and Bennett (2009) conclude their considerations of the ethical ramifications of Synthetic Biology by alluding to some of these problems, their descriptions of the relevant research activities accept proponents’ ideas of technological progress and its legitimacy rather unquestioningly.

Normative values like wealth, innovation, growth, health and security, derived from spheres of predominantly economic, medical and military activity in what is known to itself as “the developed world”, provide a poor basis for determining humanity’s relationship with complex biological systems. It is clear that science is now losing much of its previously proud independence from such norms. As Forman

(2010) shows, the moment we attempt to investigate how modern global society places science and technology in relation to its normative values, we see that science has been downgraded and technology upgraded in cultural rank. This process has occurred during the last three decades or so, the exact period during which the basic properties and functions of living systems have started to become objects of human exploitation. Artificial Life and Synthetic Biology are both positioned as primarily technological rather than scientific enterprises, with strong links to the privileged economic base of global human power (Rabinow and Bennett, 2009). The effect of the recent elevation of technology above science can be seen in the research community itself. The methodical, disinterested scientist has been displaced by the single-minded entrepreneur, who resourcefully pursues self-interest with clever disregard for apparently irrelevant aspects of prevalent codes of practice. Attention or lip-service to ethics is integrated into a system of shallow legitimization of whatever is deemed desirable and economically achievable by those who seek, or have become accustomed to, the power that shifts into the sphere of the new technology.

Rather than accepting this state of affairs and assuming that Darwinian forces operating in various institutional, social, economic and legal systems will finally determine what is of value, we are in a position to use the forces of reason and conscience to evaluate and choose what contribution we make to science and technology. There are some broad lessons to be learned by taking history as our guide, lessons that have to do largely with the state of ignorance, rather than knowledge, that obtains in any particular epoch. Humanity's current global crises are aggregations of the effects of many local actions conceived and conducted largely in the absence of any perception of their possible broader consequences. However, even scientifically informed and motivated judgments can result directly in consequences that turn out, with hindsight, to be undesirable because the science of any epoch, our own included, is limited to over-arching assumptions that cannot be guaranteed to do justice to all of reality. For example, the early Darwinian naturalist Walter Buller believed that the replacement of endemic avian species in New Zealand by superior exotic types was a foregone conclusion. He shot the already rare *huia*, now extinct, so that there would be forever preserved, in far off imperial museums, good specimens of this species, unique on account of its sexually differentiate mandibles (Buller, 1873).

In what potential ways could current conceptions of Artificial Life be proved inadequate in respect of actions, performed now, being deemed, on the basis of subsequent experience, later to have been based on profound ignorance?

### Assessing future prospects

If, as has been proposed in this paper, the cardinal feature of living systems is the self-representing ("reflexive"), information-interpreter/constructor coupling which emerged on the planet in its most primitive manifestation with the origin of the genetic code some three to four billion years ago; and if, associated with major evolutionary transitions, the establishment of further couplings of that character enabled more complex versions of biological autonomy based on the exchange of symbolically encoded information between

differentiated subsystems (Barbieri, 2003); and if the general possibility of such couplings is a purely formal feature of the cosmos, not necessarily related in any specific way directly to any detailed feature of the particular physical universe that we happen to inhabit; then, because biology lacks concepts adequate for the task of answering the question "What is life?", we are indeed profoundly ignorant of the consequences that may follow from our appropriation of the fundamental processes of biological causation in pursuit of short-term institutional or societal goals.

If there is anything that should bear the name "bioethics" then it is not to be found in the endless committee considerations of the immediate consequences of experimentation in genetic manipulation, cloning or reproductive biology, but rather in a critical enquiry into the intrinsic value which various forms of life bear relative to one another simply on account of their biology. The recent appearance of "sustainability" on the global political agenda is one of the few causes for optimism, for it demonstrates a nascent recognition of not only past human failures but also the need, for survival, to give effect to the sense that the high intrinsic value that we assign to ourselves, primarily on account of our consciousness, has an intimate connection with the much more prosaic "health of the biosphere". Seen within that context the biotechnological commodification of the terrestrial version of life might indeed be interpreted as the arrogation of value which has a natural location outside of human control.

Therefore, it would seem unwise to pursue the creation of Artificial Life simply because it is technically possible to do so and because it holds the promise of further power for *H. sapiens*. There is much evidence that humanity is ill-equipped to handle the complex distribution of power over nature and global society that technologies have already conferred, often resulting in irreversible losses due to uncontrollable processes, all uncompensated by any increase in value elsewhere. The fundamental modes of biological causation are far more obscure and convoluted than those of mechanical, thermal or nuclear technology. Seizing the power offered by "living technology" and using it to further current human interests, while failing to recognize the intrinsic value of the systems being tinkered with, is likely to result in a recapitulation of errors made in the deployment of other transforming technologies. It is singularly inappropriate that scientists whose consciousness is embedded in a privileged culture which already wields global power should create and propagate, according to their perceptions of what is of value to humanity and nature, a new mode of controlling the most fundamental processes of nature – those that make life itself possible. The scientific community owes it to the rest of global society to engage in a broad-ranging discussion concerning the disposition of the power that the new technologies of Artificial Life and Synthetic Biology make available, instead of attempting to reassure a skeptical public that their unfounded fears are guaranteed to evaporate into thin air as a result of appropriate education framed in terms of current scientific concepts. This author is one scientist who does not hold to the majority opinion that Artificial Life is a value-free scientific enterprise and wishes to endorse his work as follows.

It is the author's wish that no agency should ever derive military or purely financial benefit from the publication of this paper. Authors who cite this work in support of their own are requested similarly to qualify the availability of their results.

# Evolutionary Transition through a New Multilevel Selection Model

Shelly Xiaonan Wu<sup>1</sup> and Wolfgang Banzhaf<sup>1</sup>

{xiaonan, banzhaf}@mun.ca

## Abstract

Most multilevel selection models in the literature focus on addressing the evolution of cooperation. There is, however, another aspect of multilevel selection theory. It might be able to provide explanations for evolutionary transitions, which involve the creation of higher level complexes out of simpler elements. Here, we propose a multilevel selection model to support evolutionary transitions. This model employs a genetic operator called “cooperation” to build the hierarchical structure used in multilevel selection theory, and applies two types of multilevel selection to achieve transitions. Our experiments on an extended N-player Prisoner's Dilemma game demonstrate that groups with all required skills emerge from a population of independent individuals, no matter whether skills are equally rewarded or not. Our experiments confirm that both types of multilevel selection mentioned are relevant to evolutionary transitions.

## Introduction

Our biological world is hierarchically organized. Starting from the bottom level to the top, the hierarchy includes atoms, molecules, organelles, cells, tissues, organs, organ systems, organisms, populations, communities, ecosystems and biospheres. It is also generally accepted that the simpler, smaller components appeared before the more complex, composite systems. The creation of new higher level complexes out of simpler entities is referred to as an “evolutionary transition” (Buss, 1987; Michod, 1999; Smith and Szathmáry, 1995).

How and why evolutionary transitions take place during evolution is an important question to address for biologists and sociologists. Increasingly, multilevel selection (MLS) has been suggested as a potent explanation (Michod, 1999; Smith and Szathmáry, 1995; Sober and Wilson, 1999). MLS theory posits that natural selection may simultaneously operate at multiple levels of the biological hierarchy. Multilevel selection theory has its origins in group selection theory, which initially was aimed to explain the evolution of cooperation<sup>1</sup>: Individuals are divided into groups; within-group

selection favors selfish individuals, while between-group selection favors cooperative individuals. When between-group selection dominates within-group selection, a major transition occurs and the group becomes a higher level organism in its own right (Wilson and Wilson, 2007).

The way to explain evolutionary transitions extends MLS theory in an important new way. Nevertheless, investigations of most existing MLS models focus on the conditions necessary for the emergence of cooperation during evolution. The purpose of this paper is to computationally verify the idea that evolutionary transitions can indeed occur through multilevel selection. To this end, we consider a new MLS model and investigate its ability to exploit the division of labor. A crucial step in many of the major transitions (Smith and Szathmáry, 1995) is the division of labor between components of an emerging higher level unit of evolution (Gavrillets, 2010). This new MLS model distinguishes itself from existing MLS models in two ways. First, it integrates two types of multilevel selection (Okasha, 2005), which are believed to be relevant to the evolutionary transitions, each at a different stage. To encourage a transition, group fitness (fitness of higher level units) is defined to be “decoupled” (Michod and Nedelcu, 2003) from the individual fitness (fitness of the lower level units). Second, the model does not take the existence of the hierarchical structure for granted; multicellular organisms do not exist at the beginning of life. Our model constructs the hierarchy through evolutionary transitions. The experiments shown here confirm that in appropriately defined models independent individuals are able to transit to groups with totally different functionalities using multilevel selection; in terms of the division of labor, those are groups with members executing various skills with possibly different rewards.

The remainder of this paper is organized as follows. Section 2 briefly describes multilevel selection theory, especially the two types of multilevel selection. Section 3 in-

ponent of a multilevel theory of evolution. Many strong advocates of other alternatives in explaining the evolution of cooperation have come to accept multilevel analysis (Borrello, 2005; Okasha, 2001, 2008; Wilson, 1983).

<sup>1</sup>Group selection is a longstanding controversial area in the evolution of cooperation. It recently re-emerged as an important com-

troduces our multilevel selection model. Section 4 shows experiments with the model and their results. Section 5 concludes and discusses future work.

## Multilevel Selection

Group selection (Sober and Wilson, 1999) tries to explain the evolution of cooperation by introducing selection between groups. Between-group competition allows traits to arise from evolution that are costly for individuals but beneficial to groups. This is therefore one mechanism by which cooperation is able to emerge in evolution. Individuals and groups, however, are relative: an entity can be regarded as a group for individuals at the level below, and as an individual of a group at the level above. This new perspective is now called multilevel selection (MLS) theory.

When higher level selection (i.e. between-group selection) dominates lower level selection (i.e. within-group selection), an evolutionary transition occurs (Wilson and Wilson, 2007). The reason that individuals would give up their survival and reproductive opportunity to become a part of complexes is that the complexes are able to protect their members from being eliminated by selection. For example, by hunting together or by watching predators for others, members in a group have a greater chance to survive severe competition. In addition, a consequence of higher level selection is adaptation, which minimizes conflict among lower level entities and increases cooperation. Therefore, lower level selection does not interrupt the formation of higher level entities (Okasha, 2005).

For the hierarchical structure used in MLS with a number of individual entities nested within each group entity, we need to clarify which entities should become the objects of evolution or which level should undergo evolution (Okasha, 2005). If we are interested in the changing frequencies of different individual traits, individual entities will be the objects of evolution; group entities are only a structure or an environment where fitness-affecting interactions take place. Most multilevel selection models proposed for the evolution of cooperation, such as Wilson (1975)'s and Traulsen and Nowak (2006)'s models, belong to this kind. These models focus on how to propagate the altruistic trait among individuals in a population. To this end, groups are regularly formed and evaluated. Groups with more altruists will have a higher fitness; hence cooperative individuals in such groups will have higher probabilities to be reproduced. In other words, groups are only temporary fitness-bearing entities; even though they are selected, it is not them but individuals that are reproduced, and also it is the frequency of individual traits that is changed. This type of MLS is called MLS type 1 (MLS1) (Damuth and Heisler, 1988; Okasha, 2005).

Alternatively, if we are interested in the changing frequencies of different group traits, group entities need to be the objects of evolution. They are not merely an environment to in-

dividual entities or an object of selection; they actually have their own heritable traits. Group entities with higher fitness will reproduce more offspring group entities with similar traits. Individual entities may still undergo evolution within each group entity, which leads to changes in the distribution of individual traits and potentially affects group traits. This type of MLS is called MLS type 2 (MLS2) (Damuth and Heisler, 1988; Okasha, 2005). As a result, since the entities undergoing evolution are different in these two types of multilevel selection, the evolutionary changes obtained on each level are different. MLS1 will contribute the most individual entities to the next generation, while MLS2 will contribute the most groups. Both MLS1 and MLS2 are distinct processes that can occur in nature.

According to Okasha (2005), both types of multilevel selection may be relevant to evolutionary transitions. An evolutionary transition is more complicated than the evolution of cooperation. However, before transitions take place and complexes emerge, simpler entities which constitute the complexes have to be able to work together. They need to sacrifice their individuality and exhibit cooperative traits. Therefore, in the early stage of evolutionary transitions, the evolution of cooperation has to emerge, so that cooperative traits can spread among simpler entities in the population. That is exactly what MLS1 promotes: using groups as an environment to help individual traits to propagate. Once individuals are willing to form cohesive complexes, evolution should work on complexes to gradually develop their own traits. In other words, complexes should now themselves become objects of evolution. Through selection and reproduction, complexes are better adapted to their environment and eventually become discrete units, normally with traits different from their constituents' traits. It follows that MLS2 should be applied at a later stage of an evolutionary transition.

The shift from MLS1 to MLS2 also indicates a change in the definition of group fitness. In MLS1, group fitness is defined as the average fitness of the individuals within a group, while in MLS2, group fitness is defined independent of the average fitness of its individuals. As the transition proceeds, group fitness gradually becomes "decoupled" from individual fitness (Michod and Nedelcu, 2003), until it is no longer closely related to the average individual fitness. Once group fitness is decoupled, the transition has been achieved, and new complexes have been created that assume an existence of their own.

## A New MLS Model

The concept of multilevel selection is very simple: levels are like "Russian matryoshka dolls" (Wilson and Wilson, 2008) nested one within another; selection simultaneously operates on every level and favors different types of adaptations. Many models have been proposed based on this concept (see Wu and Banzhaf (2011) for examples). However, their main

focus is to investigate under which conditions the evolution of cooperation will occur or what mechanisms could promote the evolution of cooperation. Furthermore, these models take the hierarchical structure in a MLS for granted; that is, they treat the hierarchical structure as given. Biological hierarchies, on the other hand, have developed gradually; a good example is the evolution of multicellular organisms: it did not exist at the beginning of life. We therefore need to consider other MLS models to explain evolutionary transitions: how simpler entities form complexes and how complexes emerge as discrete units with traits different from their constituents.

This contribution aims at introducing such a new multi-level selection model for evolutionary transitions. The investigation uses the division of labor as an example. Division of labor is a group trait resulting from evolutionary transitions, where low level independent entities with specialized skills cooperate to increase the reproductive success of high level complexes. Examples include the separation of germ and soma cells in simple multicellular organisms, appearance of multiple cell types and organs in more complex organisms, and emergence of casts in eusocial insects (Gavrilets, 2010).

We adopt the extended N-player Prisoner's Dilemma (NPD) game to study the division of labor. The NPD game (Sober and Wilson, 1999) is the classical setting for addressing the evolution of cooperation. Once cooperation is reached, all players possess the same cooperative trait, which is also the only trait required for cooperation. Even if such cooperation breaks down by loosing some individuals, the rest are still capable of cooperating with others. Evidently, the game does not serve the need for investigating the division of labor unless extensions are made. We first change the NPD game by attaching a new trait called "skill" to each player; then we redefine the goal of the NPD game: find  $N$  players who not only are willing to cooperate but also possess all required skills.

The general framework of our model is illustrated in Fig. 1. This model accommodates two types of entities:

Figure 1: A general framework of the new MLS model

individuals (white circles) and groups (black circles). The initial population contains individuals and groups on level 0, which are composed of two randomly selected individuals. The genome of individuals carries two genes. One gene has two variants (alleles); one allele codes for cooperators, the other for defectors. When the former trait is expressed, the individual is said to be a cooperator; otherwise, it is a defector. The other gene encodes the skill possessed. An individual's fitness is determined by the following equations, depending on whether it is a cooperator (C) or a defector (D):

$$f_{C_i}(x) = base + w \left( \frac{b(n_i q_i - 1)}{n_i - 1} - c \right), \quad (0 \leq i < m) \quad (1)$$

$$f_{D_i}(x) = base + w \frac{b n_i q_i}{n_i - 1}, \quad (0 \leq i < m) \quad (2)$$

where  $m$  is the number of groups in the population;  $base$  the base fitness of cooperators and defectors;  $q_i$  the fraction of cooperators in group  $i$ ;  $n_i$  the size of group  $i$ ;  $b$  and  $c$  are the benefit and cost caused by the altruistic act, respectively;  $w$  is a coefficient. From the above fitness definitions, it becomes clear why the initial population must contain groups on level 0: those groups are the smallest units in which the individual fitness can be evaluated. This fitness definition also implies that cooperation is not supported at the individual level, as cooperators always have lower fitness than defectors. Because individuals are unaware of what skills are needed without higher level entities being formed, the skill trait has no effect on the individual fitness.

Groups in the evolution of cooperation simply pool individuals together; however, groups in our model have their own genotype definition, which is represented by a boolean list. Each position in the list is connected to a unique skill, so that the genotype of a group can keep track of all different skills of its members. When a skill is possessed by at least one cooperator in a group, the corresponding position in the genotype is set to true (we say is activated); when the skill is no longer possessed by any cooperator in that group, we inactivate the position by setting it to false. Again, compared to groups in the evolution of cooperation, groups here require their members to develop different skills, not just to cooperate. As a result, groups exhibit more traits than simply the cooperative trait of individuals. Genetically, groups in our model are ready for evolutionary transitions.

From level 0, an operator called "cooperation" starts to build the hierarchical structure level by level. In each generation, it selects two existing groups proportional to fitness to form a new group. For example, as highlighted in Fig. 1, a group on level 0 and a group on level 2 can be made to cooperate in a new group on level 3. After the cooperation operator is applied, the genotype of the new group contains all unique skills from the two parent groups. This operator allows evolution to tinker with varying group memberships in order to find the best combination of individuals and groups

at lower levels for a higher level function. It in fact is a genetic operator for selecting and reproducing groups; therefore, heritable traits of groups can pass from parent groups to offspring groups. Other genetic operators, such as crossover and mutation, can also be applied to groups. Because groups should be the objects of evolution, multilevel selection of the MLS2 type is employed here.

Group fitness is defined as follows.

$$g(y) = \frac{\sum_{i=0}^n f_{idv}(x_i)}{n} \times \frac{active_{geno}(y)}{length_{geno}(y)} \quad (3)$$

It measures the performance of a group in two respects: (i) the average individual fitness of its  $n$  members and (ii) the percentage of activated skills in the genotype. The intention behind this fitness definition is straightforward; the first part encourages the appearance of cooperators, as cooperators improve the overall individual fitness, and the second part rewards groups in which cooperators possess as many different skills as possible. Obviously, this group fitness is not defined as the average individual fitness, but it can be either proportional to average individual fitness, or completely “decoupled” from individual fitness, depending on the influence of the second term of the fitness function. According to Okasha (2005), the former indicates the transition from MLS1 to MLS2, and the latter indicates the groups have fully emerged as discrete units. Both encourage evolution to reach transitions.

Individuals also evolve. To do so, a group is first selected proportional to fitness; an individual is then selected from this group as a parent. For simplicity, asexual reproduction is considered here. Obviously, even though the survival of individuals is now associated with the performance of their group, individuals at this stage are the objects of evolution. Groups provide context for individual fitness evaluation and selection. Hence, multilevel selection of type MLS1 is applied here.

The specific computational implementation of the framework is shown in Algorithm 1. It begins with initialization.  $N$  individuals,  $r$  percent of which are cooperators, are randomly created and exclusively paired into groups at level 0. Groups at level 0 have their fitness evaluated right away.

In each generation, only one group is created by the cooperation operator, which selects two groups proportional to fitness to create a new group. The consequence of cooperation is the increase of group complexity or the appearance of new levels in the hierarchical structure. To prevent levels from ceaselessly growing, we assign every individual a unique number as its  $ID$ ; no individuals with the same  $ID$  can appear within the same group. After fitness evaluation, the new group is added to the population  $P$ . If at that point the maximum number of groups, say  $N'$ , is reached, another group has to be removed from the population selected inversely proportional to fitness. To highlight the effect of the

cooperation operator, crossover and mutation on groups are currently not included.

We also asexually reproduce  $n$  individuals every generation. Individuals are selected proportional to fitness from another selected group, instead of from the pool of individuals. The offspring inherits its parent’s genome, and further replaces the genome of a less fit individual in the individual pool. The absolute fitness of individuals in the pool is determined by the average fitness of its copies (i.e. individuals with same  $ID$ ) in all groups. Individuals from the pool are allowed to participate in composing more than one group, so they may have multiple copies in different groups. Depending on group composition, they have different fitness within groups. So the simplest way to determine their absolute fitness is to average the fitness of all copies.

After an individual in the pool is replaced, the change needs to be implemented in all groups that contains the copy of the replaced individual. The group fitness and individual fitness of affected groups need to be updated, accordingly.

We repeat the process until a termination condition has been reached or the population converges.

In summary, this new model distinguishes itself from other multilevel selection models in two ways. First, it integrates two types of multilevel selection, both of which are believed to be relevant to the evolutionary transitions (Okasha, 2005). Individual evolution with the help of group selection is analogous to multilevel selection type 1 (MLS1). It propagates cooperators in the population, which is a prerequisite of evolutionary transitions. Group evolution is then analogous to multilevel selection type 2 (MLS2). The selection pressure on group levels forces groups to evolve adap-

tations for regulating conflicts among their members. The adaptations indicate that groups emerge as discrete entities with heritable traits. Second, instead of taking the hierarchical structure resulting from evolutionary transitions for granted, our model introduces a “cooperation” operator to create higher level complexes out of simpler ones.

## Experiments

In the experiments, we closely examine the transition by our multilevel selection model to the division of labor from a population of independent individuals. First, we examine the ability of our model to evolve groups fulfilling various numbers of skills, when all skills receive the same reward. Second, we examine the dynamics within the model and the responses of individuals when different skills are given different rewards.

### Experimental Setup

The experiments are conducted on the extended NPD game with a population of 200 individuals and a maximum of 50 groups on level 1 and above. The initial fraction of cooperators in the population is 0.5; half of the individuals play cooperators in the game, while the other half are defectors. Eq. 1 and Eq. 2 are used to calculate the fitness of cooperators and defectors within a group, respectively. The base fitness *base* is set to 10, benefit *b* to 5, cost *c* to 1, and coefficient *w* to 1 in these two equations<sup>2</sup>. Group fitness is calculated according to Eq. 3. Group size is a self-adaptive parameter affected by the cooperation operator.

Because the purpose of these experiments is to study the division of labor, our investigation will focus on the effects of two parameters: the number of desired skills and the rewards associated with each skill. For each parameter setting, we ran the model 20 times, each with 5000 generations. We measure the performance of the model by the probability of fixation to cooperators  $P_{fixation}$  and the number of activated skills  $S_{activated}$ .  $P_{fixation}$  is computed as the ratio of the number of runs where population converges to cooperators over 20 runs. We also collect the convergence speed  $S_{converge}$  in each run, which is the number of generations after which group fitness stops to change.

### Varying Skills

The first experiment is given 5 different skills. At initialization, individuals independently choose to be a cooperator or a defector. In addition, they need to randomly pick a skill from 5 skills, {1, 2, 3, 4, 5}. An individual with an attached skill will perform a specific task. The best performing group

should contain only cooperators and should have all 5 skills presented in its genotype. We then gradually increase the number of desired skills to 10, 15 and 20. For each setting, we run the algorithm 20 times. The results are collected in Table 1. The probability of fixation  $P_{fixation}$  with a value of 1 is obtained under all settings, which indicates that defectors, despite a relatively high individual fitness, are eliminated from the population, whereas cooperators dominate the population eventually. MLS1 is the explanation for this result. More importantly, the best performing group for each setting develops all required skills through evolution. This demonstrates that MLS2 is at work. It is not surprising to see the larger the number of desired skills, the slower the population was to reach the equilibrium on group fitness. This is simply a reflection of the problem becoming harder when the number of desired skills is raised.

To get a better idea of how the division of labor develops through evolution, we select a typical run for each of {5, 10, 15, 20} roles for further analysis. Figure 2 depicts the maximum and average number of unique skills of all groups over 500 generations. Starting from at most 2 skills, the best performing groups gradually evolve to perform more and more different skills until the number of desired skills is reached (see Fig. 2a). This growth is due to the guidance provided by the group fitness. Take the run for 20 desired skills for example. We collect the following information from this run: group fitness, the number of activated roles, and the percentage of cooperators in the best performing group, as well as the percentage of cooperators in the population; that is plotted in Fig. 3.

Group fitness (refer to Eq. 3) is determined by the average individual fitness and the percentage of activated skills. We plot the percentage of cooperators, instead of the average individual fitness, in the best group because of two reasons; we can easily extrapolate the average individual fitness from this percentage, and it also shows the fixation process in the best group. Figure 3 clearly shows how the percentage of cooperators and the number of activated roles affect the group fitness. Interestingly, we notice that the population converges to cooperators first, and then the best group develops all required skills. The same trend is also observed in other runs with {5, 10, 15} skills. This observation indicates that cooperators spread in the population before the evolutionary transition happens, a result confirming the discussion about the relationship between MLS1 and MLS2. Group fitness, in turn, influences the execution of individual evolution and group evolution (i.e. cooperation operator). Since defectors bring no fitness benefit on group levels, they are eliminated from the population by group selection at reproduction; hence the percentage of cooperators in the best group and in the population increases steadily towards 1. As shown in Fig. 2b, the average number of activated skills never comes close to the number of desired skills. This implies that the population maintains groups with various

<sup>2</sup>Sensitivity analysis of our model wrt. the initial fraction of cooperators and selection pressure (*w*), as well as a performance comparison with an improved Traulsen’s group selection model (Wu and Banzhaf, 2011) can be found in (Wu, 2011). These experiments confirm that our model promotes cooperation over a wider range of parameter settings.

Settings	$P_{fixation}$	$S_{activated}$	$S_{converge}$
$role = 5$	1	5	96.3
$role = 10$	1	10	181.55
$role = 15$	1	15	247.60
$role = 20$	1	20	301.25

(b) Average number of unique skills

Figure 2: The changes of the maximum and average number of unique skills in a typical run.

skills. They are potential building blocks, out of which the cooperation operator is able to test different combinations of existing groups, and gradually hones in on optimal groups with all required skills.

In summary, our model is able to successfully evolve groups with all desired skills for the extended NPD game; or we can say that our model is able to evolve groups to engage in the division of labor between equally rewarded skills.

Figure 3: The changes of group fitness, percentage of cooperators and activated roles when 20 skills are set.

## Varying Rewards

We continue the exploration of whether or not our model can evolve the division of labor, but this time skills are unequally rewarded. The different rewards put extra pressure on accomplishing the task, as it attracts individuals to specialize on the most rewarding skills while avoiding the less rewarding skills.

To distinguish skills with different rewards, we refer to the “leader/follower” situation described by Goldsby et al. (2009). Individuals who have skill 1 are appointed as leader of that group, while individuals performing other skills are followers. Leaders receive different reward than followers, but followers, no matter what specific skills they have, receive no other rewards. A coefficient,  $\alpha$ , is used to control how much reward a leader can receive. Coefficient  $\alpha$  basically is a multiplicative of the individual fitness; the individual fitness of a leader is calculated as the product of  $\alpha$  and the individual fitness obtained by Eq. 1 or Eq. 2.

We vary the value of  $\alpha$  in the range of  $\{0.5, 2, 4, 8, 64\}$  on each of  $\{5, 10, 15, 20\}$  roles, and run the model on each setting 20 times. The performance is summarized in Table 2. Clearly for each setting the population converges to cooperators as a result of MLS1, and the best performing group is composed of cooperative individuals with all required skills as a result of MLS2.

Because the group fitness can hardly converge in this experiment, the convergence speed  $S_{converge}$  is judged by the stabilization of  $P_{fixation}$  and  $S_{activated}$ . Fig. 4 displays a typical run when the number of desired skills is set to 5 and coefficient  $\alpha$  is set to 8. Although the percentage of cooperators in the population and the number of activated skills in the best group converge quickly (around generation 350), group fitness and the percentage of leaders in the best group never stop increasing. After generation 350, the percentage of leaders is the only factor that changes the group fitness. Leaders in this case receive much higher rewards than followers, and maximizing this percentage at the same time maximizes the group fitness. Therefore, both values

Table 2: The performance of runs when leaders are assigned with various rewards.

Figure 4: A typical run when skills=5 and  $\alpha=8$ .

are constantly improving. Because there is no upper bound on group size, the cooperation operator keeps creating larger groups with more leaders; therefore an equilibrium distribution of different roles can hardly be reached.

To facilitate the investigation on how different rewards affect the division of labor, we restrict the maximum group size to 20. We plot in Fig. 5 the percentage of leaders in the best performing group collected from a typical run with 5 desired skills when  $\alpha$  is set to each of  $\{0.5, 2, 4, 8, 64\}$ . When  $\alpha$  is set to 0.5, 5% of 20 individuals, which is only 1 individual, play the role as a leader, while when  $\alpha$  is set to 2, 55% of the group, that is 11 individuals, choose to be a leader; similarly, 15 out 20 individuals (75%) become the leader when  $\alpha$  is 4 or 8, and 16 leaders (80%) when  $\alpha$  is 64.

When  $\alpha$  is less than 1, leaders are in fact receiving a penalty, not a reward. Very naturally, individuals avoid be-

Figure 5: The percentage of leaders in the best group when  $\alpha$  is set to 0.5, 2, 4, 8, 64, respectively.

coming a leader, but because of the selection pressure on the group level, the role of a leader must be present in a group. Therefore, the best group ends up with only 1 leader, which maximizes the group fitness. By contrast, when  $\alpha$  is greater than 1, individuals strive to be leaders because of the positive reward. An  $\alpha$  value of 64 shows another extreme distribution of different roles. Driven by such a significant reward, the best group only has 4 individuals as followers, each for the rest 4 skills, while all other individuals play the role as a leader. The higher the reward, the greater the number of leaders in a group, and the slower the population converges (see  $S_{converge}$  column in Table 2).

The experiment perfectly shows the adaptability of our model in response to changes in group selection pressure, and the importance of selection pressure on group levels in

developing division of labor. Selection pressure eliminates defectors from a population, adjusts the distribution of roles according to the received reward or penalty, and forces all skills to be present even though some of them have lower fitness than others.

## Conclusion

In this paper, we considered a new multilevel selection model to investigate evolutionary transitions. This model introduces a genetic operator called “cooperation” to create higher level complexes out of simpler ones of lower levels. Different types of selection, MLS1 and MLS2, are integrated in the model to determine whether or not the complexes are able to transit to discrete units with their own heritable traits. We test the transition ability of the new model on an extended N-player Prisoner’s Dilemma game for achieving the division of labor from a population of independent individuals. The experiments confirm that our model is able to evolve groups fulfilling various numbers of skills whether skills are equally rewarded or not. The experiments also demonstrate that multilevel selection, both MLS1 and MSL2, are necessary for transitions to occur. MLS1 propagates cooperators in a population. Only when participating individuals are willing to cooperate, will evolutionary transitions occur. MLS2 forces complexes to evolve adaptations for regulating conflicts among their members. The adaptations are guided by group fitness, which in our model is decoupled from individual fitness to promote the appearance of new group traits. In future work, we seek to adapt this model for evolutionary computation to solve problems where transitions are needed.

## Abstract

A virtual elastic robot is proposed which has a body with multiple degrees of freedom. It is capable of fitting its body to the given surrounding environment. This study focuses to allow the elastic robot to adapt to various environments. The intended robot is modeled by rigid objects connected by spring joints in a circular structure. Its control system manipulates spring actuators to realize elastic movements. This paper aims to acquire its control system for the robot to behave autonomously. A behavior acquisition is implemented as an optimization problem by the use of Evolutionary Computation. A physical simulation on the computer is carried out to achieve given tasks for the virtual elastic robot. The task is set to achieve a locomotion which moves toward a destination on a flat ground. Simulation results show that the elastic robot acquires a locomotion. Moreover, we assume a complicated circumstance in which obstacles are placed. In order to allow the robot to adapt to a complicated circumstance, we propose "Behavior Composed" to design a complicated behavior from several simple behaviors. These experimental results prove that the robot is capable of acquiring an adaptive locomotion in specific circumstances.

## Introduction

An autonomous robot is capable of adapting itself to the surrounding environment. This paper focuses on a behavior acquisition for it which can behave to achieve a given task. Accomplishing the task is regarded as a learning problem for autonomous robots. It has been studied actively in areas such as evolutionary robotics and artificial life.

In order to construct an adaptive behavior, a bottom-up approach or evolutionary approach is adopted in recent works. This approach aims to construct an optimum control system so as to achieve a given task by a parameter optimization. It is generally implemented by the use of evolutionary computation. There are many studies to acquire autonomous behaviors by computer simulations (Sims, 1994). As the typical methodology, a virtual creature (Sims, 1994) is proposed to generate the geometric morphology for a model structure and a neural system for controlling a creature automatically. The virtual creature indicated a problem what shape would be optimum to accomplish a task. Similarly, a

behavior emergence and an evolution of the artificial creature become a significant problem in the area of artificial life.

The virtual creature (Sims, 1994) is expected to design the specialized shape in a specific environment. However, the obtained model cannot exploit its adaptive ability in other environment. Therefore, we have focused on an autonomous robot which has a body with multiple degrees of freedom (DOF) and its behavior acquisition. It can behave flexibly such as an amoeba and a snake. There are many studies to design an adaptive behavior for their original robots (Yim et al., 2000; Kamimura et al., 2005; Ishiguro et al., 2008; Yoneda et al., 2009).

The self-reconfigurable robots have a multiple DOF body and consist of simple modules (Yim et al., 2000; Kamimura et al., 2005). Controlling the robot is generally studied by the use of a rule-based control which is described by the specific behavior rule for each module (Yim et al., 2000). Then, an evolutionary heuristic approach is adopted instead of a traditional rule-based approach to control its behavior (Kamimura et al., 2005). However the obtained behaviors are a only simple. The robot cannot behave in the complicated situation. Then, an amoeboid robot (Ishiguro et al., 2008) is proposed to make it possible to behave flexibly. It has a circular structure body which is connected by springs joints and behaves based on a mathematically-modeled protoplasmic streaming motion which is the specific feature of an amoeba. Although it can behave to move toward a light source, it has not obtained composite behaviors.

In those background, we have focused on a circular structure spring robot as a multiple DOF robot, an elastic circular robot (Yoneda et al., 2009). Previously, we have shown that the robot can acquire a locomotion by the use of the decentralized autonomous control system and evolutionary computation. In recent works on behavior acquisition for multiple DOF robots, it is confirmed that the robot can achieve a simple task. For instance, the straight locomotive task on a flat ground without obstacles is regarded as a simple task. However, their robots cannot behave properly in a complicated circumstance in which obstacles are placed. There-

fore, this study aims to acquire an adaptive behavior in a complicated circumstance. We propose "Behavior Composed" which consists of several simple behaviors to design an adaptive behavior for a multiple DOF robot. Learning experiments are carried out to design "Behavior Composed" for the elastic circular robot. Simulation results show the effectiveness of the proposed control approach.

The rest of this paper is composed as follows. Section II explains about a concept of proposed control system, "Behavior Composed". Section III proposes an elastic circular robot consisting of modular units. Section IV describes learning experiments to acquire an autonomous locomotion and shows some experimental results. Section V describes learning experiments to design "Behavior Composed" to adapt to the complicated circumstance. Section VI concludes this study with some remarks and gives some directions toward the future work.

### "Behavior Composed"

In order to acquire an autonomous composite behavior for a mobile robot, the subsumption architecture (Brooks, 1986), which is a layered control system, is proposed as a typical approach. It consists of several primitive behaviors, such as "avoid objects", "wander", "explore", "build maps" and so on. They are assigned to each layer hierarchically based on their priorities. The robot behaves properly by using a selected primitive behavior as the situation demands. This control system shows good performance in a complicated situation. However, its behavior is an unnatural behavior, because each primitive behavior is previously designed.

Then, we have proposed "Behavior Composed" to design an adaptive behavior by the use of Evolutionary Computation (Furukawa et al., 2010). Fig. 1 shows the concept of "Behavior Composed". It consists of several primitive behaviors, "Behavior Simple". "Behavior Simple" is obtained by a learning experiment of a simple task. As the situation demands, the robot combines several "Behavior Simple" to design "Behavior Composed". For instance, a wandering behavior is a combination of three behavior simples, "avoid object", "runaway" and "halt" (Fig. 1).

We have implemented "Behavior Composed" by using an Artificial Neural Network (ANN) (Furukawa et al., 2010). "Behavior Composed" consists of Neural Controller ("Behavior Simple") and Neural Selector (Fig. 2). In the previous work (Yoneda et al., 2010), we conduct two types of learning experiments (simple task and complicated task). The simple task aims to acquire locomotion on a flat ground as a primitive behavior. Then, the complicated task aims to acquire "Behavior Composed" in which obstacle is placed. From experimental results, we confirmed that the robot is capable of an adaptive behavior by switching several "Behavior Simple". This paper focuses on the decentralized "Behavior Composed" that each actuator is controlled by the independently-selected "Behavior Simple".

### Elastic Circular Robot

#### Body System

An intended elastic robot is modeled by connecting rigid modules circularly with spring joints (Fig. 3). All modules have the same prismatic shape. They are connected to four modules by two spring actuators and two spring joints. This robot can behave by the elastic motion of springs and the friction force between the modules and ground. The robot behavior is controlled by manipulating elastic velocities of each spring actuator. Accordingly, all modules move by propagating spring forces to the whole modules efficiently.

The followings are physical properties used for the robot. The robot is constructed from 20 modules. The density of each module is 2,700[kg/m<sup>3</sup>]. The coefficient of restitution of each module is 0.3. The coefficient of dynamic friction between the modules and the ground is 0.4. The coefficient of static friction between the modules and the ground is 0.6. The natural length of each spring actuator is 0.2[m]. The natural length of each spring joint is 0.4[m]. All spring lengths are able to range from 0.5-fold to 1.5-fold in length. The spring constant is 500[N/m].

#### Sensor System

This elastic robot aims to achieve a locomotive task that the robot mainly moves toward the goal. Then, a goal sensor is installed on each module to perceive a target location. The goal sensor of the *i*-th module is capable of perceiving a

distance  $d_{Li}(t)$  measured from the  $i$ -th module to the goal at time  $t$ . However, when the obstacle is placed between the  $i$ -th module and the goal, the sensor cannot perceive its goal (Fig. 4). Similarly, an obstacle sensor is installed on each module to measure a distance to the nearest obstacle. The obstacle sensor of the  $i$ -th module is capable of perceiving a distance  $d_{Oi}(t)$  which is the shortest distance to the nearest obstacle at time  $t$ .

### Spring Actuator

Expansion and compression of springs make mainly this module move. Each spring actuator is controlled independently by adding an elastic force calculated by Eq. (1).

$$f_i(t + \Delta t) = A_i(t) \sin(\omega_i(t)\Delta t + \phi_i(t)) \quad (1)$$

where  $f_i(t)$  is the elastic force of the  $i$ -th spring actuator at time  $t$ ,  $A_i(t)$  is the amplitude,  $\omega_i(t)$  is the angular velocity,  $\phi_i(t)$  is the accumulated phase ( $\phi_i(0) = 0$ ,  $\phi_i(t + \Delta t) = \phi_i(t) + \omega_i(t)\Delta t$ ). If  $f_i(t) > 0$ , the spring is expanded, and if  $f_i(t) < 0$ , it is compressed. Thus, the behavior of the whole body is controlled by manipulating  $A_i(t)$  and  $\omega_i(t)$  for the  $i$ -th spring actuator.

### Neural Controller

In order to control the robot behavior, each spring actuator has a neural controller. Each neural controller is implemented by ANN to acquire an autonomous behavior in evolution. Neural controller manipulates an elastic force independently for the corresponding spring actuator to realize a decentralized autonomous control system. The controller has eight input neurons and two output neurons to calculate control parameters  $A_i(t)$  and  $\omega_i(t)$ .

In this paper, we implement two types of neural controller. The first one is  $C_L$  which has a light sensor to perceive a light source. The other is  $C_{LO}$  which has a light sensor and an obstacle sensor to perceive a light source and the nearest obstacle. Input parameters of controller are sensor information of connected modules and state variables of the actuator. For two modules  $a$  and  $b$  that are connected by the  $i$ -th spring actuator, the target information ( $L_a(t)$  and  $L_b(t)$ ) is calculated from a distance  $d_{La}(t)$  and  $d_{Lb}(t)$  by Eq. (2). Similarly, The obstacle information ( $O_a(t)$  and  $O_b(t)$ ) is calculated from a distance  $d_{Oa}(t)$  and  $d_{Ob}(t)$  by Eq. (3).

$$L_i(t) = \begin{cases} e^{-\alpha d_{Li}(t)} & (\text{if module } i \text{ receives light}) \\ 0 & (\text{otherwise}) \end{cases} \quad (2)$$

$$O_i(t) = e^{-\beta d_{Oi}(t)} \quad (3)$$

where  $\alpha$  and  $\beta$  are constant values. We set  $\alpha = 0.8$  and  $\beta = 1.0$ .  $L_i(t)$  and  $O_i(t)$  take 1.0 at the maximum value and decays in the inverse ratio to the measured distance.

As state parameters for the  $i$ -th actuator, a current spring length  $l_i(t)$ , an accumulated phase  $\phi_i(t)$ , an amplitude  $A_i(t)$ , phase coherences  $R(\phi_i(t), \phi_{i-1}(t))$ , and

Figure 4: Sensor system and neural controller

$R(\phi_i(t), \phi_{i+1}(t))$  are also input to the controller. The phase coherences are phase differences between the  $i$ -th spring actuator and adjacent actuators. They are calculated by Eq. (4).

$$R(\phi_a(t), \phi_b(t)) = \frac{1}{2} \| e^{j\phi_a(t)} + e^{j\phi_b(t)} \| \quad (4)$$

Then, the controller outputs  $A_i(t)$  and  $\omega_i(t)$  as control parameters for Eq. (1). Fig. 4 shows a configuration diagram of the ANN which has a feed-forward network with a three-layered structure. The controller  $C_L$  has eight input neurons and the controller  $C_{LO}$  has ten input neurons. Both controllers have ten hidden neurons and two output neurons. The synaptic weights of ANN, bias values of neuron and temperature coefficients of the sigmoid function are optimized to acquire an adaptive behavior.

## Acquisition of "Behavior Simple"

### Behavioral Acquisition

A simulation experiment is carried out to achieve a task for a given elastic circular robot. This experiment implements a numerical simulation to optimize parameters of ANN for all spring actuators to acquire an adaptive behavior. All ANNs have the same parameters to simplify the parameter optimization. Then all ANNs are a homogeneous neural controller. In order to optimize parameters assigned to one of ANNs, we adopt the real-coded genetic algorithm (RCGA).

In order to allow the robot to accomplish a task, the simulation environment is implemented by the use of a physics computing library PhysX<sup>1</sup>. PhysX<sup>1</sup> is able to numerically calculate a position and a velocity of the object in consideration of a gravity, a friction, and collision detections. Additionally, we assume a noisy environment as a fluctuation effect in the real world. Then, noises are added to the ANN in each simulation step. The noise is a normal real random number and its strength is 1.0% against each input value.

<sup>1</sup>NVIDIA PhysX

[http://www.nvidia.com/object/physx\\_new.html/](http://www.nvidia.com/object/physx_new.html/)

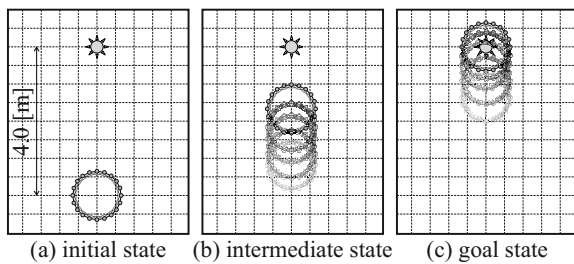

Figure 5: An outline of a task to move toward a light source

## Experimental Conditions

A learning experiment is carried out to acquire an adaptive behavior for the robot. It aims to acquire a locomotive behaviors, moving toward a light source, as a "Behavior Simple". Fig. 5 is an outline of the learning experiment. In this task (Fig. 5), a light source is placed around 4.0[m] from the center of gravity of the robot at the initial condition. The robot behaves autonomously by using the controller  $C_L$ . The obtained behaviors are evaluated by Eq. (5).

$$E_1 = \sum_{t=0}^{N_s} \sum_{i=1}^{N_m} d_{Li}(t) \quad (5)$$

where,  $N_s$  is the number of steps in a simulation and  $N_m$  is the number of modules of which the robot consists.  $E_1$  plays a role of a fitness function to evaluate a photo-tactic behavior. It evaluates an accumulated distances between each module and the light source during one episode simulation. RCGA optimizes the controller  $C_L$  so as to minimize  $E_1$  and results become adaptive behaviors.

As experimental conditions, the simulation step time  $\Delta t$  is 1/60 [sec]. The number of simulation steps in one episode simulation  $N_s$  is 3,600. As optimization conditions for RCGA, the number of individuals is 30, the number of generations is 500, the probability of crossover is 80 [%] and the probability of mutation is 30 [%]. They are determined empirically and this work does not discuss about a difference in those parameters. In order to observe obtained behaviors, we conduct this learning experiment five trials in the same conditions.

## Experimental Results

Fig. 6 shows a diagram which shows the evaluated value along the vertical axis and the number of generations in RCGA along the horizontal axis. The evaluated values for the best and worst trial, and the average evaluated value of all trials are plotted in this diagram. In this figure, the obtained evaluated value of each trial converges as the RCGA generation elapses. Fig. 8 shows snapshots of the obtained behaviors at the 500th generation in RCGA. For this behavior, Fig. 7 shows a diagram which shows the distance between the robot and the light source along the vertical axis and the elapsed simulation steps along the horizontal axis.

Figure 6: An evaluated value of the locomotive task in each RCGA generation

Figure 7: A distance to the destination in each simulation step

As the RCGA generation elapses, it is observed that behaviors are obtained to move toward the light source and stay close to its goal. Therefore, this experiment shows that the robot is capable of achieving the locomotion task.

An optimization experiment shows that the elastic robot acquire a locomotive behavior to achieve a given task. Then, we observe a motion mechanism for the obtained behavior. Fig. 9 shows a diagram which shows the elastic force calculated by using the obtained controller along the vertical axis and the elapsed simulation steps along the horizontal axis. In this charts, lines assigned by "a", "b", "c" and "d" correspond to four actuators respectively in Fig. 8. Fig. 9 indicates a motion at the 1,000th step while the robot is moving. It is observed that four actuators output their elastic forces with the same frequency. Additionally, they make a phase difference locally from a front actuator to a rear actuator in the direction of movement (Fig. 8(b)).

In this way, phase differences of output values make it possible to propagate elastic forces to the whole body effectively. Then, we observe the global phase difference for all actuators. Fig. 10 shows an analysis result for all actuators. The horizontal axis and the vertical axis show the elapsed simulation steps and the label of each actuator. This figure indicates the sign of the elastic force of each actuator in a motion at the 1,000th step. In this chart, the mark "A", "B", "C" and "D" correspond to four parts in Fig. 8. From this result, it is confirmed that all actuators make a phase difference from a front part to a rear part in the movement direction.

Figure 8: Obtained locomotive behaviors at the 500th generation

Figure 9: An output elastic force in each simulation step

Figure 10: An output sign in each simulation step

## Acquisition of "Behavior Composed"

### Complicated Task

The experiment in the previous section aims to acquire a locomotion which behaves toward a light source. However, the previous experiment is not supposed to accomplish a task in consideration of an obstacle. Fig. 11 is an outline of the complicated task. This task also aims to move toward the light source on a flat ground. However, the obstacle is placed to interrupt light information. In the initial state, the robot can perceive its goal incompletely (Fig. 11(a)). Then, the robot has to explore its goal to reach there.

In order to show the difficulty to achieve the task, we verify behaviors for the locomotive controllers which are obtained in the previous section. Fig. 12, 13, 14 and 15 show the verification results. Fig. 12 and 14 show snapshots of behaviors by using the obtained controller in RCGA trials. Fig. 13 indicates the sign of the elastic force of each actuator in a motion of Fig. 12 at the 1,000th step like Fig. 10. Fig. 15 also indicates the sign of the elastic force of each actuator in a motion of Fig. 14 at the 1,000th step. From Fig. 12 and

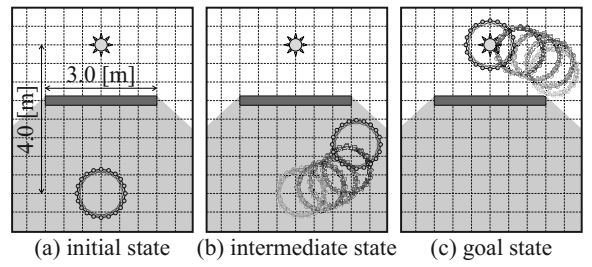

Figure 11: An outline of a task to search a light source

Figure 12: A verification result of the searching task for the locomotive controller obtained in the first trial

Figure 13: An output sign in each simulation step for the locomotive controller obtained in the first trial

14, those behaviors cannot behave properly. Because, those controllers have not learned the situation which cannot perceive the light source in the previous experiment. Although they cannot achieve the task, we confirm that their behavior has different characteristics in the unlearning situation by comparing Fig. 13 and 15.

### Behavioral Acquisition of "Behavior Composed"

We observed that the robot cannot behave properly by the use of the obtained locomotive controller (Fig. 12 and 14). Then, in the complicated task (Fig. 11), a learning experiment is carried out to acquire an adaptive behavior which avoids the obstacle and moves toward the light source. This experiment aims to acquire "Behavior Composed" to achieve the task. In order to solve this problem, we focus on the obtained locomotive behaviors in the previous section. In the previous experiment, we observed that some behaviors are obtained by conducting optimization trials repeatedly. They are capable of achieving the locomotive task (Fig. 5). However, we confirmed that they have diverse be-

Figure 14: A verification result of the searching task for the locomotive controller obtained in second trial

Figure 15: An output sign in each simulation step for the locomotive controller obtained in the second trial

haviors in unlearning situation (Fig. 11). The purpose of this experiment is to examine how to establish "Behavior Composed" by combining diverse behaviors.

### Experimental Conditions

In order to establish "Behavior Composed", a neural selector is installed on each actuator. Fig. 16 shows a configuration diagram of a neural selector. It outputs priorities to determine the appropriate "Behavior Simple" with a maximum priority. Each priority  $p_{ij}$  is corresponding to the  $j$ -th optimized controller ("Behavior Simple") for the  $i$ -th actuator. In this experiment, we set three types of controllers which obtained in the previous section as "Behavior Simple". They are chosen randomly from five obtained controllers, and capable of locomotion as the common capability. Then, each actuator selects an appropriate controller by the use of its neural selector at each simulation step.

This experiment implements numerical simulation to optimize parameters assigned to the ANN for all neural selectors like the previous learning experiment. All ANNs also have the same parameters. The optimization evaluates obtained behaviors based on Eq.(6).

$$E_2 = \sum_{t=0}^{N_s} \sum_{i=1}^{N_m} L_i(t) + A \quad (6)$$

where,  $N_s$  is the number of steps in a simulation,  $N_m$  is the number of modules of which the robot consists, and  $A$  is the transit area cost (Fig. 17). The first term plays a role of a fitness to evaluate a photo-tactic behavior. It evaluates how

Figure 16: ANN structure of neural selector

Figure 17: An evaluation of an area cost

much all modules receive a light during one simulation. The second term plays a role of a fitness to evaluate an exploring behavior. Then, when the robot cannot perceive the light source,  $E_2$  evaluates the transit area. RCGA optimizes the neural selector so as to maximize  $E_2$  and results become adaptive behaviors. This optimization is expected to acquire behaviors that a robot avoids the obstacle and moves toward a bright area.

In order to show the effectiveness of the proposed approach, we conduct the same experiment without "Behavior Composed" as a comparison experiment. In this experiment, we set the robot which has the controller  $C_{LO}$  to perceive the light source and the nearest obstacle. This comparison experiment optimizes the controller  $C_{LO}$  like the previous experiment. Then, we confirm the evaluated values and the obtained behaviors for two types of learning experiments.

As experimental conditions, the simulation step time  $\Delta t$  is 1/60 [sec]. The number of simulation steps in one episode simulation  $N_s$  is 5,400. The optimization conditions for RCGA use a set of values the same as the previous experiment. In order to observe obtained behaviors, we also conduct this experiment five trials in the same conditions.

### Experimental Results

Fig. 18, 19 and 20 are experimental results for the optimization of the controller  $C_{LO}$ . Fig. 18 shows a diagram which shows the evaluated value along the vertical axis and the number of generations in RCGA along the horizontal axis. The evaluated values for the best and worst trial, and the average evaluated value of all trials are drawn in this diagrams. For this result, Fig. 19 and 20 show snapshots of the obtained

Figure 18: An evaluated value of the searching task in each RCGA generation

Figure 19: Obtained searching behaviors at the 50th generation

Figure 20: Obtained searching behaviors at the 500th generation

behaviors for the best trial at the 50th and 500th generations in RCGA. It is observed that behaviors are obtained to reach the light source as the RCGA generation elapses. However, The converged evaluated value of the worst trial is about one third of the converged value of the best trial.

Similarly, Fig. 21, 22 and 23 are experimental results for the optimization of a neural selector to acquire "Behavior Composed". Fig. 21 shows a diagram which shows the evaluated value along the vertical axis and the number of generations in RCGA along the horizontal axis. Fig. 22 and 23 show snapshots of the obtained behaviors for the best trial at the 50th and 500th generations in RCGA. In this result, it is observed that the obtained behavior achieves the given task even a behavior obtained at the 50th generation (Fig. 22). Moreover, each trial obtains a better evaluated value than one of the comparison experiment. Then, these results show that "Behavior Composed" has a good performance to establish an adaptive behavior.

For the obtained behavior (Fig. 23), we observe a feature

of the optimized neural selector. Fig. 24 indicates the elastic force of each actuator at the 1,000th step. The horizontal axis and the vertical axis show the elapsed simulation steps and the label of each actuator. Fig. 25 shows a selected "Behavior Simple" in a motion at the 1,000 step. In those figures, the mark "A", "B", "C" and "D" correspond to four parts in Fig. 23(a). From Fig. 24, the robot can behave making proper phase difference like Fig. 10. Additionally, from Fig. 25, we observe that the obtained neural selector switches two "Behavior Simple" periodically. In particular, by comparing Fig. 24 and 25, we also confirm that the switching frequency of "Behavior Simple" equals to the frequency of an elastic motion. Then, the neural selector would switch "Behavior Simple" to make the specific rhythm pattern and phase differences between neighboring actuators.

Now, we observe the behavior, which reaches the light source, in a motion. Fig. 26 shows a selected "Behavior Simple" in a motion at the 3,000th step. Then, when the robot reaches the light source, its neural selector mainly uses one "Behavior Simple". This mean that each "Behavior Simple" has a locomotive ability in this situation.

## Conclusions and Future Works

We have focused on an elastic robot and its physical simulation. Behavioral acquisition for the virtual elastic robot in simulation can be regarded as a learning problem how the robot acquires the adaptive behavior. Evolutionary computation is a successful approach to this learning problem. This study is summarized as follows.

1. A locomotive behavior is acquired when each actuator makes a phase difference of an elastic force from a front actuator to a rear one in the movement direction.
2. "Behavior Composed" is acquired to adapt to the unlearning situation by combining obtained locomotive behaviors, "Behavior Simple".

The searching task shows that the proposed approach is capable of acquire an adaptive behavior at the only 50th generation. It is equivalent to the obtained behavior which obtained at the 500th generation without "Behavior Composed". Then, our approach is possible to acquire proper behavior effectively in a short time. For these experiments, moving images are put on our website<sup>2</sup>. The followings are the rest as some challenges in a future work.

1. Analyzing a switching mechanism mathematically for the obtained "Behavior Composed".
2. Applying "Behavior Composed" to the other multiple DOF robots which have other types of body structure.

## Abstract

Creating gaits for legged robots is an important task to enable robots to access rugged terrain, yet designing such gaits by hand is a challenging and time-consuming process. In this paper we investigate various algorithms for automating the creation of quadruped gaits. Because many robots do not have accurate simulators, we test gait-learning algorithms entirely on a physical robot. We compare the performance of two classes of gait-learning algorithms: locally searching parameterized motion models and evolving artificial neural networks with the HyperNEAT generative encoding. Specifically, we test six different parameterized learning strategies: uniform and Gaussian random hill climbing, policy gradient reinforcement learning, Nelder-Mead simplex, a random baseline, and a new method that builds a model of the fitness landscape with linear regression to guide further exploration. While all parameter search methods outperform a manually-designed gait, only the linear regression and Nelder-Mead simplex strategies outperform a random baseline strategy. Gaits evolved with HyperNEAT perform considerably better than all parameterized local search methods and produce gaits nearly 9 times faster than a hand-designed gait. The best HyperNEAT gaits exhibit complex motion patterns that contain multiple frequencies, yet are regular in that the leg movements are coordinated.

## Introduction and Background

Legged robots have the potential to access many types of terrain unsuitable for wheeled robots, but doing so requires the creation of a gait specifying how the robot walks. Such gaits may be designed either manually by an expert or via computer learning algorithms. It is advantageous to automatically learn gaits because doing so can save valuable engineering time and allows gaits to be customized to the idiosyncrasies of different robots. Additionally, learned gaits have outperformed engineered gaits in some cases (Hornby et al., 2005; Valsalam and Miikkulainen, 2008).

In this paper we compare the performance of two different methods of learning gaits: parameterized gaits optimized with six different learning methods, and gaits generated by evolving neural networks with the HyperNEAT generative encoding (Stanley et al., 2009). While some of these

Figure 1: The quadruped robot for which gaits were evolved. The translucent parts were produced by a 3D printer. Videos of the gaits can be viewed at <http://bit.ly/ecalgait>

methods, such as HyperNEAT, have been tested in simulation (Clune et al., 2009a, 2011), we investigate how they perform when evolving on a physical robot (Figure 1).

Previous work has shown that quadruped gaits perform better when they are *regular* (i.e. when the legs are coordinated) (Clune et al., 2009a, 2011; Valsalam and Miikkulainen, 2008). For example, HyperNEAT produced fast, natural gaits in part because its bias towards regular gaits created coordinated movements that outperformed gaits evolved by an encoding not biased towards regularity (Clune et al., 2009a, 2011). One of the motivations of this paper is to investigate whether any learning method biased towards regularity would perform well at producing quadruped gaits, or whether HyperNEAT's high performance is due to additional factors, such as its abstraction of biological development (described below). We test this hypothesis by comparing HyperNEAT to six local search algorithms with a parametrization biased toward regularity.

An additional motivation is to test whether techniques for evolving gaits in simulation, especially cutting-edge evolu-

tionary algorithms, transfer to reality well. Because HyperNEAT gaits performed well in simulation, it is interesting to test whether HyperNEAT can produce fast gaits for a physical robot, including handling the noisy, unforgiving nature of the real world. Such tests help us better understand the real world implications of results reported only in simulation. It is additionally interesting to test how more traditional gait optimization techniques compete with evolutionary algorithms when evolving in hardware. A final motivation of this research is simply to evolve effective gaits for a physical robot.

## Related Work

Various machine learning techniques have proved to be effective at generating gaits for legged robots. Kohl and Stone presented a policy gradient reinforcement learning approach for generating a fast walk on legged robots (Kohl and Stone, 2004), which we implemented for comparison. Others have evolved gaits for legged robots, producing competitive results (Chernova and Veloso, 2005; Hornby et al., 2005; Zykov et al., 2004; Clune et al., 2009a, 2011, 2009b,c; Téllez et al., 2006; Valsalam and Miikkulainen, 2008). In fact, an evolved gait was used in the first commercially-available version of Sony’s AIBO robot (Hornby et al., 2005). Except for work with HyperNEAT (Clune et al., 2009a, 2011, 2009b,c), the previous evolutionary approaches have helped evolution exploit the regularity of the problem by manually decomposing the task. Experimenters have to choose which legs should be coordinated, or otherwise facilitate the coordination of motion. Part of the motivation of this paper is to compare the regularities produced by HyperNEAT to those generated by a more systematic exploration of regularities via a parameterized model.

## Problem Definition

The gait learning problem aims to find a *gait* that maximizes some performance metric. Mathematically, we define a gait as a function that specifies a vector of commanded motor positions for a robot over time. We can write gaits without feedback — also called open-loop gaits — as

$$\vec{x} = g(t) \quad (1)$$

for commanded position vector  $\vec{x}$ . The function depends only on time.

It follows that open-loop gaits are deterministic, producing the same command pattern each time they are run. While the commanded positions will be the same from trial to trial, the actual robot motion and measured fitness will vary due to the noisiness of trials in the real world.

For the system evaluated in this paper, we chose to compare open-loop gaits generated by both the parameterized methods and HyperNEAT. An interesting extension would

Figure 2: (a) Top-down perspective of the robot with the nine joints and associated servos labeled. (b) The robot in a flat pose with the hip joint centered. (c,d,e) Various views of a pose in which the hip joint is rotated.

be to allow closed-loop gaits that depend on the measured servo positions, loads, voltage drops, or other quantities.

The ultimate goal was to design gaits that were as fast as possible. Our performance metric was thus displacement over the evaluation period of 12 seconds. Details of how this displacement was measured are given below.

## Experimental Setup

### Platform Details

The quadruped robot in this study was assembled from off-the-shelf components and parts printed on the Objet Connex 500 3-D Printing System. It weighs 1.88 kg with the on-board computer and measures approximately 38 centimeters from leg to opposite leg in the crouch position depicted in Figure 1. The robot is actuated by 9 AX-12+ Dynamixel servos: one inner joint and one outer joint servo in each of the four legs, and one servo at the center “hip” joint. This final unique servo allows the two halves of the robot to rotate with respect to each other. Figure 2 shows this unique motion, as well as the positions and numerical designations of all nine servos. Each servo could be commanded to a position in the range  $[0, 1023]$ , corresponding to a physical range  $[-120^\circ, +120^\circ]$ . The computer and servos can be powered by two on-board batteries, but for the tests presented in this paper power was provided by a tethered cable.

All of the computation for gait learning, fitness evaluation, and robot control was performed on the compact, on-board CompuLab Fit-PC2, running Ubuntu Linux 10.10.

Figure 3: A Nintendo Wii remote provided the location of the robot by tracking the infrared LED mounted on the robot’s antenna. The position was measured in pixels and transmitted from the Wii remote to the robot via bluetooth.

The slowest portion of code was HyperNEAT, which took less than one second per generation to run (excluding physical evaluations). Thus, we chose not to offload any computation. All gait generation, learning, and fitness evaluation code, except HyperNEAT, was written in Python and is available on our website (<http://bit.ly/ecalgait>). HyperNEAT is written in C++. We controlled the servos with the Pydynamixel library, sending commanded positions at 40Hz. The robot connected to a wireless network on boot, which enabled us to control it via SSH.

Robot gaits are defined by a Python *gait function* that takes time (starting at 0) as a single input and outputs a list of nine commanded positions (one for each servo). To safeguard against limb collision with the robot body, the control code cropped the commands to a safe range. This range was  $[-85^\circ, +60^\circ]$  for the inner leg servos,  $[-113^\circ, +39^\circ]$  for the outer leg servos, and  $[-28^\circ, +28^\circ]$  for the center hip servo.

### Fitness Evaluation Details

To track the position of the robot and thus determine gait fitness, we mounted a Nintendo Wii remote on the ceiling and an infrared LED on top of the robot (Figure 3). The Wii remote contains an IR camera that tracks and reports the position of IR sources. The resolution of the camera was 1024 by 768 pixels with view angles of about  $40^\circ$  by  $30^\circ$ , which produced a resolution of 1.7mm per pixel when mounted at a height of 2.63m. At this height, the viewable window on the floor was approximately 175 x 120 cm.

A separate Python tracking server ran on the robot and interfaced with the Wii remote via bluetooth using the CWiid library. Our fitness-testing code communicated with this server via a socket connection and requested position updates at the beginning and end of each run.

As mentioned earlier, the metric for evaluating gaits was the Euclidian distance the robot moved during a 12-second run on flat terrain. For the manual and parameterized gaits, the fitness was this value. The HyperNEAT gaits stressed the motors more than the other gaits, so to encourage gaits that did not tax the motors we penalized gaits that caused the servos to stop responding. When the servos stopped responding they could, in nearly all cases, be restarted by cycling power, though over the course of this study we did have to replace four servos that were damaged. The penalty was to set the fitness to half of the distance the robot actually traveled. We tested whether the servos were responding after each gait by commanding them to specific positions and checking whether they actually moved to those positions. This test had the additional benefit of rewarding those gaits that did not flip the robot into a position where it could not move its legs, which HyperNEAT also did more than the other learning methods. Because the fitness of HyperNEAT gaits were often halved, in results we compare actual distance traveled in addition to fitness for the best gaits produced by each class of gait-generating algorithms.

Since only a single point on the robot — the IR LED — was measured for the purposes of computing fitness, it was important that the position of the IR LED accurately reflect the position of the robot as a whole. To enforce this constraint, the robot was always measured while in the *ready* position (the position shown in Figure 1). This was done to prevent assigning extra fitness to, for example, gaits that ended with the robot leaning toward the direction of travel (this extra distance would not likely generalize in a longer run, which is why we did not want to reward this behavior).

In order to measure the start and end position in the same pose, and to ensure fair fitness evaluations with as little noise as possible, we linearly interpolated the motion of the robot between the ready position and the commanded gait,  $g(t)$ . As shown in Figure 4, the instantaneous robot limb configuration during the first and last portions of the evaluation was an interpolation between the initial ready position and  $g(t)$ ; during the rest of the evaluation, the robot followed the commanded gait exactly.

The only human intervention required during most learning trials was to occasionally move the robot back into the viewable area of the Wii remote whenever it left this window. Initially this was a rare occurrence, as the gaits did not typically produce motion as large as the size of the window (roughly 175 x 120 cm). However, as gaits improved, particularly when using HyperNEAT, the robot began to walk out of the measurement area a non-negligible fraction of the time. Whenever it did so, we would discard the trial and

Figure 4: Motion was interpolated linearly between a stationary pose and the commanded gait  $g(t)$  for one second at the beginning of each run and two seconds at the end, as shown above. The position of the robot was measured at the beginning and end of each run (red circles) in the ready pose.

repeat it until the gait finished within the window. While this process guaranteed that we always obtained a measurement for a given gait before proceeding, it also biased some measurements downward. Because the performance of the robot on a given gait varied from trial to trial, a successful measurement was more likely to be obtained when the gait happened to perform poorly. This phenomenon was negligible at first, but became more pronounced as gaits began traversing the entire area. HyperNEAT gaits were especially likely to require additional trials, meaning that the reported performance for HyperNEAT is worse than it would have been otherwise. Future studies could employ an array of Wii remotes to increase the size of the measurement arena.

## Gait Generation and Learning

We now describe the classes of gait-generating algorithms.

### Parameterized Gaits

By a *parameterized gait*, we mean a gait produced by a parameterized function  $g(t; \vec{\theta})$ . Fixing the parameters  $\vec{\theta}$  yields a deterministic motion function over time. We tried several parametrizations on the robot and, upon obtaining reasonable early success, settled on one particular parametrization, which we call *SineModel5*. Its root pattern is a sine wave and it has five parameters (Table 1).

Intuitively, *SineModel5* starts with 8 identical sine waves of amplitude  $\alpha$  and period  $\tau$ , multiplies the waves for all outer motors by  $m_O$ , multiplies the waves for all front motors by  $m_F$ , and multiplies the waves for all right motors by

Parameters in $\vec{\theta}$	Description	Range
$\alpha$	Amplitude	[0, 400]
$\tau$	Period	[.5, 8]
$m_O$	Outer-motor multiplier	[-2, 2]
$m_F$	Front-motor multiplier	[-1, 1]
$m_R$	Right-motor multiplier	[-1, 1]

Table 1: The *SineModel5* motion model parameters.

$m_R$ . To obtain the actual motor position commands, these waves are offset by fixed constants ( $C_O = 40$  for outer motors,  $C_I = 800$  for inner motors, and  $C_C = 512$  for the center hip motor) so that the base position (when the sine waves are at 0) is approximately a crouch (the position shown in Figure 1). To keep the size of the model search space as small as possible, we decided to keep the ninth (center) motor at a fixed neutral position. Thus, the commanded position for each motor as a vector function of time is as follows (numbered as in Figure 2):

$$\vec{g}(t) = \begin{bmatrix} \alpha \cdot \sin(2\pi t/\tau) \cdot m_F + C_I \\ \alpha \cdot \sin(2\pi t/\tau) \cdot m_O \cdot m_F + C_O \\ \alpha \cdot \sin(2\pi t/\tau) + C_I \\ \alpha \cdot \sin(2\pi t/\tau) \cdot m_O + C_O \\ \alpha \cdot \sin(2\pi t/\tau) \cdot m_R + C_I \\ \alpha \cdot \sin(2\pi t/\tau) \cdot m_O \cdot m_R + C_O \\ \alpha \cdot \sin(2\pi t/\tau) \cdot m_F \cdot m_R + C_I \\ \alpha \cdot \sin(2\pi t/\tau) \cdot m_O \cdot m_F \cdot m_R + C_O \\ 0 + C_C \end{bmatrix}$$

### Learning Methods for Parameterized Gaits

Given the *SineModel5* parameterized motion model (see previous section) and the allowable ranges for its five parameters (Table 1), the task is discovering values for the five parameters that result in fast gaits.

If we choose a value for the five dimensional parameter  $\vec{\theta}$ , then a given physical trial gives us one measurement of the fitness  $f(\vec{\theta})$  of that parameter vector. Two things make learning difficult. First, each evaluation of  $f(\vec{\theta})$  is expensive, taking 15-20 seconds on average. Second, the fitness returned by such evaluations has proved to be very noisy, with the standard deviation of the noise often being roughly equivalent to the size of the measurement.

We test the ability of different *learning algorithms* to choose the next value of  $\vec{\theta}$  to try, given a list of the  $\vec{\theta}$  values already evaluated and their fitness measurements  $f(\vec{\theta})$ .

We evaluated the following six different learning algorithms for the parameterized motion models:

*Random*: This method randomly generates parameter vectors in the allowable range for every trial. This strategy serves as a baseline for comparison.

*Uniform random hill climbing*: This method repeatedly starts with the current best gait and then selects the next  $\vec{\theta}$  by randomly choosing one parameter to adjust and replacing it with a new value chosen with uniform probability in the allowable range for that parameter. This new point is evaluated, and if it results in a longer distance walked than the previous best gait, it is saved as the new best gait.

*Gaussian random hill climbing*: This method works similarly to Uniform random hill climbing, except the next  $\vec{\theta}$  is generated by adding random Gaussian noise to the current best gait. This results in all parameters being changed at once, but the resulting vector is always fairly close to the

previous best gait. We used independently selected noise in each dimension, scaled such that the standard deviation of the noise was 5% of the range of that dimension.

*N-dimensional policy gradient ascent:* We implemented Kohl and Stone's (Kohl and Stone, 2004) method for local gradient ascent for gait learning with noisy fitness evaluations. This strategy explicitly estimates the gradient of the objective function. It does this by first generating  $n$  parameter vectors near the initial vector by perturbing each dimension of each vector randomly by either  $-\epsilon$ , 0, or  $\epsilon$ . Then each vector is run on the robot, and for each dimension we segment the results into three groups:  $-\epsilon$ , 0, and  $\epsilon$ . The gradient along this dimension is then estimated as the average score for the  $\epsilon$  group minus the average score for the  $-\epsilon$  group. Finally, the method creates the next  $\vec{\theta}$  by changing all parameters by a fixed-size step in the direction of the gradient. For this study we used values of  $\epsilon$  equal to 5% of the allowable range in each dimension (ranges listed in Table 1), and a step size scaled such that if all dimensions were in the range  $[0, 1]$ , the norm of the step size would be 0.1.

*Nelder-Mead simplex method:* The Nelder-Mead simplex method creates an initial simplex with  $d + 1$  vertices for a  $d$  dimensional parameter space. It then tests the fitness of each vertex and, in general, it reflects the worst point over the simplex's centroid in an attempt to improve it. Several additional rules are used to prevent cycles and local minima; see Singer and Nelder (2009) for more information.

*Linear regression:* To initialize, this method chooses and evaluates five random parameter vectors. It then fits a linear model from parameter vector to fitness. In a loop, the method chooses and evaluates a new parameter vector generated by taking a fixed-size step in the direction of the gradient for each parameter, and fits a new linear model to all vectors evaluated so far, choosing the model to minimize the sum of squared errors. The step size is the same as in *N-dimensional policy gradient ascent*.

Three runs were performed per learning method. To most directly compare learning methods, we evaluated the different methods by starting each of their three runs, respectively, with the same three randomly-chosen initial parameter vectors ( $\vec{\theta}_A$ ,  $\vec{\theta}_B$ , and  $\vec{\theta}_C$ ). Runs continued until the performance plateaued, which we defined as when there was no improvement during the last third of a run.

## HyperNEAT Gait Generation and Learning

HyperNEAT is an indirect encoding for evolving artificial neural networks (ANNs) that is inspired by the way natural organisms develop (Stanley et al., 2009). It evolves Compositional Pattern Producing Networks (CPPNs) (Stanley, 2007), each of which is a genome that encodes an ANN phenotype (Stanley et al., 2009). Each CPPN is itself a directed graph, where the nodes in the graph are mathematical functions, such as sine or Gaussian. The nature of these functions can facilitate the evolution of properties such as sym-

Figure 5: HyperNEAT produces ANNs from CPPNs. ANN weights are specified as a function of the geometric coordinates of each connection's source and target nodes. These coordinates and a constant bias are iteratively passed to the CPPN to determine each connection weight. The CPPN has two output values, which specify the weights for each connection layer as shown. Figure from Clune et al. (2011).

metry (e.g. a Gaussian function) and repetition (e.g. a sine function) (Stanley et al., 2009; Stanley, 2007). The signal on each link in the CPPN is multiplied by that link's weight, which can magnify or diminish its effect.

A CPPN is queried once for each link in the ANN phenotype to determine that link's weight (Figure 5). The inputs to the CPPN are the Cartesian coordinates of both the source (e.g.  $x = 2$ ,  $y = 4$ ) and target (e.g.  $x = 3$ ,  $y = 5$ ) nodes of a link and a constant bias value. The CPPN takes these five values as inputs and produces two output values. The first output value determines the weight of the link between the associated input (source) and hidden layer (target) nodes, and the second output value determines the weight of the link between the associated hidden (source) and output (target) layer nodes. All pairwise combinations of source and target nodes are iteratively passed as inputs to a CPPN to determine the weight of each ANN link.

HyperNEAT can exploit the geometry of a problem because the link values between nodes in the ANN phenotype are a function of the geometric positions of those nodes (Stanley et al., 2009; Clune et al., 2009c, 2011). For quadruped locomotion, this property has been shown to help HyperNEAT produce gaits with front-back, left-right, and four-way symmetries (Clune et al., 2009a, 2011).

The evolution of the population of CPPNs occurs according to the principles of the NeuroEvolution of Augmenting Topologies (NEAT) algorithm (Stanley and Miikkulainen, 2002), which was originally designed to evolve ANNs. NEAT can be fruitfully applied to CPPNs because of their structural similarity to ANNs. For example, mutations can add a node, and thus a function, to a CPPN graph, or change its link weights. The NEAT algorithm is unique in three main ways (Stanley and Miikkulainen, 2002). Initially, it starts with small genomes that encode simple networks

Figure 6: ANN configuration for HyperNEAT runs. The first two columns of each row of the input layer receive information about a single leg (the angles requested in the previous time step for its two joints). The final column provides the previously requested angle of the center joint and, to enable periodic movements, a sine and cosine wave. Evolution determines the function of the hidden-layer nodes. The nodes in the output layer specify new joint angles for each respective joint. The unlabeled nodes in the input and output layers are ignored. Figure adapted from Clune et al. (2011).

and slowly complexifies them via mutations that add nodes and links to the network, enabling the algorithm to evolve the topology of an ANN in addition to its weights. Secondly, NEAT has a fitness-sharing mechanism that preserves diversity in the system and gives time for new innovations to be tuned by evolution before competing them against more adapted rivals. Finally, NEAT tracks historical information to perform intelligent crossover while avoiding the need for expensive topological analysis. A full explanation of NEAT can be found in (Stanley and Miikkulainen, 2002).

The ANN configuration follows previous studies that evolved quadruped gaits with HyperNEAT in simulation (Clune et al., 2011, 2009a), but was adapted to accommodate the physical robot in this paper. Specifically, the ANN has a fixed topology (i.e. the number of nodes does not evolve) that consists of three  $3 \times 4$  Cartesian grids of nodes forming input, hidden, and output layers (Figure 6). Adjacent layers were allowed to be completely connected, meaning that there could be  $(3 \times 4)^2 = 288$  links in each ANN (although evolution can set weights to 0, functionally eliminating the connection). The inputs to the substrate were the angles *requested* in the previous time step for each of the 9 joints of the robot (recall that gaits are open-loop, so actual joint angles are unknown) and a sine and cosine wave (to facilitate the production of periodic behaviors). The sine and cosine waves had a period of about half a second.

The outputs of the substrate at each time step were nine numbers in the range  $[-1, 1]$ , which were scaled according

to the allowable ranges for each of the nine motors and then commanded the positions for each motor. Occasionally HyperNEAT would produce networks that exhibited rapid oscillatory behaviors, switching from extreme negative to extreme positive numbers each time step. This resulted in motor commands to alternate extremes every 25ms (given the command rate of 40Hz), which tended to damage and overheat the motors. To ameliorate this problem, we requested four times as many commanded positions from HyperNEAT ANN's and averaged over four commands at a time to obtain the actual gait  $g(t)$ . This solution worked well and did not restrict the expressiveness of HyperNEAT.

As with the parameterized methods, three runs of HyperNEAT were performed. Runs lasted 20 generations with a population size of 9 organisms in 3 species, allowing a bare minimum of diversity within and between NEAT species. These numbers were necessarily small given how much time it took to conduct evolution directly on a real robot. The remaining parameters were identical to Clune et al. (2011).

## Results and Discussion

### Learning Methods for Parameterized Gaits

The results for the parameterized gaits are shown in Figure 7 and Table 2. A total of 1217 hardware fitness evaluations were performed during the learning of parameterized gaits, with the following distribution by learning method: 200 random, 234 uniform, 284 Gaussian, 174 gradient, 172 simplex, 153 linear regression. The number of runs varies because each run plateaued at its own pace. The best overall gait for the parameterized methods was found by linear regression, which also had the highest average performance. The Nelder-Mead simplex also performed quite well on average. The other local search methods did not outperform random search; however, all methods did manage to explore enough of the parameter space to significantly improve on the previous hand-coded gait in at least one of the three runs. No single strategy consistently beat the others: for the first trial Linear Regression produced the fastest gait at 27.58 body lengths/minute, for the second a random gait actually won with 17.26, and for the third trial the Nelder-Mead simplex method attained the fastest gait with 14.83.

One reason the randomly-generated SineModel5 gaits were so effective may have been due to the SineModel5's bias toward regular, symmetric gaits. This may have allowed the random strategy — focusing on exploration — to be competitive with the more directed strategies that exploit information from past evaluations.

### HyperNEAT Gaits

The results for the gaits evolved by HyperNEAT are shown in Figure 8 and Table 2. A total of 540 evaluations were performed for HyperNEAT (180 in each of three runs). Overall the HyperNEAT gaits were the fastest by far, beating all the parameterized models when comparing either average

	Average	Std. Dev.
Previous hand-coded gait	5.16	—
Random search	9.40	6.83
Uniform Random Hill Climbing	7.83	4.56
Gaussian Random Hill Climbing	10.03	6.00
Policy Gradient Descent	6.32	7.39
Nelder-Mead simplex	12.32	3.35
Linear Regression	14.01	12.88
Evolved Neural Network (HyperNEAT)	29.26	6.37

Table 2: The average and standard deviation of the best gaits found for each algorithm during each of three runs, in body lengths/minute.

Figure 7: Average results ( $\pm$  SE) for the parameterized learning methods, computed over three separately initialized runs. Linear regression found the fastest overall gait and had the highest average, followed by Nelder-Mead simplex. Other methods did not outperform a random strategy.

or best gaits. We believe that this is because HyperNEAT was allowed to explore a much richer space of motions, but did so while still utilizing symmetries when advantageous. The single best gait found during this study had a speed of 45.72 body lengths/minute, 66% better than the best non-HyperNEAT gait and 8.9 times faster than the hand-coded gait. Figure 9 shows a typical HyperNEAT gait that had high fitness. The pattern of motion is both complex (containing multiple frequencies and repeating patterns across time) and regular, in that patterns of multiple motors are coordinated.

The evaluation of the gaits produced by HyperNEAT was more noisy than for the parameterized gaits, which made learning difficult. For example, we tested an example HyperNEAT generation-champion gait 11 times and found that its mean performance was 26 body lengths/minute ( $\pm$  13 SD), but it had a max of 38 and a min of 3. Many effective HyperNEAT gaits were not preserved across generations because

Figure 8: Average fitness ( $\pm$  SE) of the highest performing individual in the population for each generation of HyperNEAT runs. The fitness of many high-performing HyperNEAT gaits were halved if the gait overly stressed the motors (see text), meaning that HyperNEAT’s true performance without this penalty would be even higher.

a single poor-performing trial could prevent their selection. The HyperNEAT learning curve would be smoother if the noise in the evaluations could be reduced or more than one evaluation per individual could be afforded.

## Conclusion and Future Work

We have presented an array of approaches for optimizing a quadrupedal gaits for speed. We implemented and tested six learning strategies for parameterized gaits and compared them to gaits produced by neural networks evolved with the HyperNEAT generative encoding.

All methods resulted in an improvement over the robot’s previous hand-coded gait. Building a model of gait performance with linear regression to predict promising directions for further exploration worked well, producing a gait of 27.5 body lengths/minute. The Nelder-Mead simplex method performed nearly as well, likely due to its robustness to noise. The other parameterized methods did not outperform random search. One reason the randomly-generated SineModel5 gaits performed so well could be because the gait representation was biased towards effective, regular gaits, making the highly exploratory random strategy more effective than more exploitative learning algorithms.

HyperNEAT produced higher-performing gaits than all of the parameterized methods. Its best-performing gait traveled 45.7 body lengths per minute, which is nearly 9 times the speed of the hand-coded gait. This could be because HyperNEAT tends to generate coordinated gaits (Clune et al., 2011, 2009a), allowing it to take advantage of the symmetries of the problem. HyperNEAT can also explore a much larger space of possibilities than the more restrictive 5-dimensional parameterized space. HyperNEAT gaits

Figure 9: Example of one high-performance gait produced by HyperNEAT showing commands for each of nine motors. Note the complexity of the motion pattern. Such patterns were not possible with the parameterized SineModel5, nor would they likely result from a human designing a different low-dimensional parameterized motion model.

tended to produce more complex sequences of motor commands, with different frequencies and degrees of coordination, whereas the parameterized gaits were restricted to scaling single-frequency sine waves and could only produce certain types of motor regularities.

Because all 1217 trials were done in hardware, it was difficult to gather enough data to properly rank the methods statistically. One direction for future work could be to obtain many more trials. However, a more effective extension might be to combine frequent trials in simulation with infrequent trials in hardware (Bongard et al., 2006). The simulation would produce the necessary volume of trials to allow the learning methods to be effective, and the hardware trials would serve to continuously ground and refine the simulator. One could also guide evolution to the most fertile territory by penalizing gaits that produced large discrepancies between simulation and reality (Koos et al., 2010). Another extension would be to allow gaits that sensed the position of the robot and other variables to enable the robot to adjust to its physical state, instead of providing an open-loop sequence of motor commands. All of these approaches would likely improve the quality of automatically generated gaits for legged robots, which will hasten the day that humanity can benefit from their vast potential.

# Landmark Vector Model with Quantized Distance for Homing Navigation

Seung-Eun Yu<sup>1</sup> and DaeEun Kim<sup>1</sup>

<sup>1</sup>Biological Cybernetics Lab, Yonsei University, Seoul, South Korea

## Abstract

Inspired by astonishing navigation ability of insects and other animals, many studies observed their behaviors, and considered biomimetic application to robotic systems by investigating mechanisms based on various senses. In this paper, we suggest a new landmark vector model for homing navigation with quantized distance information. The method is highly successful for homing navigation in both perspectives of angular error and success rate. This work has been published in Yu and Kim (2011).

## Introduction

Animals have developed navigation skills based on various senses. Desert ants and honeybees are known to use visual information (Collett, 1996), turtles migrating long distance rely on magnetic compass (Luschi et al., 1996), while other studies have shown that birds use olfactory cues to navigate (Papi, 1990). Many studies have focused on designing bio-inspired navigation algorithms for robotic systems inspired by the excellent performance animals demonstrate. Among them, vision-based homing navigation has been studied through a number of bio-inspired algorithms. One of the simplest method suggested, inspired by desert ants and honeybees, is the ‘snapshot model’ (Cartwright and Collett, 1983).

In the snapshot model, currently obtained visual information is compared to that in the snapshot image taken at home location. Several different methods were suggested to process the snapshot images for homing navigation. One of the methods based on the concept is the average landmark vector (ALV) model by Lambrinos et al. (2000).

The ALV model is one parameter method where the average landmark vector is obtained by averaging every unit-length landmark vectors perceived in the snapshot. Comparing the average landmark vectors obtained from snapshots taken at the current location and at home location, it is sufficient to guide the agent for the homing direction. The ALV model is based on a simple representation of the environment with powerful performance results in homing navigation, but the model necessarily requires a reference compass information.

Figure 1: Image shift of landmarks when the agent moves from the position  $P$  to  $C$  with moving distance  $d$ . The head orientation angle changes by  $\psi$ , and the viewing angle of a landmark is  $\theta$  and  $\theta + \delta$  in two positions, respectively (modified from Yu and Kim (2010)).

In this paper, we propose a new landmark-based navigation algorithm without any reference compass. The method we suggest is the distance-estimated landmark vector model (DELV) using quantized distance estimation along with the rotational landmark arrangement matching. This work has been published in Yu and Kim (2011).

## Methods

While the ALV model (Lambrinos et al., 2000) considers landmark vectors in unit length, and perceives only angular directions of landmarks ignoring their distances, the DELV model includes distance information as well as the angular position of landmarks in the landmark vector. Both methods share similar concept in perceiving landmark information as a vector form, but the matching process between information in two snapshots have a different point of view in exploiting the landmark vectors.

### Distance estimation and quantization

The DELV method includes distance information of landmarks in the landmark vector representation, which can be obtained by inducing the image motion. Using an omnidirectional camera, the mobile robot is able to monitor 360° view of its surroundings, and the angular position of landmarks observed in the view is shifted as the robot moves

one step forward. Fig. 1 describes the geometric relationship between angular shift and the distance, and Eq. 1 shows the distance estimation based on the relationship.

$$R = \frac{d \sin(\theta - \psi)}{\sin(\delta + \psi)} \quad (1)$$

As in Eq. 1, the estimation of landmark distance is affected by variables such as  $\theta$ ,  $\delta$  and  $d$ , and their accuracies can affect the estimation results. The angular position of landmarks  $\theta$  and  $\theta + \delta$  is sensitive to noise in the captured image, while the moving distance  $d$  is influenced by odometry error. In addition, it may be plausible to argue that insects or other animals perceive the distances to landmarks in a relative manner rather than in the absolute values. Therefore, we apply quantization on the estimated distance to landmark vectors. Through arrangement matching of landmark vectors for heading direction estimation and homing direction computation, it is shown that the landmark vector model with quantized distance is effective, which will be described in more details.

### Rotational matching of landmark vectors

The landmark vector set perceived at home location is stored as a reference map in which the landmark vectors at an arbitrary location will be projected to obtain a homing direction. By reversely projecting the landmark vector obtained at the current location to the reference map, the end point of each landmark vector would represent the vector from the home location to the current location. With  $N$  landmarks available in the environment, the estimation on the current position  $p^k(x)$  is defined as the average of the landmark vectors projected on the reference map. Assuming the appropriate arrangement  $k$ , the equation is given as:

$$p^k(x) = \frac{1}{N} \sum_{i=1}^N [V_i^R(x_o, \alpha_r) - V_i^k(x, \alpha)] \quad (2)$$

where  $V_i^R(x_o, \alpha_r)$  is the landmark vector for the  $i$ -th landmark in the reference map, and  $V_i^k(x, \alpha)$  is the  $i$ -th landmark vector with the matching order  $k$  at the current location  $x$ .

Without a reference compass, the DELV method solves the correspondence problem between landmarks in a pair of snapshots with the rotational arrangement matching of landmark vectors. The variance of end points of the projected landmark vectors is used as the criterion for finding the best matching order  $z$  and heading direction  $\alpha_z$  as:

$$\arg \min_{k, \alpha} \left[ \sum_{i=1}^N \left( [V_i^R(x_o, \alpha_r) - V_i^k(x, \alpha) - p^k(x)]^T [V_i^R(x_o, \alpha_r) - V_i^k(x, \alpha) - p^k(x)] \right) \right] \quad (3)$$

### Results and discussion

Vector map results in Fig. 2 (a) to (c) indicate the decided homing direction with the suggested method for three different quantization levels. Angular error curves in Fig. 2 (d) efficiently compares

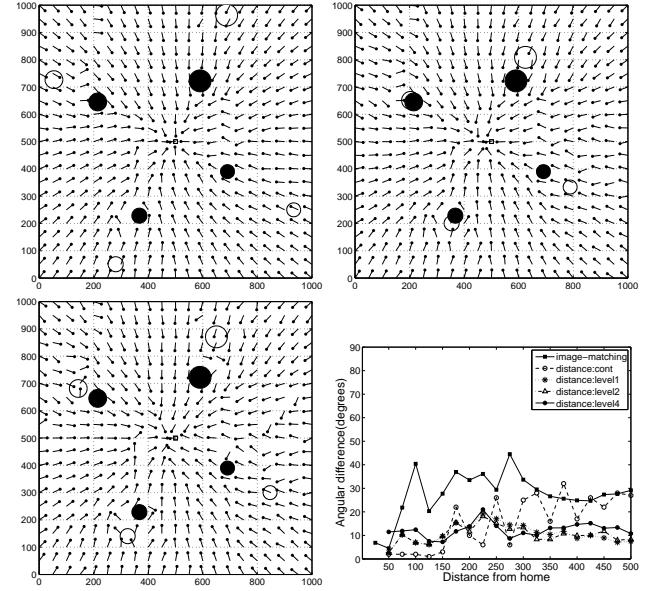

Figure 2: Vector map results with quantization in (a) level 1, (b) level 3, and (c) level 5, respectively and (d) error curves

the results and show low angular errors. As a result, the DELV model with quantized distance shows homing ability with simple representation of environments and low complexity in computation even without any reference compass information. The quantization of distances to landmarks may allow some errors in heading direction search and current location estimation, but experimental results showed that the method leads to the homing direction decision.

## Abstract

The dynamics of real-world systems often involve multiple processes that influence system state. The timescales that these processes operate on may be separated by orders of magnitude or may coincide closely. Where timescales are not separable, the way that they relate to each other will be important for understanding system dynamics. In this paper, we present a short overview of how modellers have dealt with multiple timescales and introduce a definition to formalise conditions under which timescales are separable.

We investigate timescale separation in a simple model, consisting of a network of nodes on which two processes act. The first process updates the values taken by the network's nodes, tending to move a node's value towards that of its neighbours. The second process influences the topology of the network, by rewiring edges such that they tend to more often lie between similar individuals. We show that the behaviour of the system when timescales are separated is very different from the case where they are mixed. When the timescales of the two processes are mixed, the ratio of the rates of the two processes determines the system's equilibrium state. We go on to explore the impact of heterogeneity in the system's timescales, i.e., where some nodes may update their value and/or neighbourhood faster than others, demonstrating that it can have a significant impact on the equilibrium behaviour of the model.

## Introduction

Real-world adaptive systems typically involve many interacting parts and processes operating at multiple timescales. However, models of these systems often proceed by identifying a single substantive timescale. Faster processes are often idealised as essentially instantaneous, while slower processes are often treated as a constant background influence that parametrises the model's dynamics.

For instance, Kauffman's (1993) NK landscape model of adaptation on rugged fitness landscapes has a single substantive timescale. At each step the genotype of a genetically fixated population is updated to one of the fitter adjacent genotypes. In reality, a newly discovered fitter mutant takes time to reach fixation. This process is idealised as instantaneous. During a single run of Kauffman's model, the parameters  $N$

and  $K$ , which determine the length of a genome and the degree of epistasis within it, are held fixed. They parametrise the system's dynamics. Of course in reality both  $N$  and  $K$  vary as a consequence of evolutionary change. The security of Kauffman's idealisations hinges on whether these processes are separable: the faster processes are much faster, and the slower processes much slower, than the timescale of the process that he focuses on. There are various interpretations of this kind of concept and in the scope of this paper we define *separation of timescales* as follows. The timescales of two processes are separated if one process leads the system into equilibrium before the other process influences the system. This means when the second process sets in, the system has already reached equilibrium.

Where processes take place over similar timescales and affect each other, i.e., they are coupled, dealing with these interacting timescales becomes an important issue. For real-world systems there are further considerations that may be significant. To what extent is there component-wise *heterogeneity* in the rates at which different components operate? While, on average, a genome's alleles might mutate with probability  $p$ , it may be the case that some alleles are more vulnerable to mutation than others. While, on average, the children in a schoolyard might update their social ties at rate  $r$ , some might update these ties more often than others. Moreover, a system's timescales might vary with time. The traffic on a network might be diurnal, with higher rates during the day. The rate of plasticity in a neural component might decay with the age of the component.

Here we are interested in exploring these issues in the context of adaptive processes modelled on networks. In the co-evolutionary networks literature (Gross and Blasius, 2008), two processes are typically modelled: one governing the tendency for nodes to change their *state*, and one governing *topological change* in the network. These two processes may occur on separable timescales where interactions between the two processes can perhaps be neglected. If the timescales for the two processes are not separable, their interplay will affect the behaviour exhibited by the network.

Here we explore a very simple coevolutionary network in

which both state and topology evolve over time. We first vary the rates of change for both processes and demonstrate that their ratio impacts on the equilibrium state of the network. We proceed to explore the impact of heterogeneity in timescale, demonstrating that it can impact on both the distribution of node states and the topology at equilibrium. Before introducing the simple model and its results, we review some literature demonstrating the issue of timescale in modelling adaptive systems. We conclude with discussion of the results presented here and ideas for future work.

## Dealing with timescale

### Synchrony vs. asynchrony

Several studies have revealed that models of adaptive systems can be sensitive to the updating scheme chosen. Using a synchronous model of the iterated prisoner's dilemma, Nowak and May (1992) found complicated spatial patterns within which co-operation persisted. Using an asynchronous update scheme for the same model, Huberman and Glance (1993) found that spatial patterns disappeared with defection the only strategy adopted. While Kauffman (1993) has shown that synchronous Random Boolean Networks can exhibit many stable cyclic behaviours, glossed as analogous to the multiple cell types that may result from the same genome, Harvey and Bossomaier (1997) showed that the same Random Boolean Networks with asynchronous update would tend to evolve to a fixed point.

### Multiple timescales

Artificial life has typically considered multiple adaptive timescales in the context of interactions between learning and evolution (Ackley and Littman, 1992; Belew and Mitchell, 1996), such as the Baldwin effect (Hinton and Nowlan, 1987). Further examples where the separation of timescales is critical to adaptive dynamics include the interaction between processes of neurotransmission and (much slower) neuromodulation (Buckley et al., 2004, 2005; Buckley, 2008; Husbands et al., 2010), and the interaction between the evolution of individual behaviours and ecological relationships (e.g., Powers et al., in press; Watson et al., in press; Van Der Laan and Hogeweg, 1995).

### Timescales on networks

Most research involving dynamic networks has focused on addressing either the dynamics 'on' a network, or the dynamics 'of' the network (Gross and Blasius, 2008). The dynamics 'on' a network describe the state transitions of the network's nodes, while the dynamics 'of' a network describe topological changes. Research on so-called coevolutionary networks recognises that these processes are inherently reflexive, with network state influencing topological change (as when edges are formed between similar nodes), and topology constraining state change (as when neighbours exchange information) (Blasius and Gross, 2009; Gross and

Blasius, 2008; Gross and Sayama, 2009). Coevolutionary networks have been the subject of recent study in the context of the epidemic spread of diseases (Newman, 2002; Zhong et al., 2010; Funk and Jansen, 2010; Van Segbroeck et al., 2010), cascading network behaviour (Watts, 2002), opinion dynamics (Kozma and Barrat, 2008; Demirel et al., 2011), diffusion of innovations / information (Onnela and Reed-Tsochas, 2009; Ke and Yi, 2008), evolution of social groups (Palla et al., 2007), the growth of social networks (Sun and Wang, 2008), co-operation (Pacheco et al., 2006; Van Segbroeck et al., 2009), community formation (Bryden et al., 2010), synchronisation (Zhu et al., 2010) and global adaptation (Watson et al., in press). The dynamical interplay of state update and rewiring processes are typically central to the evolution of these systems.

### Heterogeneous timescales

Typically, models make a simplifying assumption that all components update their state at a shared characteristic rate, while structural relationships change at some other arbitrary rate. However, some models have explored systems with heterogeneous rates. Van Segbroeck et al. (2009), for instance, found that increased diversity in their model accelerates the rate of evolution to an equilibrium state where co-operation is a robust and dominant strategy. Pacheco et al. (2006) employed variable re-wiring rates in a social agent model. Their results suggest that introducing heterogeneity has an effect on the system as a whole which can change the frequency of co-operation observed at equilibrium.

### A simple model

To study the influence of timescale separation we introduce an abstract model based on models of opinion dynamics that include adaptive change in network topology as well as the spread of opinions over the network (e.g., Kozma and Barrat, 2008). Here, nodes have an internal value and tend to update this value in the direction of their neighbours' values. The second process changes the network topology by rewiring edges between nodes such that nodes disconnect from dissimilar neighbours and connect to nodes with more similar values.

To illustrate what kind of processes this model could be related to we could assume that each node's value represents the opinion of a different person and that edges represent social interactions between people. In this setup, we can imagine that either rewiring or state update might be the faster process. If we assume a node's value represents something such as the religion a person believes in or a political affiliation, we can assume that this value changes very slowly. We can further assume that therefore a person would more readily change to associate with individuals sharing a similar opinion than change their own opinion to match that of their neighbours. In this case, the rewiring process would be faster than the value update process. At the other end of

Figure 1: A typical network after initialisation.

the spectrum, we could assume a node's value represented a person's preference for meeting friends at one restaurant rather than another. In this case the individuals would be likely to change their opinion based on the opinions of their friends, rather than changing their friends on the basis of their restaurant preference. In between these two extremes we can think of intermediate cases where individuals have a preference for socialising with individuals that share a similar opinion, but also change their own opinion towards that of their neighbours.

### The model

The model consists of a network of  $N$  interconnected nodes (here  $N = 100$ ). Each node has a single value in the interval  $[0.0, 1.0]$ . Even though a node's value can be any value between 0 and 1, each starts with the value 0.0 or 1.0, with equal probability. Nodes are connected by undirected, unweighted edges, meaning an edge is either present or absent and if node  $a$  cuts a tie to  $b$ ,  $b$  also loses its connection to  $a$ . Self-connections are not allowed. To initialise the network between the nodes, we specify an average degree  $d$  and generate a random network by making an edge between each possible pair of unique nodes with probability  $\frac{d}{N-1}$ . In the examples presented here, we use an average degree of  $d = 10$ . A visualisation of a typical network after initialisation is given in Figure 1.

**Value Update:** When a node  $i$  updates its value, it chooses a random individual  $n$  from the set of its neighbours. It then discovers the value of its neighbour  $v(n)$  and calculates the difference  $v(n) - v(i)$  between the neighbour's value and its own. The node then updates its state towards the state of its neighbour, proportional to the difference in values:  $v(i)_{t+1} = v(i) + m(v(n) - v(i))$ . The factor  $m$  determines the maximal change that can occur in one step. Here we choose  $m = 0.01$ , to ensure that it takes several updates for two nodes to reach the same value. If the updating node and

its chosen neighbour have the same state, i.e.,  $v(i) = v(n)$ , the update results in no change to  $v(i)$ .

**Rewiring:** When node  $i$  rewires, it compares its own value to the values of its neighbours, identifying the neighbour with which it is most dissimilar,  $n$ . The node  $i$  then generates a list of all neighbours of all of its neighbours, comprising all nodes that are two edges away. Members of this list that are already neighbours of  $i$  are discarded. If the list is non-empty,  $i$  drops the connection to  $n$  and rewires this edge to a randomly chosen member of the list of neighbours' neighbours. This implies that, if an individual is already connected to all neighbours of its direct neighbours, an attempt to rewire will result in no topological change.

**Timescales:** In each step of the algorithm, a list is generated containing all nodes that are ready to update their state in the current time step. These nodes are then updated in a random order, one at a time. After this, the same procedure is repeated for all nodes ready to rewire. Whether a node is ready to update or rewire depends on the timescales of the two processes. The relation of the timescales is incorporated in the model as follows. Each node is assigned two values,  $V_i$  and  $R_i$ , specifying the number of time steps in the interval between two consecutive value updates for  $i$  and two consecutive rewiring events for  $i$ , respectively. In the case of homogeneous timescales, all nodes have identical values for  $V$  and identical values for  $R$ , i.e.,  $\forall i V_i = V$  and  $\forall i R_i = R$ . In the case of heterogeneous timescales this constraint does not hold and values for the two rates may differ from node to node. The algorithm stops when neither the state update nor rewiring process effects any change in the network. We will consider this stopping criterion in more detail next.

**Equilibration:** Both the value update and the rewiring process can only change the system's state if there is a local difference between two nodes. A local difference is present if two nodes that are connected by an edge have non-identical values. This difference can be reduced by updating the value of one or both nodes or by deleting the edge between the two nodes and rewiring it to a node with a more similar value. Once there are no local differences in the system anymore, neither the value update process nor the rewiring process change the system's state when invoked. Therefore both processes need a value difference between connected nodes to operate. Thus, we can see the difference in values between connected nodes as some kind of energy available to the two processes to use for changing the system's state. Both processes can only operate if there is energy left in the system and both processes reduce the energy, at least locally. One way of formally defining this energy is as the sum of absolute value differences between all pairs of connected nodes,  $e = \sum_{i,j \text{ connected}} |v(i) - v(j)|$ .

The energy specified in this way reduces over time and

once it has reached zero, the system's state cannot change any more. Therefore, we can use reaching zero energy as a formal stopping criterion and terminate the algorithm when the energy has reached zero. Note that, from the initial conditions considered here, each process is capable of reducing energy to zero in the absence of the other.

In the case of homogeneous timescales, whether they are separated depends on the ratio of the values  $V$  and  $R$ . For  $R \gg V$  the timescales of the two processes are separated, with only the value update process influencing the dynamics. We also have separation of timescales in the opposite case,  $V \gg R$ , where the rewiring process dominates the dynamics. Let us now specify further when exactly the timescales are separated to find values for the parameters  $V$  and  $R$  for which we can be certain the timescales are separate. Based on the definition presented in the introduction, the timescales of the two processes are separate if one process acts after the other process has reached equilibrium. Based on the equilibrium definition as a zero energy state, we define the equilibrium points  $t_R$  and  $t_V$  as the number of steps the rewiring or value update process takes in isolation to reduce the energy of the system to zero and therefore reach equilibrium. We measure these two points for a particular set of initial conditions by running the algorithm with only one of the two processes operating. Measuring the time the system takes to reach zero energy when only one process acts on it is the equilibrium time for that process,  $t_V$  or  $t_R$ . If the second process acts only after the system has reached equilibrium, it is unable to change the system state as there is no energy for it to exploit (i.e., no value difference between connected nodes). This means that the timescales of the two processes are separated in two cases. The first case is when  $V > t_R$ , meaning that the value update only happens after the rewiring process has brought the system to equilibrium. In the second case, for  $R > t_V$ , the rewiring process happens after the value update process has already reduced the system's energy to zero. In any other case the timescale are mixed to some degree.

## Results

We now observe the system behaviour for varying ratios  $\frac{R}{V}$ , first for homogeneous timescales and then for varying degrees of heterogeneity.

### Homogeneous timescales

If only the rewiring process is active and its rate is the same for all nodes, the system reaches equilibrium after  $t_R \approx 10.0$  steps. If only the state update process is active, it takes longer for the system to reach equilibrium,  $t_V \approx 6500$ . Having measured these values, we can assign values to the parameters  $V$  and  $R$  for which the timescales are separated and one of the two processes dominates the dynamics.

Setting  $V = 100$  and  $R = 1$ <sup>1</sup> the timescales are separated

<sup>1</sup>Note that the equilibrium times measured above assume that

as  $V > t_R = 10$ , with only the rewiring process influencing the dynamics as it reaches equilibrium before the state change process has time to affect the network.

The equilibrium state of the system under these parameters is shown in Figure 2a<sup>2</sup>. Since the network is initially populated by equal numbers of nodes with value 0.0 and value 1.0, the rewiring process removes edges between dissimilar nodes and replaces them with edges linking nodes with identical value, forming two homogeneous components, one containing all the nodes with value 0.0 and the other containing the nodes initialised with value 1.0. At the other extreme,  $V = 1$  and  $R = 10000 > t_v$ , only the state update process shapes the network. Figure 2j depicts the equilibrium state under these conditions. Node values have gradually changed towards the average value of the initial population until all nodes have exactly this value. Since all the nodes have identical values no rewiring can take place and the network topology does not change at all.

Intermediate cases where the timescales are mixed are shown in Figures 2b–2i. Where the rewiring process is fast relative to the state update process, the network breaks up into several components, each eventually consisting of nodes with the same value, but with values differing significantly between the components (see, e.g., Figure 2b). Where the system's dynamics are more influenced by the state update process (see, e.g., Figure 2e) the values adopted by different components tend to be less diverse and closer to the system mean. Eventually, the state update dynamic is fast enough to equilibrate the network before the rewiring process can cause it to fragment (see, Figures 2h–2j).

These results show that the system reaches the predicted equilibrium when the timescales are separated. For the intermediate cases with mixed timescales however, the ratio between the two timescales determines which equilibrium the system ends up in and the character of this equilibrium, in terms of the node values and the network topology.

Figure 3 depicts how the distribution of node values at equilibrium varies with  $\frac{R}{V}$ . It shows that for very low values of  $\frac{R}{V}$ , the rewiring process dominates the system dynamics and only the initial values (0.0 and 1.0) are present. As  $\frac{R}{V}$  increases, we observe more and more intermediate values, converging to the average value in the system. For high values of  $\frac{R}{V}$ , there is only one value present in the system, corresponding to the mean of the system's initial values.

A similar transition can be observed for the topology of the network. Figure 4 depicts how the distribution of component sizes at equilibrium varies with  $\frac{R}{V}$ . Here we observe that when rewiring dominates, the two network components have nearly the same size, consisting of roughly half of the nodes each (one is larger as a consequence of the ini-

the process considered happens each time step ( $V = 1$  or  $R = 1$ ). We therefore set the frequency of the faster process to 1.

<sup>2</sup>In the examples presented here, the same initial network shown in Figure 1 is used.

tial random allocation of value to the population of nodes). For mixed timescales, components are smaller and isolated nodes (with component size 1) exist. As we move towards

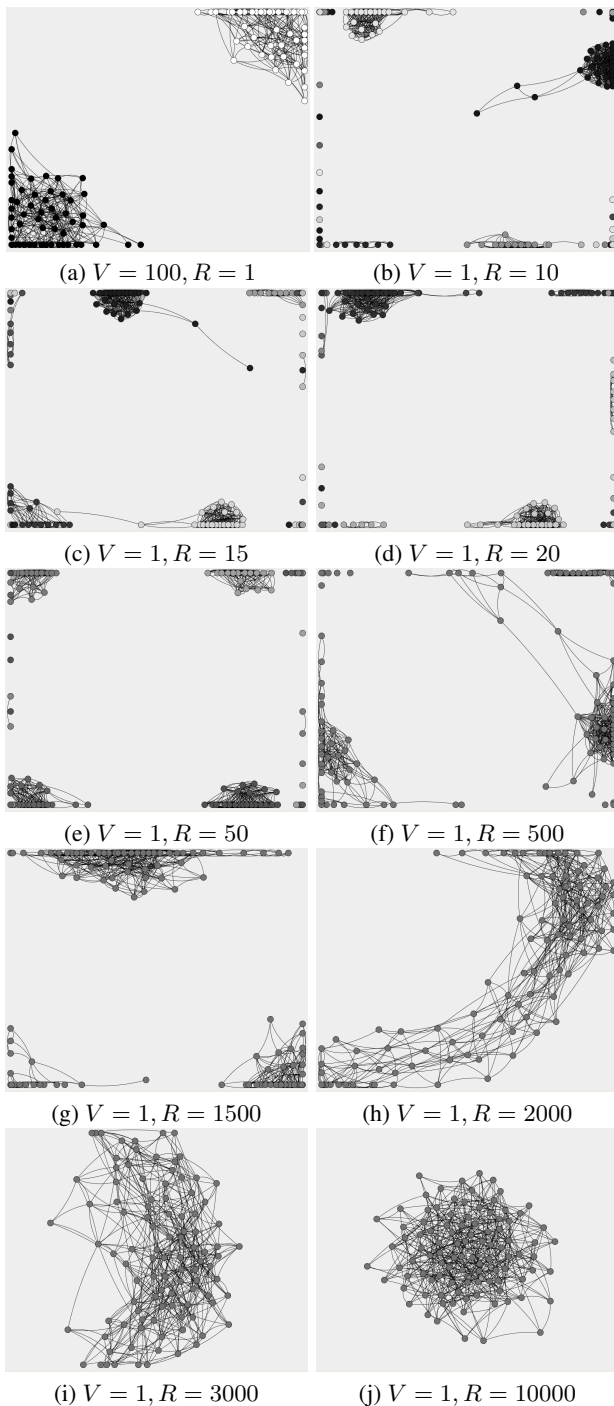

Figure 2: Networks at equilibrium for different values of  $R$  and  $V$ . Node shading indicates the nodes states, with the heaviest shading indicating 0.0 and no shading indicating 1.0.

Figure 3: Values present in the equilibrium state for different ratios  $\frac{R}{V}$ . For each value the system is started with the same initial conditions.

Figure 4: Component sizes present in the equilibrium state for different ratios  $\frac{R}{V}$ . For each value the system is started with the same initial conditions.

the regime where the state update process dominates the systems dynamics, larger components exist at equilibrium. Once state update is the only active process, only one connected component is present at equilibrium.

Comparing these two graphs, we observe that the apparent thresholds in system behaviour exhibited by node values and network topology are different. From the perspective of node values, we can see three regimes separated by two threshold values of  $\frac{R}{V}$ . First, a transition occurs around  $\frac{R}{V} = 0.5$ , with a second qualitative change in the equilibrium behaviour at around  $\frac{R}{V} = 250$ . However, when we consider the network's equilibrium topology, the equivalent transitions seem to occur around  $\frac{R}{V} = 0.1$  and  $\frac{R}{V} = 2500$ .

Figure 5: Node values present at equilibrium for different levels of heterogeneity in the value update and rewiring intervals. Only  $\alpha$ , which specifies the heterogeneity of timescales, is varied here (with  $\alpha = \alpha_V = -\alpha_R$ ). The runs are otherwise identical and share the same initial conditions. For each value of  $\alpha$  all node values,  $v(i)$ , present at equilibrium are displayed.

### Heterogeneity in timescales

We now consider the case where some nodes might update their value or their neighbourhood faster than others. We model this by allocating each node,  $i$ , a pair of values,  $V_i$  and  $R_i$ , governing the individual rates of change for value and neighbourhood, respectively. The  $V_i$  and  $R_i$  values are Pareto-distributed, meaning that while most of the values are close to the characteristic population mode,  $V$  or  $R$ , a few are significantly different, due to the long tail of the distribution. Values are generated by transforming a uniform random variable  $U$  by the functions  $\frac{V}{U^{1/\alpha_V}}$  for  $V_i$  and  $\frac{R}{U^{1/\alpha_R}}$  for  $R_i$  (Newman, 2004). The parameters  $\alpha_V$  and  $\alpha_R$  determine the spread of values in each distribution. We set  $\alpha_R$  to a negative value and  $\alpha_V$  to a positive value so that the tails of the distribution point towards each other. Large absolute magnitudes for  $\alpha$  (such as  $\alpha = 100$ ) lead to a relatively small average distance between the resulting values and the modal value,  $V$  or  $R$ , whereas small absolute values for  $\alpha$  (e.g.,  $\alpha = 2.5$ ) produce a larger spread. This introduction of heterogeneity into the model means that each node has its own internal clocks governing when to update its state and when to rewire.

The effect of heterogeneity on the value process is assessed for the case in which  $V = 1$  and  $R = 50$ , as this is an intermediate case where both processes influence the dynamics. Figure 5 shows that for a low degree of heterogeneity in both processes (higher values of  $\alpha$ ) the distribution of values present at equilibrium is not very different from the base case without heterogeneity. For higher levels of heterogeneity, however, the diversity of values increases

significantly. The effects of heterogeneity on the network topology are illustrated in Figures 6 and 7 for  $V = 1$  and  $R = 2000$ , as this ratio of  $\frac{R}{V}$  is the threshold separating single component equilibria from multi-component equilibria. Without heterogeneity, the network forms one component (Figure 7a) with a degree distribution that differs from that of the initial network (compare Figures 6a and 6b). In the presence of heterogeneity however, the network fragments into eleven components (Figure 7b) with a qualitatively different degree distribution (Figure 6c).

### Discussion

The results presented here show that in the cases where the timescales are separated, the system behaves as we would expect: if only the value update process is active, there is no topological change and the values of all nodes converge to the average of the initial network. If only the rewiring process acts on the system state, we only observe changes in topology and the network splits into two components, with nodes being sorted according to their initial value. The number of components in that case depends only on the number of initial values present in the system. For example, if we initialise the system with three (e.g. 0.0, 0.5, 1.0) different values instead of two the network fractures into three clusters. To sum up, when timescales are sufficiently separated, the system behaves in the same way as an equivalent system with the slower process ‘switched off’.

The results also show that if the timescales are not separated, the exact ratio between the rates of the two processes influences the system’s equilibrium state. If the rewiring process dominates the dynamics, the values we find in the system in equilibrium differ significantly. As the value update process gains more influence, the values of the components found in the equilibrium state become more and more similar. We can explain this behaviour by observing the system dynamics over time. Starting from a random initial network, the rewiring process stretches the network into a predominantly white and a predominantly black end. In between, there are nodes of intermediate value. At this stage, if the rewiring is fast, the network fractures at several points. In the case where the value process is the main influence on the system, the values of nodes are more similar at the point when the rewiring sets in, as sufficient time has passed for the node values to become more similar. Therefore, the rewiring fractures the network into fewer and larger clusters.

Furthermore, we have shown that heterogeneity changes the state the system reaches in equilibrium. Although the influence of heterogeneity is clearly visible, it is not as strong as we had anticipated. The heterogeneous case needs to be investigated further as we do not fully understand how heterogeneity in the rates influences the dynamics.

We have presented a definition for timescale separation in the case of homogeneous and therefore well defined rates, but we need an extended definition for the case of hetero-

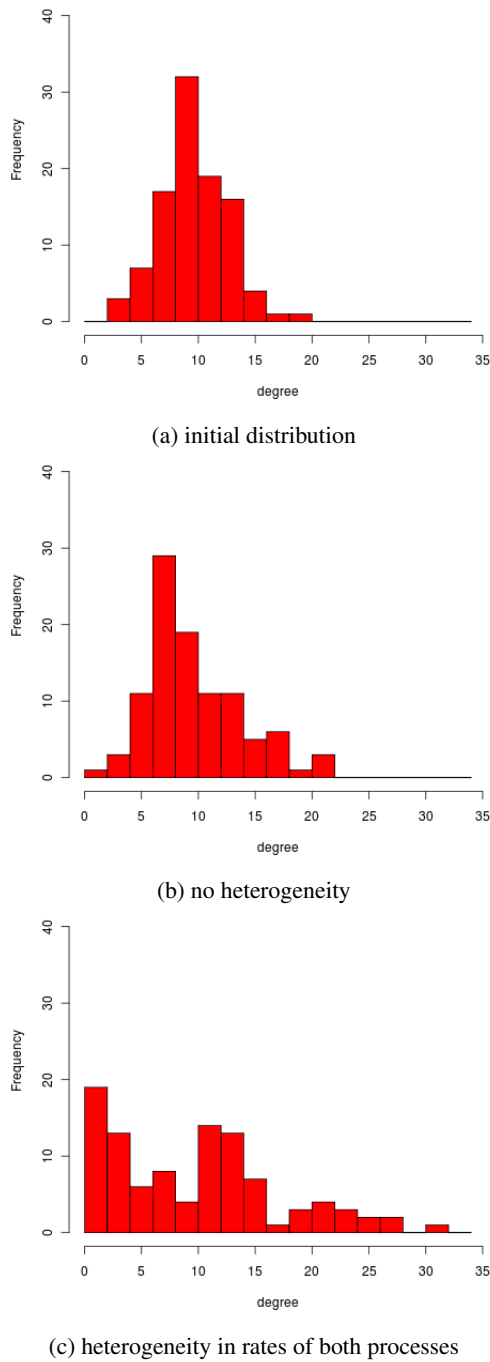

Figure 6: Histogram of the degree distribution under different conditions. The rate parameters used are  $V = 1$  and  $R = 2000$ . In the heterogeneous case the  $\alpha$  values are  $\alpha_V = 2.1$  and  $\alpha_R = -4.1$ .

geneous rates. There are of course further complications in real-world systems that we have not considered in the model presented here. For example, processes often have dynamic rates, i.e., the change of the rate is a process itself, perhaps influenced by the current state of the system.

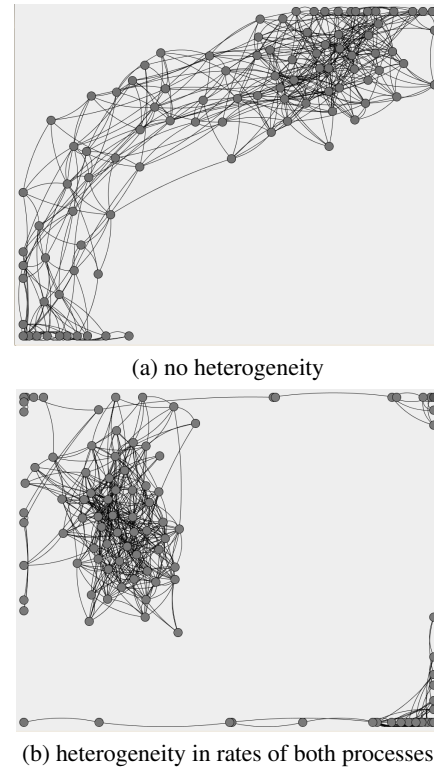

Figure 7: The effect of heterogeneity on network topology for  $V = 1$ ,  $R = 2000$ ,  $\alpha_V = 2.1$  and  $\alpha_R = -4.1$ .

## Conclusions

In this paper we have presented an initial investigation of timescale separation in adaptive networks, by identifying examples from the literature of different ways of dealing with multiple timescales and proposing a definition of timescale separation, based on the time taken by a system to reach equilibrium under the action of individual processes. Given this definition, we confirmed that, if the timescales of two processes are sufficiently separated, we can ignore their interaction. Where timescales do not separate cleanly, however, the system dynamics exhibit higher variability and hence become more difficult to predict. Heterogeneity complicates matters further as it can result in the system relaxing to different equilibria in comparison to the same system under homogeneous conditions. Where we can not be certain that the timescales are sufficiently separated in a system under consideration, we should expect the dynamics to be sensitive to the interplay between the timescales of the processes present.
